Symptoms of vitamin D poisoning can occur as early as 12 days or as late as 6 years after the commencement of therapy (Paterson, 1974). In the present case the acute toxic effects, in the form of suicidal depression, occurred 15 years after treatment with a daily dose of 1.25 mg of calciferol and 1.8 g of calcium gluconate. A failure to regularly monitor the patient's serum calcium, and adjust the calciferol dosage accordingly, had led to the hypercalcaemia remaining undetected.

The case under discussion had other features seen commonly in hypercalcaemia, i.e. abdominal pains and calcification in a lung. A less prominent aspect was the normocytic normochromic anaemia seen in the patient (Gabriel *et al*, 1970). It is postulated that this type of anaemia results from damage to the kidneys or the marrow by the hypercalcaemia.

This patient was falsely assumed to have had postoperative hypoparathyroidism. As a consequence of this incorrect diagnosis she received inappropriate medication with calciferol and calcium gluconate for the next 15 years. By that stage she had developed a severe depressive illness, which necessitated inpatient treatment.

As the patient committed suicide by drowning 18 months after discharge from hospital, at a time when the hypercalcaemia had been corrected, the aetiological relevance of the chronic hypercalcaemia to the patient's presenting illness must be in some doubt.

The Scottish legal verdict of 'not proven' is perhaps the most appropriate comment on the significance of the association but this case report may prompt others to seek or publish details of more convincing cases.

Tuberous Sclerosis and the Autistic Syndrome

A case of tuberous sclerosis presenting with autistic behaviour is described. Although tuberous sclerosis is a rare cause of the autistic syndrome, it should be more strongly suspected when autistic behaviour is associated with seizures in a young child.

Tuberous sclerosis, inherited in an autosomal dominant fashion, is a rare disease with a multiplicity of clinical presentations including mental retardation, seizures, adenoma sebaceum, nodular sclerosis of the cerebral cortex and tumours of the kidneys, eyes and other organs. It was Bourneville in the late nineteenth century who first recognised this condition as a pathological entity and he named it 'tuberose sclerosis' because of the potato-like or tuberous appearance of the brain lesions on gross examination.

The possible neuropsychiatric manifestations of tuberous sclerosis have been described (Critchley & Earl, 1932): early mental deterioration, mutism, absent speech development, bizarre attitudes and stereotyped behaviours especially in the hands and fingers, and primitive movements such as rocking and swaying. The parallels with Kanner's descriptions of early infantile autism are obvious. Below we describe a case of tuberous sclerosis which was initially diagnosed as infantile autism and discuss the early diagnosis of tuberous sclerosis with this atypical picture.

Case report

S.E., a 7-year-old black male was referred to a children's inpatient mental unit by school psychology services for contingency management of behavioural problems. School assessment had revealed that he could not be taught or managed in a classroom situation. His main problems were hyperactivity, poor language function consisting of single words only, and autistic behaviours such as repetitive rocking and chewing of non-edible objects. He interacted minimally with peers and exhibited poor eye contact. Intellectual assessment prior to admission put him at an unspecified level of retardation.

He was the product of a normal pregnancy, weighing 7 lb 2 oz at birth. Soon after birth, he developed neonatal hyperbilirubinaemia which was treated with phototherapy. Development was normal until 8 months of age, when he developed a seizure disorder. Infantile spasms and possible tuberous sclerosis were considered at that time, but EEG and biopsy of hypopigmented skin lesions were non-conclusive.

The patient was treated with anticonvulsants for 2 years and remained free of seizures. However, speech delay, mental retardation and abnormal behaviour were obvious from the age of 3 years.

Physical examination at the time of admission to the unit revealed adenoma sebaceum of the face. Skull X-ray and head CT scan showed numerous intracranial subependymal calcifications. Eye examination was positive for a retinal phakoma.

Discussion

Although there is some overlap between the neuropsychiatric manifestations of tuberous sclerosis (Critchley & Earl, 1932) and infantile autism, tuberous sclerosis presenting with autistic behaviour is a rarely reported phenomenon (Creak, 1963; Mansheim, 1979). In our review of the reported cases, including the above report, we found that all patients had a history of onset of a seizure disorder before the age of 2 years. While the early onset of seizures is a predominant and fairly constant clinical feature of tuberous sclerosis (Pampligione & Moynahan, 1976), this is in contrast with the age pattern of seizures seen in autistic children (Rutter, 1970; Deykin & Macmahon, 1979) where the peak incidence of seizures tends to be at puberty.

We conclude that the clinical suspicion of tuberous sclerosis must be raised when the behavioural syndrome of autism is associated with seizures in a young child. While early diagnosis in tuberous sclerosis may not affect the ultimate prognosis, it will certainly be important for parental screening and genetic counselling.

Asperger's Syndrome and Aminoaciduria:

A Case Example

An 18-year-old male, originally diagnosed as suffering from infantile autism but with a developmental history and clinical picture in keeping with Asperger's syndrome, and showing current signs of impairment of higher cerebral functioning, is presented. The subject and several males of his family present behavioural disturbances of an enduring type. An aminoaciduria was discovered in the subject and his father. A possible relationship between the metabolic disturbance and the neurological and behavioural disturbance is raised. Mechanisms for this relationship are discussed, including sporadic hyperlysinaemia.

The relationship between organic and functional disorders has bedevilled theorists and practitioners for decades, and will continue to do so. Establishing a causal link between a metabolic lesion and problem behaviour is a difficult task. The following case presentation suggests such a connection. Unfortunately not all the pieces of the puzzle were available to make a complete picture, but sufficient is known to suggest an interesting possibility. The case also illustrates the usefulness of keeping an open mind about clinical data, with a willingness to rethink a problem, even in chronic cases.

Case presentation

'A' is an 18-year-old, unemployed male, born in England of Dutch-Indonesian parents. He was referred to the Adult Psychiatric Ward of a general hospital, because of a self-inflicted wrist laceration, 3–4 weeks of deteriorating behaviour and work performance at a Work Rehabilitation Centre, and despair by the Centre staff that his unemployability seemed due to a 'schizoid-autistic type personality'.

'A' was the eighth and ultimate offspring, following an uneventful pregnancy and delivery. Mother reports no problems in early infancy and initial milestones were adequately gained. He was noted to be different from other children as he became mobile and independent. Restlessness, a tendency to isolate himself and severely impaired speech development were the main features. Language skills were not acquired by the age of 5. He was a difficult child to make contact with and never related with others.

Following clinical assessment and a diagnosis of autism, he attended a school for autistic children. The parents were told that he had an above average IQ. Mother felt he was different to other children at the school in that he seemed more in contact with his surroundings. In 6 months he rapidly developed abilities, could speak coherently as well as read and write, and moved to an ordinary school.

The family emigrated to New Zealand and 'A' continued schooling in ordinary classes. Academic progress was reasonable with particular emphasis on mechanical and memory abilities. He continued to be a loner who exhibited an extreme need for perfection. A tendency to focus on microscopic details of rather idiosyncratic subjects was evident as was extreme emotional reaction to sudden environmental changes.

From 4 through 11 'A' would frequently wake in the night in a very agitated state talking of a vision which was described as a large black mask he could see in his room. There were no other descriptions of potential perceptual or delusional phenomena.

The isolation, minimal social involvement and preoccupation with singular pursuits continued during secondary education. At the time of impending secondary school examinations 'A' took an overdose of mother's nortriptyline. A convulsion and admission to a neurological ward resulted. Atypical involuntary movements, unsteadiness of gait, mild dysarthria and a mild right ptosis were noted. An EEG showed non-specific disturbance, most marked anteriorly. This featured low amplitude, fast activity and some low amplitude theta waves. No epileptiform activity was seen however. A CT scan performed was normal: 'A' was discharged with a diagnosis of 'hereditary neurological disorder not otherwise specified'.

After moderate success in the Sixth Form examinations he left school and was unable to find employment. The Labour Department referred him to a Work Rehabilitation Centre from where he was referred to the psychiatric service.

Family history

There is a very strong history of psychiatric disorder and personality disorder in the family. The paternal grandfather was an alcoholic with an explosive temper and frequent physical violence. The paternal grandmother had several admissions to mental hospitals and died in one, the exact nature of the disorder is not known—she was said to be violent at times. 'A's' father has had frequent business problems of 'unsound' deals. His wife sees him as a man with no insight into his own actions, lacking feelings for others and accordingly having bad social relationships. Interestingly, 'A's' father reports he is the best of a bad bunch when referring to his own siblings.

The maternal grandfather was very obsessional, frequently depressed and committed suicide. Mother has had prescriptions of antidepressant medication on a number of occasions.

Of the five male sibs four are seen as disordered. This tends to follow the same pattern with social inability, difficulties accruing from lack of concern for others, evasiveness, isolation, and physical slowness and clumsiness. Of the three female sibs only one shows disorder, which is quite different from the brothers, with extreme mood swings, confusion and illogicality. Her disorder only became evident at the age of 11, whereas the parents consider the boys have a lifetime of disordered patterns.

Examination findings

'A' was a tall, ungainly youth who was difficult to make contact with. He at times exhibited a number of small brief jerky, purposeless, seemingly involuntary movements of the hands, arms and trunk. When talking his breathing was poorly co-ordinated with the speech patterns. Little affect was displayed apart from considerable frustration when he was not able to perform cognitive testing.

He talked volubly without evidence of associative disorder. There were occasional grammatical errors and an intense preoccupation with particular subjects such as drugs, bee-keeping, and an intention to buy a racing cycle. There was no evidence of delusions or perceptual disorder.

He was fully orientated with good short- and long-term memory; concentration was adequate as was calculating ability. Slight dysarthria was evident. Rhythm disturbance in speech was typified by a questioning type raising of intonation at the end of a non-question statement. An echolalic tendency was evident, particularly of questions about social interaction or feeling state. Comprehension of simple and complex commands of either verbal or written type was good and there were no difficulties in reading or written expression.

Basic visuospatial organisation was adequate but on more complex copying tasks there was a lack of constructional ability. Performance of complex motor tasks and rapid alternating hand movements were impaired. An unusual gait was noted, especially lack of arm movement when walking. When asked to perform motor tasks, secondary and unwanted motor activity, such as the assumption of an unusual posture of an arm or hand was evident.

Psychometric data on the Weischler Adult intelligent scale (WAIS) (Weischler, 1958) showed a full scale IQ of 108, with a verbal IQ of 120, a performance IQ of 92, with a verbal/performance difference of 28. There was a subtest scatter with markedly low scores on Block Design, Object Assembly and Digit Symbol. The Graham & Kendall Memory for Design Test (Graham & Kendall, 1960) showed him to have borderline function.

Case summary

The developmental unfolding and old case records originally diagnosed as infantile autism, but on review consistent with Asperger's syndrome, showing the atypical speech patterns, problems with social interactions, repetitive activities, problems of motor co-ordination and pre-occupations with limited specialised topics (Wing, 1981) is presented briefly. There is evidence both on clinical examination and psychometric evaluation of deficits in higher cerebral functioning. These findings, coupled with the strong family history of behavioural disturbance in many of the male members, raised the possibility of some inherited and metabolic neurological disorder.

Investigations

Basic biochemical and haematological screening showed no abnormality. Chromosome pattern was normal male. An EEG showed signs similar to the previously described, namely anterior low-amplitude fast and theta activity.

Serum amino acid screen was normal. A urinary amino acid screen showed gross abnormality with elevation of arginine, ornithine, histadine, threonine, and serine. This picture is similar to that described as hyperdibasicaminoaciduria (Wasler, 1983). Further testing confirmed a transport mechanism deficit in that there was a less than normal elevation of serum lysine in response to a lysine load (Rajantie *et al*, 1980).

The strong family history of disturbed interpersonal behaviour with a striking male predominance encouraged us to screen the family for aminoaciduria. It was unfortunate that samples could not be obtained from the sibs. We were able to obtain samples from both parents. This showed the father to possess a similar aminoaciduria but to a lesser degree, whilst mother's urinary amino acid pattern was normal.

Discussion

We present a case with a history consistent with Asperger's syndrome, showing a current behavioural problem and signs of higher cortical dysfunction. Also demonstrated is an aminoaciduria of similar type to the described hyperdibasic aminoacidurias (Whelan & Scriver, 1968; Kihara *et al*, 1973; Rajantie *et al*, 1980; Wasler, 1983). Association of the two findings in a causal sense must remain speculative. The possibility that the psychiatric syndrome relates to aminoaciduria is heightened by the presence of the aminoaciduria in the subject's father and by the strong trend for male members of the family to display an unusual but uniform social deficit coupled with a motor skill deficit, suggesting a genetically sex linked mechanism.

The particular defect of the amino acid metabolism seen in this case is at variance with other reported disorders of basic amino acids (Whelan & Scriver, 1968; Kihara *et al*, 1973; Scriver & Rosenberg, 1973; Rajantie *et al*, 1983; Wasler, 1983). Typically elevations of urinary arginine, ornithine and lysine, are seen. Our case has, in addition, elevated serine, threonine and histadine. There is, however, added similarity to other described hyperdibasicaminoacidurias in the deficient handling of a lysine load, suggesting transport defect (Rajantie *et al*, 1980). The rarity of this defect has limited study. Reports (Wasler, 1983) would suggest at least two different syndromes; one is declared in early life and includes gross mental handicap, and the other can appear later with less profound but progressive mental impairment.

Reports of possible association of psychiatric symptoms and aminoacidurias involving the dibasic group are limited. Reviewing hyperdibasic aminoaciduria, Kihara *et al* (1973) consider that the amino acid metabolic abnormality is a result of a genetically determined alteration in the transcellular transport mechanism for the dibasic aminoacids. The finding of inability to handle lysine load is further supporting evidence of this. Whelan & Scriver (1968) discuss hyperdibasicaminoaciduria and its relationship to mental retardation. The possibility that the pathological agent is serum lysine is raised by both authors. They cite work that had been carried out, primarily with rats, showing sporadic hyperaminoacidemia can seriously impede the process of cerebral production of proteins. The suggestion ensuing from these observations is that sporadic episodes of hyperlysinaemia either experienced *in utero* or early infancy might seriously disrupt the development of particular aspects of nervous system integration.

Though obviously this case report raises far more questions than it is able to answer we feel it points to a potential area of worthwhile ongoing research. The human nervous system development is quite incomplete at birth and continues rapidly in early infancy. The development is especially evident in the neocortical areas and it is perhaps no accident this case displays deficits consistent with function ascribed to those areas. The importance of further studies to substantiate our speculation can be seen when considering the disorder phenylketonuria (Scriver & Rosenberg, 1973). When untreated this presents a severely debilitating neurological disorder. Comparatively recent development of simple screening procedures in the new born has allowed detection of cases before irreversible neurological damage has been caused and strict attention to diet removes the unpleasant sequelae.

If the hypothesised link between the hyperdibasicaminoaciduria and neurological system impairment is substantiated then we may both explain and even prevent some of the more unusual psychiatric syndromes such as Asperger's Syndrome that currently bedevil us.

Acknowledgements

The Gastroenterology Laboratory, Auckland Hospital, provided urinary amino-acid analyses.

We are grateful to those members of the family who provided samples for analysis, and to the parents and patient for permission to present this case.

Expressed Emotion in the Families of the Mentally Handicapped: A Pilot Study

The birth of a mentally handicapped child to a couple is a traumatic event. It has even been compared with a bereavement. In the crisis of family handicap, however, there is also anxiety, fright, guilt and shame. Some of these reactions have been denied by families but it has to be borne in mind that mothers of abnormal babies, although they are not aware of it consciously, may be protective and dominant (Prechtl, 1963). The reactions of parents of mentally handicapped may swing from extremes of overprotection to complete rejection. On the other hand, there is stress both emotional and physical in looking after the handicapped day in, day out. The amount of the emotional stress has not been quantified, but of the many forms of interactions between parent and offspring, over-involvement, criticism, hostility, and warmth can be evaluated using the Expressed Emotional scales.

Method

Expressed Emotion was assessed on the basis of the scales of (i) Hostility, (ii) Critical Comments, (iii) Positive remarks, (iv) Warmth—as has been done with the schizophrenic patients (Vaughn & Leff, 1976). The parents or next of kin of mentally handicapped individuals were interviewed according to a modified version of the Camberwell Family Interview Schedule. The reliability of such an interview schedule as a research tool has been established by Brown & Rutter (1966). The interview lasted 45–60 minutes. The biological father was alive in only four of the cases. The interview was tape recorded and the tapes were rated according to the training received. Out of the ten tapes, four were taken at random and checked by other research workers trained in the use of the scale (Table II).

The parents or carers looked after mentally handicapped individuals of both sexes between the ages of 16 and 50. The lower limit of 16 years was fixed, because this is the youngest age at which patients are admitted to Ely hospital. The upper limit of 50 years was arbitrarily chosen, because of the possibility that in the case of patients older than this, the parents may be dead or less able to respond in the interview by virtue of their age. The parents or carers of ten mentally handicapped individuals within the described age range were interviewed. The patients were chosen at random from a list of those who live at home but come to Ely hospital for short term care for regular family relief. It was explained to the interviewees that all the information they gave would be strictly confidential and used for research purposes only.

Discussion

The Expressed Emotion (EE) scale is being used with various populations. Apart from the pioneering work on schizophrenic patients, the Camberwell Family Interview Schedule is being modified and used with a population of intractable epileptic and autistic individuals. This pilot study attempted to use the instrument to evaluate EE in families looking after a mentally handicapped member. A striking finding was the total absence of hostility which can be explained by the fact that fathers (who tend to show more hostility than the mothers) were too few in

number and not interviewed separately. Critical comments which correlate with hostility reached a score of one in four of the families. Warmth was rated at 2–3 almost uniformly, whereas positive remarks were found in three of the families. Emotional over-involvement (EOI) also reached the accepted threshold in three of the families. In another two families, EOI was rated 2.

The study was started on the premise that parents of mentally handicapped members, have suppressed feelings which should be explored. The point in using a semi-structured interview based on the CFI was that like the parents of schizophrenics, parents of mentally handicapped usually know very little about the condition of their offspring and spend much of their day-to-day life with them. The 'face to face' contact was more than 40 hours a week, this has to be considered in the context of both the physical and the mental limitations of the individuals. Indeed some of the families said that the inability to have a conversation made the time spent together more intolerable.

The population chosen was in the 16–50 year age group. The life pattern resembled that of chronic schizophrenics who attend either a day centre or an industrial therapy unit. However, because of the age of the handicapped individuals, the parents had had a long time to adjust and therefore could appear to be more accepting of the situation. Moreover, in the case of older individuals it was often difficult for parents or carers to recall and discuss emotions that were aroused nearly two decades ago. However, the older parents or carers in contradistinction with younger parents or carers, had specific problems relating to their age group. One was anxiety about what would happen when they died or became physically unable to look after their handicapped relative. In those cases where there was physical handicap, parents said they could no longer cope with lifting and other physical effort involved in bathing and dressing. A more appropriate age group may therefore be the 5–10 year group.

Parents of mentally handicapped people also differ from parents of schizophrenics in many ways. Mental handicap is invariably detected during the first few years of life. This presents the parents with the option of either rejection or total dedication. This could also account for the low score of hostility which was observed. On the other hand there was no remarkable increase in the rating for warmth or emotional over-involvement which would reflect self-sacrifice through utter devotion.

In schizophrenia, even though the parents and some professionals may dispute the diagnosis, there are periods of remission which may give parents hope that the condition is not irredeemable. On the other hand, in mental handicap, once the diagnosis is made, some parents will go to great lengths to deny its reality.

As far as the questionnaire is concerned, the modified version is even shorter than the revised version of Vaughn & Leff (1976). Its brevity suggests that there are areas which need expanding namely regarding irritability and quarrelling. Observations made during the interviews indicate that there is a sense of dissatisfaction which should be taken into consideration in any further work. Despite these reservations, the overall rating of EOI is still very relevant in connection with mental handicap. It will enable the identification of those families who could be helped to cope with their feelings, thus allowing them to give their handicapped dependant the maximum scope for the development of potential.

Acknowledgements

I would like to thank Dr Valerie Cowie for inspiring me to embark on this study, Christine Vaughn and Joy Abati for guidance with modification of the questionnaire and co-rating some of the tapes, and the Community Nursing Department at Ely hospital.

Delusional Infestation and Dementia: A Case Report

The case of an 82-year-old woman with delusional infestation and senile dementia of the Alzheimer type is reported. Her symptoms of infestation ceased dramatically with pimozide given for 5 weeks, and did not recur during follow-up over 9 months. The importance of organic factors in patients with this disorder is emphasised.

The syndrome of delusional infestation is a clinical state in which the patient has the unshakeable false belief that her skin is infested with live organisms. The condition has been variously described in the English literature under the names acarophobia, delusion of parasitosis, parasitophobia, dermatophobia and Ekbom's syndrome (Skott, 1975; Berrios, 1985), but we suggest that the term 'syndrome of delusional infestation' is a more accurate description and will be used here.

The syndrome was first described by the French dermatologist Thibierge in 1894 and is well known to dermatologists (Lyell, 1983) but less so to psychiatrists. The typical patient is a woman in late middle age who presents to a dermatologist complaining of cutaneous sensations which are delusionally attributed by her to a skin infestation with creatures such as lice, worms, maggots, fleas, bacteria and fungi. As proof of the infestation she may bring along an envelope containing the alleged organisms, which usually turn out to consist only of skin debris. The dermatologist is unable to find any evidence of infestation, and often the skin of the patient looks normal. However delusional infestation can occasionally be superimposed on a pre-existing skin disorder (Wilson & Miller, 1946; Wilson, 1952; Tullett, 1965; Hopkinson, 1970), follow on from a previous skin infection (Wilson & Miller, 1946; Hopkinson, 1973), or be associated with self-induced dermatoses resulting from attempts to remove the organisms with instruments or chemicals (Klauder, 1936; Wilson & Miller, 1946; Wilson, 1952; Obermayer, 1961; Tullett, 1965; Paulson & Petrus, 1969). The patient holds her conviction with absolute certainty and cannot be persuaded otherwise; any suggestion of referral to a psychiatrist usually meets with a flat refusal. She may go to extraordinary lengths to get rid of the creatures: fumigation of clothing, bedding and furniture may be demanded, and pest control officers (Edwards, 1977) and public health officials (Schrut & Waldron, 1963) consulted. These patients are very difficult to treat, but useful management guidelines have been provided by Gould & Gragg (1976).

The causes of delusional infestation are multiple; in this paper we wish to draw particular attention to the potential role of organic cerebral factors in the aetiology of this syndrome by describing the unusual case of delusional infestation occurring in a woman with dementia.

Case report

The patient is an 82-year-old married childless woman with no previous history of physical or psychiatric illness or family history of dementia. Her husband had noticed early signs of memory impairment and loss of domestic efficiency in his wife over the previous 6 months with an exaggeration of her premorbid personality traits of suspiciousness and possessiveness, but she had shown no evidence of delusional ideation or depression of mood. She was initially seen at home at the request of her general practitioner because of her complaint of skin infestation of 1 month's duration. She claimed that unseen flying insects had been settling on her face at night when she was in bed, and had laid their eggs in her skin and hair. The eggs had hatched and she could feel insects crawling in her skin. She wrapped her head and face in a silk turban at night and washed her hair regularly with vinegar to deter the insects. She spent many hours during the day in front of a magnifying mirror picking at her face with a pin to remove the eggs; periodically she would hold up the pin in triumph and coerce her husband into agreeing that he could see an egg impaled on the end. Her husband was also forced by her to arrange for a pest control officer to spray their bedroom with insecticide. However at no time did her husband believe that his wife was infested. Her general practitioner found no evidence of skin infestation on physical examination and treatment with chlorpormazine 50 mg *t.i.d.* failed to dislodge her delusion.

Mental state examination revealed an elderly slightly suspicious woman with excoriations on her nose and left cheek. She showed no depression of mood, hallucinations or delusions other than those concerning the insects. However she was disorientated in time and had evidence of both short- and long-term memory impairment, scoring only 18 out of 34 points on Hodkinson's Mental Test (1973). Her delusional system was well organised and she lacked insight into her illness, believing that she needed treatment from a dermatologist rather than psychiatric help.

A provisional diagnosis of delusional infestation associated with a possible dementing illness was made and pimozide at a dose of 8 mg daily prescribed. She responded very well to this treatment at home and her delusions completely resolved within a few days. However the drug was stopped after 5 weeks when she showed extrapyramidal side-effects. Physical examination and laboratory and radiological investigations to rule out systemic disease and secondary forms of dementia were normal; an EEG showed a bilateral excess of slower components and a CT brain scan revealed slight ventricular dilatation and cerebral atrophy. There has been a continual decline in her memory, intellect and personality over the ensuing 9 months in keeping with a clinical diagnosis of senile dementia of the Alzheimer type, and she has been regularly admitted to hospital during this period to give her husband some respite. However her symptoms of infestation have not recurred despite the discontinuation of pimozide.

Discussion

Before a diagnosis of delusional infestation is made, it is necessary to ensure that the patient is not actually infested. However as Champion (1983) points out, this is far from simple as scabies and other mite infestations can be easily overlooked, and a thorough physical examination is essential.

Most patients who present with a delusion of infestation are suffering from either a psychiatric illness or an organic disorder; in a small minority, there may be an interplay of both pathologies, or the organic factor may be entirely coincidental.

Delusional infestation occurs most commonly in the context of monosymptomatic hypochondriacal psychosis (MHP), a psychiatric illness characterised by a fixed, usually bizarre, solitary delusional belief of bodily disease or abnormality, which is unaccompanied by disintegration of personality, delusional elaboration or psychotic deterioration (Reilly, 1977; Munro, 1978, 1980). Delusional infestation may also arise in the course of an affective or schizophrenic illness (Wilson & Miller, 1946; Hopkinson, 1970, 1973) when it is accompanied by other relevant psychiatric symptoms, and also in folie à deux (Macnamara, 1928; Partridge, 1950; Wilson, 1952; Paulson & Petrus, 1969; Hopkinson, 1970, 1973; Evans & Merskey, 1972; Mester, 1975).

A clinical picture resembling delusional infestation has been reported in toxic and metabolic disorders such as delirium tremens (Lishman, 1978), cocaine psychosis (Tullett, 1965), amphetamine abuse (Skott, 1975), pellagra (Aleshire, 1954; Fish, 1967), and vitamin B12 deficiency (Pope, 1970), in which pathological cutaneous sensations may be experienced.

Ladee (1966) has reviewed the earlier evidence implicating the role of cerebral-organic factors in the aetiology of some cases of delusional infestation. The syndrome has been observed in patients with cortical and subcortical atrophy who show no intellectual impairment (Campanella, 1969; Schott *et al*, 1973; Heim & Morgner, 1980; Ungvári & Pethö, 1980; Sone, 1983), and in patients with brain tumours (Liebaldt & Klages, 1961; Miller-Kreuser, 1962; Ungvári & Pethö, 1980), alcoholic encephalopathy (Ungvári, 1984) and cerebral infarction (Valbuena Briones *et al*, 1984). Previous cases of delusional infestation associated with dementia have also been described by Wieser & Kayser (1966), Bauer & Mosler (1970) and Ganner & Lorenzi (1975).

The delusion of infestation in our patient, unlike most delusions in dementia, was fixed and well-systematised. Ekbom's (1938) suggestion that the delusion has its origin in true cutaneous sensations which are misinterpreted and not hallucinatory experiences, may be relevant in some cases with an organic aetiology; the abnormal skin sensations of senile pruritus may act as a fertile focus for the development of delusional infestation in the elderly, especially in those with cognitive impairment. Other systemic conditions to exclude in this age group include liver and renal disease, lymphomas, polycythaemia, iron deficiency, thyroid disease, carcinoma and drug reactions, all of which can cause a generalised pruritus without skin lesions (Champion, 1983).

Some workers (Riding & Munro, 1975; Munro, 1978; Reilly *et al*, 1978) have found pimozide to be particularly useful in the treatment of MHP patients with delusions of infestation, although its efficacy in other forms of the syndrome remains debatable. However, our patient's delusion resolved much too quickly for the improvement to be coincidental and suggests a specific beneficial effect of pimozide.

In conclusion, this case illustrates that delusional infestation, especially when it occurs in the elderly, may be symptomatic of an underlying organic disorder.

A Case of Resistant Schizophrenia

SIR: It is gratifying that our colleagues at the Joint Hospital (Roberts *et al, Journal,* December 1986, **149,** 789–793) have discovered neuroleptic-resistant schizophrenia. However, had they visited any of the large psychiatric hospitals, which they seem to prefer to call asylums, they would be likely to find a number of patients with this disorder.

Notwithstanding the failure of electroconvulsive therapy in this patient, I would suggest that lithium should be tried. Sometimes 'continuously floridly psychotic behaviour' has a masked affective component, as Crammer suggests in the paper.

We have reported the case of a 27-year-old married lady who required high doses of depot neuroleptics to control episodes of schizophrenia (as diagnosed at that time) associated with very disturbed behaviour and to maintain prophylaxis (Barnes & Bridges, 1980). Her severe symptoms were improved, but certainly not controlled, by the use of ECT. However, there was a good response to lithium, although, ultimately, she was found to be most settled on haloperidol (20 mg t.d.s.) and carbamazepine (400 mg t.d.s.) with procyclidine. Her compliance on this medication is good, and it has kept her out of hospital so far for the past four years. I should add that she was transferred originally to my care at Bexley Hospital from the Bethlem Royal Hospital, where it was considered that she was doing too much damage to both the staff and the fabric and hence "asylum" was needed.

Anorexia Nervosa and Dysmorphophobia

SIR: I should like to comment upon Sturmey & Slade's paper (*Journal,* December 1986, **149,** 780–782). Anorexia nervosa and dysmorphophobia are functional disorders which usually occur in young individuals and are characterised by disturbances of the body image. In the former condition subjects characteristically perceive themselves as fatter than they are, as with the reported patient who "considered herself to be generally too 'broad'", whereas in dysmorphophobia, subjects typically complain about one particular aspect of their appearance, such as the nose, chin, mouth, breasts, or penis (Morselli, 1886; Hay, 1970; Thomas, 1984).

In anorexia nervosa and in the reported patient weight loss occurs, and consequently observed appearance cannot be considered normal. In dysmorphophobia there is a subjective feeling of ugliness or physical defect which the patient feels is noticeable to others, although appearance is within normal limits (Morselli, 1886).

I think that it is incorrect to consider that their patient exhibits dysmorphophobia, as the disturbance in body image was not localised, abnormality of body size was present, and there was a primary diagnosis of anorexia nervosa from which the dissatisfaction with appearance developed.

Making these distinctions is important if one wishes to identify and study a homogenous group of dysmorphophobics where an over-valued idea concerning appearance, in the absence of underlying classifiable psychiatric disease, is the principal abnormality.

SIR: The report on anorexia nervosa and dysmorphophobia (Sturmey & Slade, *Journal,* December 1986, **149,** 780–782) demonstrates how easy it is to further complicate psychiatric nosology.

Certainly the history suggests that the patient warrants a diagnosis of anorexia nervosa; many of the classical features are present, including a disturbed body image. Dysmorphophobia, however, is confused yet again by an initial emphasis on physical appearance and then referring to it as a social phobia. Here the term is superfluous, because the feature of disturbed body image is a diagnostic criterion of anorexia nervosa. If the authors used this method of 'overlapping nosology', then why didn't they call the report "A study of anorexia nervosa, dysmorphophobia, social phobia, anxiety neurosis, obsessive-compulsive neurosis, and personality disorder, etc."?

It would be interesting to follow up this patient for a time. If her brother has another "schizophrenic attack" (*sic*) and she follows suit then we can label her "schizophrenic" and start all over again!

Munchausen's Syndrome and Drug Dependence

Sir: London & Ghaffari (*Journal,* November 1986, **149,** 651–654) report on the failure of treatment in a patient with Munchausen's syndrome approached primarily as a problem of dependence on drugs. The demand for pethidine injections is as much a hallmark of this syndrome as is the assertion that the patient is allergic to contrast dyes. The authors state that their patient was in the Royal Army Medical Corps. This is a common assertion (O'Shea *et al.* 1982, 1984). It is rarely true in my experience.

The strongest theory to date of the origins of Munchausen's syndrome suggests that it is a trait learned in childhood: a 'Munchausen mother' induces fictitious diseases in her child; the child later assists the mother in fabricating such illnesses; the young adult goes out into the world seeking mothering with the only language he knows that will procure it – i.e. illness behaviour. Doctors respond with admission, investigations, and treatments, and reject when they find out that the patient has lied (Meadow, 1985; O'Shea, 1984). Most workers now accept that Munchausen patients fall somewhere within the spectrum of psychopathy, and in those cases of Munchausen's syndrome which appear to begin in adult life, scrutiny will nearly always reveal underlying psychopathy.

London & Ghaffari describe the family diseases of their patient in detail, and yet feel that the RAMC was responsible for his being "introduced" to a medical environment. Incidentally, even proxy cases may lie about their nursing experiences (Meadow, 1985).

Autocastration and Biblical Delusions in Schizophrenia

Sir: I read with interest the paper by Waugh (*Journal,* November 1986, **149,** 656–659). I remember being called one Sunday to a surgical ward at the Queen Elizabeth Hospital, Woodville, South Australia, as the duty psychiatrist. The patient I was called to see had, the previous day, removed his own penis and genitalia, and also his tongue, with a scalpel. He had also attempted to perforate his ear drums, and there were superficial lacerations to his upper eyelids. It became clear later that he had also considered cutting off his right hand. He was about 30 years old, Chinese-Malaysian, and a medical practitioner.

I saw the patient twice on succeeding days, and he was able to communicate lucidly by means of pencil and paper. Like Waugh's patient, his thought content conveyed a sense of relief at having totally removed his genitals and also his tongue. His reasoning was that he could no longer do evil or speak it. He did not refer to Matthew 19:12, or any other biblical verse specifically, but he clearly felt that he had done what he had in order to atone for masturbation, lustful thoughts, and the use of obscene language. He felt that he had made his peace with the Almighty.

Larry Culliford

Sutton Hospital
Sutton
Surrey SM2 5NF

Sir: I would like to suggest a name for the syndrome described by Waugh. 'Klingsor's syndrome' seems to be the obvious choice. Klingsor was a character in Wagner's *Parsifal* who unmanned himself in a vain effort to gain entry to the brotherhood of Grail Knights. The suggested title thus incorporates both the element of autocastration and the religious motive described by Waugh.

Parasuicide and unemployment

SIR: I am unable to agree with Platt's concluding remarks (*Journal*, October 1986, **149**, 401–405) "we are faced with incontrovertible evidence... that the overall level of parasuicide could be reduced even more if there were a return to fuller employment." As he points out, we are not in any position to decide between the two types of explanation put forward by Hawton & Rose, i.e. the possibility of an indirect causal link between unemployment and parasuicide and the theory that the psychologically vulnerable may be more likely to become and remain unemployed. If the second theory proves to be correct it does not follow that a return to fuller employment would affect the levels of parasuicide.

DONALD BERMINGHAM

London SE1 7EH

Multi-author papers

SIR: An article published some years ago describing the fatal course of an unusual illness was described by a reviewer as an instance of sixteen men on a dead man's chest. Shaw *et al* offer us nineteen men on a drug company chest (*Journal*, October 1986, **149**, 515–517). The distinction of the contributors is elevated by their unusual qualifications, e.g. MSCPsych. I, PLAB Exam, 1979 and DHO. No MRCPsych Pt I (Failed), but surely a Royal College Journal has a view on the use of these other distinctions? Should not the authors be only those who accept full responsibility for design of the study and intellectual content of the paper? On the latter point, can the conclusion "citalopram is an effective and acceptable antidepressant" be justified by the data presented? The numbers involved are not clearly stated, no significant differences in efficacy were found, and the confidence intervals were not stated.

SYDNEY BRANDON
DAVID CLAYTON

NOTE: 'MSCPsych' was a typographical error and should read 'MRCPsych'. *DHO* was italicised, which is editorial style to indicate a post held, in this case District Health Officer – Ed.

Attachment Dynamic in Adult Life

SIR: We agree with Heard & Lake (*Journal*, October 1986, **149**, 430–438) that attachment offers a valuable conceptual tool to identify relevant variables related to the characterisation of neuroses and personality disorders. Attachment, extensively investigated in ethological and developmental studies, focuses on explanatory concepts rather than mere descriptive generalisations. It is surprising, therefore, that DSM–III, Axis II, despite using relationships to others as a central feature of many personality disorders, has neglected the richness of attachment in the delineation of social relationships.

We can also agree that most adults establish 'preferred relationships' with others. We do not agree that all preferred relationships are attachment relationships. Clearly, all of this hinges on how attachment is defined. The authors state: "'Preferred relationships' refers to relationships in which individuals regularly expect to find opportunities for companionable and/or supportive interactions... People who are so classed constitute an individual's attachment network... The concept of preferred relationships in the attachment network circumvents difficulties in describing attachment relationships and affectional bonds in adults".

The implications of this model are that preferred relationships are synonymous with attachment relationships, and an individual's attachment network is simply a subset, defined by intensity and intimacy, of the social support or affiliative network. But this approach to attachment relationships assumed that (a) attachment can be characterised using the same criteria as affiliation (e.g. if affiliative relationships provide companionship, attachment relationships provide preferred or more salient companionship), and (b) attachment and affiliation serve the same functions – attachment, again, doing the job more and better. Both of these assumptions are problematic.

In accordance with the implications of Bowlby's (1969) theory, attachment is restricted to dyadic relationships in which proximity to a special other is sought or maintained to provide a sense of security. The principal function of adult attachment is protection from danger (as it is during childhood) although adults recognise other dangers to existence than those recognised by infants and children: specifically, threats to the individual's self-concept and integrity (Hinde, 1982; West *et al*, 1986). Affiliative relationships have a quite different function, serving to promote exploration and expansion of interests from the secure base provided by attachment.

In our view, Heard & Lake have confused similarity in mechanisms for maintaining attachment and affiliative systems with a congruence of the systems. Identifying the mechanisms used to promote and maintain social relationships is obviously important to the understanding of disorders involving these mechanisms. But differentiating the function and characteristics of particular types of social relationships is equally important for discriminating the variety of disorders. For example, an inability to experience intimacy is experientially and clinically different from an inability to experience security within an intimate relationship. The first we would term a disorder of the affiliative system; the second, of the attachment system. To attempt to 'circumvent' these distinctions hinders rather than aids conceptualisation in this field of research.

Zinc in Senile Dementia

SIR: I wonder why Ken & Gibb (*Journal*, August 1986, **149**, 221–223) chose patients in their comparison group who were suffering from disorders in which low zinc levels have been reported. Srinivasan (1984) reviews psychiatric disorders in which low zinc levels occur: these include affective disorders, confusional states, and schizophrenia, all of which were included in the comparison group. The study would have been more valuable if a comparison had been made with a healthy, non-psychiatrically ill control group who were matched for age and sex with the dementia group, and it is possible that low zinc levels in dementia could then have been demonstrated.

49 Chromosome Anomaly

SIR: We describe another patient with 49 XXXXY anomaly (*Journal*, February 1986, **148**, 209–210 and 210–212).

Case report: A male, aged 34, has been an in-patient for the last 22 years. He was born with the cord around his neck and was cyanosed at birth. His developmental milestones were delayed. He had recurrent chest infections as a child. His mother was 34 and his father was 39 years old at his birth, and he is the youngest of three siblings.

On physical examination, he is 5 ft ¾ ins in height and his head circumference is 52½ cm. He has a small face, with palpebral fissures slanted upwards and outwards. He is severely myopic, and has left-sided club foot. He has a narrow chest and does not have any facial or body hair, although he does have a few axillary and pubic hairs. His penis is small and his testes are undescended. He had phymosis at birth, which has been operated on in the past.

He is passive, friendly, and attention-seeking, and has a high-pitched voice. He likes music, discos, and parties and is also interested in swimming. He is fully ambulant and his self-help skills are good. He is able to read and write. His IQ was tested in 1981, when the WAIS score was 60. He had unexplained recurrent falls in 1983, and an EEG showed bilateral cortical dysfunction maximal over temporal regions. He had no more falls after he was started on carbamazepine.

It is interesting that despite 49 XXXXY anomaly and some perinatal damage this patient is functioning at the level of mild-to-moderate mental handicap.

Post-ictal Syndrome after ECT

SIR: James & Simpson (*Journal*, September 1984, **145**, 337–338) invited comment on the observation of a second spontaneous fit after the second ECT given to a young woman suffering from a psychotic depressive illness associated with refusal to eat or drink.

Recently a similar observation was reported locally. A 24-year-old woman suffering a depressive illness had received a 12th right unilateral treatment. The treating doctor reported that about a minute after a tonic-clonic seizure she displayed further arm and leg movements lasting approximately 30 seconds, and concluded that she had undergone a second epileptic seizure.

By chance the young woman was taking part in a study, and thus a 4-channel EEG recording was made of her treatment by an independent observer. The recording showed a clear synchronous centrencephalic spike and wave episode lasting 54 seconds immediately after electrical stimulation. Thereafter the recording showed diffuse slow activity, often in dysrhythmic runs. Approximately 45 seconds later there was a return of muscle potentials on the record, and a period of small muscle twitches and movements were seen. However, there were no further concomitant cerebral epileptic events after the initial grand mal fit. The recording continued for 380 seconds after electrical stimulation.

Motor restlessness and uncoordination are recognised features of the post-ictal syndrome (Livingston *et al*, 1980). In the absence of any epileptic phenomena on the EEG this seems a more likely explanation than that she experienced a second seizure.

The difficulty of differentiating by observation alone the motor restlessness of a post-ictal syndrome from a second epileptic seizure may not, of course, necessarily explain the clinical phenomenon observed by James & Simpson. Certaintly, if spontaneous second seizures are to occur, they would be expected to occur early in treatment as the fit threshold rises during a course of ECT (Sackeim *et al*, 1986). If a second seizure occurs after ECT, it is important to consider possible precipitants such as drugs with convulsant properties, e.g. tricyclic antidepressants and phenothiazines. The woman in the reported case was drug-free, and thus we wondered about other precipitants such as hyperuraemia or menstruation (Hopkins, 1983).

The value of routine EEG monitoring of ECT is a matter of dispute, but it is unlikely that such clinical phenomena will be understood properly without simultaneous EEG monitoring.

Difficulties in Assessing Tardive Dyskinesia

SIR: Tardive dyskinesia (TD) is a major side-effect of long-term administration of neuroleptics. It is important therefore that its incidence, prevalence, and response to treatment are accurately determined. Such accuracy, however, is bedevilled by difficulties in assessment, and we report a further example of this difficulty.

As part of an (unpublished) open study of the efficacy of a novel psychotropic drug (Glaxo, GRC507/75) in the treatment of TD, ten chronic schizophrenic in-patients with TD were assessed before treatment using the Abnormal Involuntary Movements Scale (AIMS) (US Department of Health, Education and Welfare, 1976) and immediately afterwards were videotaped for one and a half minutes in a standardised way (Kidger *et al*, 1980). The live and video ratings were made by two different psychiatrists; the video rater was unaware that the ratings were before treatment.

As assessed by the AIMS global rating, six patients had mild and four moderate TD; two patients on video had no evidence of TD. The AIMS subscale found that all patients had orofacial and five distal dyskinesia, while the video ratings found only six with orofacial and four with distal dyskinesia.

Videotaping of patients with TD has obvious advantages, especially when carried out serially, as the order of presentation to the rater can be randomised. The present results suggest, however, that it may be less sensitive in mild and moderate cases than the more detailed assessment by AIMS of the 'live patient'. Indeed, our impression was that patients 'froze' in front of the camera. The main drawback to the AIMS is that it does not allow for a quantitative assessment of frequency, amplitude, or duration of movements (Barnes, 1984).

Agreement between live and video ratings was higher in two previous studies (Barnes & Trauer, 1982; Firth & Ardern, 1985). In the former study, however, the patients were unaware of the reasons for videotaping; in the latter, at least one movement was rated 'moderate-severe' in the Abbreviated Rockland Rating Scale. However, evaluation of methods of treatment must focus on patients with mild TD who give informed consent to the study.

Premorbid Adjustment Scale as a Prognostic Predictor for Schizophrenia

It is difficult to formulate a medium or long-term prognosis following the onset of schizophrenia. Standard criteria such as those of type of onset (acute or insidious), predominant symptoms (Huber *et al*, 1980), or the diagnosis of subtype do not correlate satisfactorily with outcome (Bland *et al*, 1976). In the last decade some authors cited the importance of premorbid factors such as socio-familial relationship, adaptation to school, or pseudo-psychopathic or toxicophylic behaviour (Strauss & Carpenter, 1977; Wittenborn *et al*, 1977) in the outcome of these patients, with a marked relationship having been noted between these factors and personal autonomy in later years.

Cannon-Spoor *et al* (1982) recently developed the Premorbid Adjustment Scale (PAS) to evaluate aspects such as withdrawal, social relationships, independence, scholastic performance, and ability to establish socio-sexual relationships. All patients are rated on five sub-scales corresponding to childhood, early adolescence, late adolescence, adulthood, and general, with a total of 26 items. These authors suggested that a high score on this scale may detect patients likely to become chronically hospitalised or at high risk for readmission.

We studied a sample of 30 patients (11 in-patients, 19 out-patients) presenting schizophrenic disorders (DSM–III criteria) independent of subtypes (14 males and 16 females; mean age = 24.9; age range = 17–34). The rating scale was administered retrospectively in the majority of cases by five raters with the patient and his family separately (the minimum correlation between pairs of raters was $r=0.76$ ($P\leqslant 0.0001$)). The minimum duration of illness was 2 years (mean = 3.6). All were admitted to hospital at least once (mean = 3 admissions). Outcome was evaluated using Strauss & Carpenter's scale (1972), which covers duration of time spent outside hospital, social contacts, and time usefully employed over the last year, as well as absence of symptoms in the past month.

Correlation between the two scales, PAS average and Strauss, was statistically significant ($r=0.76$, $P\leqslant 0.001$ for the average score). Similar results were seen on comparing PAS sub-scales with Strauss & Carpenter's outcome scale: childhood, $r=0.49$ ($P\leqslant 0.01$); early adolescence, $r=0.69$ ($P\leqslant 0.001$); late adolescence, $r=0.61$ ($P\leqslant 0.001$); adult, $r=0.73$ ($P\leqslant 0.001$); general, $r=0.75$ ($P\leqslant 0.001$).

Ten patients had been rated as having an acute onset of less than three months, and 20 an insidious onset. Correlation between the two scales was not significant in the acute onset subgroup ($r=0.59$), while the insidious onset sub-group showed a significant correlation ($r=0.67$; $P\leqslant 0.001$).

PAS appears to be a valuable and useful aid both in daily clinical practice and for further studies investigating the factors related to schizophrenia and its outcome.

Hyponatraemia Masquerading as Malignant Neuroleptic Syndrome

Sɪʀ: We wish to report the case of a patient suffering from acute hyponatraemia with water overload presenting as malignant neuroleptic syndrome.

Case report: A 27-year-old male weighing 76 kg was admitted comatose with tremor, rigidity, pyrexia of 39°C, sinus tachycardia of 140/min, blood pressure 190/80 mmHg, urinary incontinence, and a right extensor plantar response within one day of receiving the eleventh fortnightly dose of clopenthixol decanoate (300 mg by injection) for schizophrenia. Malignant neuroleptic syndrome was tentatively diagnosed.

Laboratory investigations on admission were: white cell count 22.4 × 10/litre (85% neutrophils); Na 116 mmol/litre; measured plasma osmolality 234 mOsm/kg; urea 3.3 mmol/litre and the osmolality of the 2.2 litres of urinary output in the first 4 hours of admission was 108 mOsm/kg. Creatine kinase was 873 i.u./litre (normal range <70), and bilirubin 33 µmol/litre (normal range <17). Blood glucose and CSF examination was normal. A trace of salicylate only was found on screening for other drugs, and lithium was excluded.

Benztropine mesylate (2 mg) and normal saline (1 litre) were commenced. A rapid recovery ensued in the second 12 hours following admission, in association with a urine output of 7.2 litres in the first 24 hours. By the second day a mild degree of Parkinsonism was the only remaining sign, and the white cell count was 11.1 × 10/litre, Na 136 mmol/litre and bilirubin 21 µmol/litre.

The severe hyponatraemia with a calculated excess body water of 7.8 litres and the acute polyuria indicated that primary acute water intoxication was the key. The speedy recovery confirmed this. SIADH induced by a depot drug would have a much longer duration of effect. The raised total CK, pyrexia, and bilirubinaemia resulted from skeletal muscle hyperactivity, with some haemolysis and drug-induced cholestasis probably contributing to the bilirubinaemia. Pyrexia and varying neurological signs are features of acute severe water intoxication (Arieff & Guisado, 1976). Neutrophilia – almost certainly due to stress-related endogenous corticosteroids – pyrexia and autonomic instability are also features of the malignant neuroleptic syndrome (Abbott & Loizou, 1986). Thus plasma sodium is an important investigation in the diagnosis of malignant neuroleptic syndrome.

AIDS-Phobia

Sɪʀ: Five male patients presented to us with psychiatric symptoms associated with the fear that they had AIDS. They were tested by the enzyme-linked immunosorbent assay technique and found to have no antibody to the causative virus infection of AIDS. The common features included: an anxious neurotic premorbid personality; tendency to have low extraversion and high neuroticism scores on the Eysenck Personality Questionnaire; a history of promiscuous heterosexual contact, and symptoms and signs of an anxiety state.

Reports from Western countries have documented a similar condition, under the name 'AIDS-panic' or 'pseudo-AIDS', with obsessive and paranoid features in the premorbid personality (Schwartz, 1983; O'Brien & Hassanyeh, 1985), and a history of homosexual contact and clinical features of anxiety or depression (O'Brien & Hassanyeh, 1985; Miller *et al*, 1985). There are similarities and differences in these cross-cultural reports. Neurotic individuals appear to be more prone to develop AIDS-phobia in India than in the West. Both groups show neurotic reactions as a response to the fear. In the West a history of male homosexual exposure is usually present, as it is the predominant risk factor for AIDS. In India the infection has been found mainly among women prostitutes (Simoes *et al*, 1987), and the public have been warned of the danger of promiscuous heterosexual contact. Although the terms 'AIDS-panic' and 'pseudo-AIDS' have been used for this condition, 'AIDS-phobia' may be a better name, since it is similar to venerophobia.

Art Therapy

SIR: In his review of the book *Art Therapy for Groups* by M. Liebmann (*Journal*, December 1986, **149**, 805), Aveline, in commenting on group dynamics, states: "This imbalance is worrying and reflects a deficiency in the training of art therapists". In fact, much emphasis is placed on group dynamics in the three postgraduate Diplomas in Art Therapy: at Hertfordshire College of Art, St Albans; Sheffield University; and Goldsmiths' College, University of London. I can speak more specifically about the Goldsmiths' course, where five out of eight of the tutors are qualified group psychotherapists as well as art therapists and the other three have extensive experience of group dynamics. Our course is structured around a model of art therapy combined with group analysis, and the students participate in weekly experimental groups, including one focusing solely on group dynamics. We do not neglect individual therapy, but are known for our 'group bias'.

The profession of art therapy is fairly new and is an easy target for misconceptions concerning training and practice. Full information about the courses can be obtained from each of the three centres, and general information on art therapy can be obtained from the British Association of Art Therapy, 13c Northwood Road, London N6.

SIR: May I comment on Aveline's review of Liebman's book *Art Therapy for Groups: The Handbook of Games and Exercises*. While his criticism of the book's meagre psychodynamic content may be fair comment in the context of the powerful feelings that can be aroused by some of the exercises described, it is misleading to say that this a reflection of the "deficiency in the formal training of art therapists". On the contrary, the Postgraduate Diploma course in Art Therapy at Goldsmiths' College is firmly and extensively based on group dynamics, both theoretical and experiential.

The techniques described in the book demonstrate one approach to art therapy, which can perhaps also be used by other professionals wishing to use art in their work with patients. However, I think it is true to say that qualified art therapists have a deep concern and understanding of the emotional forces which may surface through the use of art, and are fully aware of the implications of individual and group dynamics.

A HUNDRED YEARS AGO

Lunacy and Pauperism

At a recent Poor Law Conference in Glasgow, Dr Yellowlees read a highly interesting paper on the above theme. He urged that every county or district should have two types of asylums for its pauper insane; one a hospital, fully equipped with the best means of treatment, and receiving all new cases, the size not exceeding 300. Another building, erected at half the cost, should be devoted to chronic cases only, and should receive no patients except from the cure-asylum.

Book Reviews

Editor: Sidney Crown

The Natural History of Psychiatric Disorder in Children (Maudsley Monographs 29, Institute of Psychiatry). By H. Zeitlin. Oxford: Oxford University Press. 1986. Pp 158. £15.00.

This important book, as its subtitle (*A study of individuals known to have attended both child and adult psychiatric departments of the same hospital*) makes clear, contributes more to the delineation of syndromes than to the prognosis of child psychiatric disorders. The study is based on case records, and the index group consists of 161 adult psychiatric patients who as children had attended the same psychiatric hospital. They were compared with matched groups of adult patients without evidence of childhood disorders, and of child patients not known to have attended psychiatric hospitals as adults. The work has been meticulously done but, because of the nature of the samples, the meaning of the many links established between child and adult pathology is often not at once apparent. This may account for some obscurities in the writing.

The results are a treasure trove of fascinating relationships: for example, the greater continuities of symptoms than of syndromes; the striking continuity from childhood to adult life of obsessional symptoms, greatly over-represented in this index group; and the somewhat less marked continuity of phobias. Most adult depressive neuroses arise *de novo* and most depressed children appear to outgrow their symptoms. However, the greatest continuity of depressive symptomatology was for a specially constructed syndrome based on Pearce's criteria (*Journal of the Royal Society of Medicine*, **71**, 494–500). Depressive mood was an essential component, suggesting that there is no such thing as 'masked depression' in childhood. This reviewer was especially interested in the childhood precursors of schizophrenia: 4 out of 14 adult schizophrenic patients had been given this diagnosis as children; 8, not psychotic in childhood, had presented with conduct disorders with or without emotional and developmental disorders. Two specific features characterised these children: peer isolation and the clinicians' recording of 'incongruous' or unpredictably odd behaviour.

Psychiatric referral in adult life cannot be the only criterion of poor outcome, and disturbed children who later appear at psychiatric hospitals are by no means representative of child psychiatric referrals. For a complete picture of the natural history of child psychiatric disorders we need a replication of Lee Robins' personal follow-up into adult life (*Deviant Children Grown-up*. Williams & Wilkins, 1966), this time of a group of referred children comprising the full diagnostic range, so that we can be as confident about the fate of emotionally disturbed and developmentally delayed children as we are about conduct disordered and delinquent youngsters. Meanwhile, this monograph is an essential purchase for all general and child psychiatry libraries.

Sula Wolff, *Honorary Fellow, Department of Psychiatry, University of Edinburgh*

Education and Training in Psychiatry: A Case Study in the Continuity of Medical Education. Edited by Henry Walton. London: King Edward's Hospital Fund, Oxford University Press. 1986. Pp 231. £12.00.

This book derives from a conference jointly sponsored by the Royal College of Psychiatrists, the Association of University Teachers of Psychiatry, and the now dissolved Association of Psychiatrists in Training. This was held in Cambridge in 1982, and a post-conference meeting was held 18 months later. Fourteen working parties prepared documents for the Cambridge conference, while rapporteurs presented a summary of the discussions on each document.

All this would appear to be a recipe for fragmentation, inconsistency, variable standards of presentation, and dubious conclusions. It is greatly to the credit of the editor that he has brought together a single, cohesive, and up-to-date report on a range of issues to interest what are effectively the recipients or consumers of psychiatric education. The book exemplifies the fact that education is not a short-term process contributing to a basic degree in medicine, nor even a longer-term specialist training, preceding appointment to a consultant post or its equivalent in a psychiatric field. It is a continuing process in which the participants change roles at different stages of the proceedings.

At one moment the young undergraduate, thought to be naïve and undifferentiated, is receiving the words of wisdom, but the next moment that same student is challenging the traditional views held by the teacher, causing thought and interaction between them. The same process continues through general training, specialist training, and refresher courses. Indeed, as exemplified by the title, training is only one aspect of the whole, which is a process of education throughout one's professional career.

The various chapters of the book cover specific educational topics such as teaching psychiatry to medical students, during general professional training, and in higher psychiatric training. There is discussion about what the non-psychiatric doctor needs to know. Specific knowledge about psychiatric syndromes and modes of treatment are obviously part of the basic knowledge, but there are specific psychiatric skills and attitudes best summed up under the general term 'psychological mindedness', which is of general application but on which attention can often be easily focused during the psychiatric clerkship.

Unfortunately, medical students tend to respond to the segmented medical course by segmented thinking. A medical student who showed great interest in psychiatry surprised me by referring to "supratentorial problems" when I was asked to see a patient on a neurology firm. It was made very clear that when doing neurology one thought as a neurologist and abandoned all psychiatric pretensions. As a psychiatric teacher, it gave me pause for thought. It is to be hoped that general professional training can produce a more integrated conceptualisation to the fragmented undergraduate medical training and that this psychological mindedness, already inculcated, can be spread across medical thinking.

Attention is drawn to the lack of clear educational objectives in the field of postgraduate psychiatric training. Objectives and goals are listed and form a useful basis for individual training programmes. Arising out of this list of goals comes a need for some form of assessment. This implies an evaluation by the teachers separate from any formal national examination. The Royal College of Psychiatrists has been very clear that training programmes should form the basis of an adequate education, rather than the acquisition of a diploma which is a measure of the amount of knowledge possessed by an individual over a period of a week or two; such examinations are an inadequate measure of overall qualities, although they may still be the best available in practical terms.

In the section devoted to training settings and, in particular, to liaison psychiatry, attention is again focused on the contribution by the psychiatrist to areas outside the traditional psychiatric hospital, and even the psychiatric unit in the general hospital. It is important to get the balance between the various sites at which psychiatric expertise may be offered. A residual stigma is often felt to attach to the big psychiatric hospital, in spite of occasional changes of name. Wards in general hospitals have also suffered a similar tarnish. For their own benefit, and for the benefit of patients, there is a move to develop Mental Health Services in the community, staffed by non-psychiatrists who obviate the disadvantages of a formal psychiatric service. It remains to be seen whether such manoeuvres overcome the problems and provide a separate and different service from the psychiatric service which continues its medical links, and whether duplication is avoided and two services can be financed. It is to practise in such a changing world that the trainee of today is being educated.

Professor Walton is to be congratulated on producing a neat, comprehensive review of present-day issues, well laid out in short chapters and summarised at the end in a series of emphases. It is a book which should be read by all interested in training in psychiatry, and it is difficult to think of any group of psychiatrists excluded from that description and, indeed, relatively few doctors practising in medicine.

C. P. SEAGER, *Professor of Psychiatry, University of Sheffield*

Advances in Adolescent Mental Health. Vol. 1. Mental Health Disorders in Adolescence. Edited by RONALD A. FELDMAN and ARLENE RUBIN STIFFMAN. London: Jai Press. 1986. In two parts: Part A (pp 283) and Part B (pp 262). £85.00 (Parts A and B).

These two volumes from the Centre for Adolescent Mental Health, Washington University, St Louis (which was set up in 1983) promise to be the first in an annual series of books entitled 'Advances in Adolescent Mental Health'. The editors, who are respectively the Director of the Centre and an Instructor in Social Work in Psychiatry at Washington University, claim that their aim is to report and synthesise pertinent research about all aspects of adolescent mental health, thus attempting to correct earlier inadequate dissemination of knowledge in this field.

A total of twelve completely distinct chapters cover a mixture of clinical syndromes, such as depression in adolescence, anorexia nervosa, and attention deficit disorder in adolescence, and such psychosocial issues as adolescent heterosexual behaviour, cigarette use, alcohol abuse, and suicide, homicide, and accident trends. At first sight this seems a rather random and odd range of topics, not employing any obvious overall system, but this is explained by the editors as a deliberate attempt to tackle the most topical and anxiety-provoking problems presented by this age group first.

The 27 contributors represent very varied disciplines, including paediatrics, psychology, social work, education, and sociology. Only four chapters are from departments of psychiatry. In their introductory chapter, the editors explain that they were deliberately seeking this sort of breadth of coverage but recognise that in doing so they risk foregoing intradisciplinary depth regarding any particular problem. This is all too unfortunately true and is one of my criticisms of the books. Inevitably they vary considerably, but I found the chapters on clinical syndromes disappointingly superficial and coverage of treatment approaches particularly inadequate. However, two chapters which I appreciated, particularly because they tackle subjects not commonly referred to in other books, were those on loneliness, shyness, and withdrawal in adolescence (a familiar enough problem) by Eric Ostrov, a forensic psychologist, and gender role problems by another team of clinical psychologists. Conversely, that on attention deficit disorder, again by a clinical psychologist, reads almost like a foreign language to a British child psychiatrist not in sympathy with the American approach to this syndrome.

Each chapter has a similar format, which is basically that of a literature review, and the bibliography for each runs to seven or eight pages, sometimes more, including 1984 references. This in my view represents the best value of the books: as an up-to-date source of relevant references.

My strongest criticism has to be of the cost of these volumes. One can understand why they are so expensive: they are beautifully produced, and cloth bound. However, with smaller print and thinner paper the contents could comfortably occupy a single volume, and I really do not understand why it was felt necessary to create two. It is difficult to envisage many individuals paying this sort of sum, and few professional libraries in these economically stringent times are likely to feel they can afford to. In terms of value for money, there is absolutely no comparison with the child and adolescent psychiatrists' "bible" edited by Rutter and Hersov.

PATRICIA AINSWORTH, *Lecturer/Consultant in Child and Adolescent Psychiatry, Prestwich Hospital, Manchester*

GABA and Mood Disorders: Experimental and Clinical Research (LERS Monograph Series, Vol. 4). Edited by G. BARTHOLINI, K. G. LLOYD and P. L. MORSELLI. New York: Raven Press. 1986. Pp 222. $32.50.

This book presents the proceedings of a symposium held in Paris in 1984. A substantial number of the papers describe efficacy studies of drugs synthesised by the company which has sponsored this series of monographs. The presentation is uneven, and there is little sign of editing, so that overlap and repetition are common. A significant number of the chapters contain pronouncements with no reference, or with a reference to another chapter of the book (often written by a co-worker at Synthélabo).

The book launches into the complex neuropharmacology of GABA agonists, but interpretation is hampered by the lack of explanatory chapters on the anatomy and physiology of the GABA system in the CNS. The specificity and selectivity of GABA agonists to the GABA system is not discussed. Given the fact that GABA is a major inhibitory neurotransmitter for at least one-third of CNS synapses, it is striking what little clinical effect GABA agonists have in normal subjects. It is likely that their lack of effect relates to powerful local inactivation processes for GABA in the CNS, but this important issue is not tackled. It is suggested that GABA agonists may produce effects only when GABA is pathologically altered, but the evidence put forward that this is the case in affective illness is unconvincing.

However, important messages are contained in this volume. It becomes clear that manipulation of the GABA system can modulate a wide range of other neurotransmitters and their function. Moreover, well-known physiological and pharmacological changes in other transmitters and their receptors can be markedly altered by drugs acting on the GABA system. Interesting evidence is presented that the antidepressant effect of 'classical' antidepressants and ECT relates to changes in GABA function and GABA receptors. The antidepressant efficacy of GABA agonists appears to be equivalent to conventional antidepressants, and the clinical effects seem to be rapid and associated with few side-effects. An elegant chapter on carbamazepine by Post is included, but the evidence that this drug's interesting clinical effects are mediated by GABA was underwhelming.

On balance, the negative aspects of this volume outweigh the positive. It appears to be aimed at neuropharmacologists and biological psychiatrists, but misses both targets and will satisfy neither group. The best parts of the book have appeared or will appear in papers in refereed journals.

I. N. FERRIER, *MRC Clinical Scientist and Honorary Consultant Psychiatrist, MRC Neuroendocrinology Unit, Newcastle upon Tyne*

The Biology of Depression. Edited by J. F. W. DEAKIN. London: The Royal College of Psychiatrists. 1986. Pp 224. £7.50.

Twenty years ago Coppen wrote a lengthy review entitled 'The biochemistry of affective disorders', in which he classified the possible abnormalities underlying these disorders under amine, electrolyte, and endocrine changes. There has been remarkably little conceptual change since then and although Coppen's 1967 review is not quoted by any of the authors in this collection of 11 papers, Schildkraut's catecholamine hypothesis (1965) is cited by six of them. This compact little book derives from the proceedings of a one-day meeting of the Biological Group of the Royal College of Psychiatrists, held at Manchester University in 1985, and provides a valuable update on the present stage of British research into depressive illness.

Deakin and Crow set the scene with a comprehensive but concise review of monoamine neuropharmacology, concluding with yet another reformulation of the catecholamine hypothesis: "depression results from hypoactivity of catecholaminergic reward systems, and anxiety from hyperactivity of serotoninergic punishment systems, the two systems interacting with each other such that anxiety and depression represent separate but correlated dimensions of disturbance". In spite of its ingenuity, however, one can't help wondering how testable this is, and the philosophical problem of whether any identified biological changes are primary or secondary remains. Three of the subsequent papers deal with amine receptors, three with neuroendocrinology, and one with electrolyte changes. Additional papers cover genetic and physiological studies, and Paykel provides an authoritative appraisal of current antidepressant treatments and the management of resistent depression. The studies of receptor binding sites in post-mortem brain, platelets, and rat brain have yielded largely inconsistent or negative findings. However, the growing link with neuroendocrinology looks promising, particularly clonidine-stimulated growth hormone release and tryptophan-stimulated prolactin release as *in vivo* indicators of central α_2 adrenergic and 5HT receptor function respectively.

Evidently there is still a long way to go before we can really talk about 'the biology of depression'. Nevertheless, the editor is to be congratulated on the production of a most useful book which, apart from being very good value for money, should be essential reading for anyone planning clinical research in depression and highly recommended for psychiatric trainees preparing for the MRCPsych.

DAVID J. KING, *Reader in Psychopharmacology, The Queen's University of Belfast*

Principles into Practice: A Developmental Study of a Community Mental Health Service. By AILEEN MCDERMOTT. Manchester: Manchester Free Press. 1986. Pp. 69. £3.00.

This little booklet is simplicity itself and in being so it speaks directly to the professional. It says he must improve accessibility, informality, be people-(client)-centred, and encourage consumer involvement and integration of services. The account given is of a development in the centre of Manchester of a service for young people. It says that girls especially would have been helped if it had been in local neighbourhoods. It extols the service using cafes, pubs, etc., to help people feel at ease and says that, despite even that, some still fear approaching any services, let alone psychiatric clinics with their professionalism and bureaucracy.

The contribution of volunteers and the conflicts between them and "workers" is discussed. The introverts who need peace are mentioned, as is the fact that they need defending from the over-intrusive. The pleasantness and value of using ordinary meeting places together is mentioned. There is some criticism of structural programmes into which patients are to be fitted, and more emphasis is required on "Being" rather than "Doing", we are told. There must in addition, it is insisted, be little division in our approach to people classified as copers or non-copers: we all need respect, friendship, time, and security. Going for a walk, cooking a meal, having a drink, visiting the cinema, etc. together is worthwhile, whether or not intensely personal questions are raised. In an under-employed society surely there is time for this, and maybe it is as cost-effective as "treatment". The technical language of professional groups produces to some extent their cases – its avoidance goes some way to helping people.

The short time this sensible work takes to read is as rewarding as it is thought-provoking and refreshing. We are clearly helped to ask whether we do need to remain so respectable and pompous.

F. A. JENNER, *Professor, University Department of Psychiatry, Sheffield*

Psychopharmacology of Sexual Disorders. Edited by MARK SEGAL. London: John Libbey. 1985. Pp. 171. Price £26.00.

This is a short book containing contributions from 29 authors from eight different nations whose main objective is to increase awareness of possible psychopharmacological components in human sexual dysfunction.

It is divided into two sections, Basic Science and Clinical Science, is very readable and fulfils its objectives. The Basic Science section gives an outline of the animal experimental work being done in this area. The second section looks at what is known at a clinical level in the psychopharmacology of psychosexual disorders. In the final analysis this does more to highlight what is not known rather than what is known.

The book makes two important contributions to this field. It stresses the fact that thirty, rather than ten percent of patients who present with sexual dysfunction will have a physical or organic cause for it and emphasises the heterogeneous nature of sexual disorders with a novel form of classification in Chapter 10. This classification is based on ethology rather than the more traditional symptom orientated method.

The biggest fault of the book is its attempt to cover too many topics in too short a space. This, however, gives the authors the opportunity to put forward many useful suggestions in the area of research into sexual disorders. This is probably its greatest forte and makes it highly recommendable to workers in the field.

ETHNA C. O' GORMAN, *Consultant Psychiatrist and Senior Lecturer, Queen's University of Belfast*

Handbook of Psychiatric Diagnostic Procedures. Vol. II. By RICHARD C. W. HALL and THOMAS P. BERESFORD. Lancaster, Lancs: MTP Press. 1985. Pp. 359. £39.50.

This book opens with an excellent account of clinical EEG, condensing the conceptual and methodological issues, the findings, the diagnostic yield, and the limitations of EEG into a succinct, readable chapter. The application of EEG to sleep studies is equally comprehensive but the parasomnias are dealt with dogmatically, while ignoring recent advances in child psychiatry.

Further chapters consider the identification of melancholia with sleep studies and the shortened REM latency found in endogenous depression.

Darwin's neglected work on facial emotions has only recently been revived. Facial electromyography during states of affective imagery is one demonstrative legacy which this handbook addresses in a chapter on psychomotor function. It has exciting implications for diagnosis, prognosis, and social communication. Two chapters cover evoked potentials (EP) and brain spiking; there is one on CT scanning. Between descriptions of the structural changes in syndromes and indications for CT is a rather disappointing section on CT scan research.

I am not sure how many psychiatrists would read the second half of this book, which is devoted to the laboratory evaluation of anorexia, alcoholism, drug abuse, sexuality, geriatrics, and dementia. There is a poor chapter on the diagnosis of dementia, both clinically and psychometrically.

In a chapter on the paraphilias, a series of patients is presented of whom three-quarters (mainly paedophiles) had CT scan or chromosal abnormalities or elevated testosterone levels. The discussion bypasses selection factors and issues of validity, and typifies a conceptual narrow-mindedness evident in the book.

Three future directions are singled out: computerised practice, PET scanning (a good introduction) and the endorphins – three techniques "likely to be available in the near future". A handbook for the library, notable for its survey of electrophysiology.

ROBIN JACOBSON, *Lecturer, Institute of Psychiatry, London*

The Psychiatric Emergency: Its Recognition and Management. Edited by EUGENE O'NEIL. New York: The Haworth Press. 1986. Pp. 128. $24.95.

Of all the emergencies that may occur in general practice and within hospitals, the ones that generate most anxiety seem to be psychiatric. Any book which helps explain the problems and as a consequence diffuse the anxiety must be welcome. This small book, the proceedings of a conference, does not pretend to be exhaustive but has a series of lectures of considerable value. I particularly like the description of the work of the social worker as an initial assessor in a hospital emergency room and the way in which the authors tactfully coped with the doctor/PSW relationship. The lecture on drug emergencies is a concise and clear description of this large area of practice although the need to be over-inclusive results in a failure to stress the common presentations. The fact that manic patients may require much higher doses of psychotropic drugs should be corrected and the brief, almost naive chapter on affective disorders is in strict contrast to the more obsessional classifications in a chapter on Alzheimer's disease. The final chapter on alternatives to hospital in-patient care is of limited use to British practitioners and stresses the need for a broader survey of the problems that present urgently. If anything it emphasises the frustration of doctors and patients alike in mobilising alternatives to in-patient care. The book is useful for family doctors and social workers as well as hospital practitioners. It could be recommended more if the scope were expanded and the price less.

BERNARD ADAMS, *Consultant Psychiatrist, University College Hospital, London*

Recent Advances in Psychogeriatrics – I. Edited by TOM ARIE. Edinburgh: Churchill Livingstone. 1985. Pp. 235. £25.00.

How much psychogeriatrics is advancing depends on how one defines an advance. Interest has grown, even in academic departments, and books have multiplied disproportionately. There has been much repetition and much that is of indifferent quality. This book, however, is a useful and up-to-date compendium of reviews of many of the fields in Old Age Psychiatry; the topics are relevant and the literature surveyed contemporary.

Chapters deal with structural regeneration in the brain; epidemiology; survival in dementia; the genetics of dementia; the heterogeneity of Alzheimer's disease; the reversible dementias; quality of care in institutions; affective disorders in old age; measurement; new radiological techniques; international comparisons; education; and WHO programmes.

Many of the contributors have made significant advances in research and in practice and they write with authority. Each chapter has an extensive bibliography and the references, some going up to 1985, are abundant and wide-ranging.

LOÏC HEMSI, *Consultant Psychiatrist, St George's Hospital, London*

Law, Psychiatry and Morality: Essays and Analysis. By ALAN A. STONE. Washington, DC: American Psychiatric Association. 1986. Pp 277. £12.95 pb.

Dr Stone, a Professor of Law and Psychiatry at Harvard University, is an example of an exceedingly useful academic hybrid, unknown in this country but by no means exceptional in the USA. Because of his legal expertise Dr Stone is accustomed to the casuistry and double-talk of lawyers, and, when the necessity arises, can play them at their own game. This facility makes his book all the more valuable to forensic psychiatrists, untutored in the law, who are accustomed to call a spade a spade rather than a triple-edged offensive weapon.

Although I found the whole of this book eminently readable there are chapters or essays of outstanding importance, such as, for example, Chapter I: Political Misuse of Psychiatry: A Tale of Two Generals. In it Dr Stone compares the fate of two army generals, Petro Grigorenko of the Soviet Union and Edwin Walker of the United States, both charged with crimes against the state. As Dr Stone explains, "It should be emphasised that both generals' 'fixed ideas' attacked the most delicate political question of their nation, the corruption of the Soviet Revolution and the racism of the world's greatest democracy". It could be equally emphasised that also on trial was the integrity of the psychiatrists, or indeed of psychiatry itself, in their individual countries. Did the psychiatrists involved succumb to the temptation of becoming political tools of the Politburo on the one hand or the Kennedy administration on the other?

Dr Stone examines the evidence with scrupulous fairness. His conclusion from a legal standpoint is that, "It is the American legal system's constitutional safeguards which protected General Walker. It is the absence of such safeguards that led to the 'psychiatric terrorism' in General Grigorenko's case". And from the standpoint of psychiatry he makes a fervent plea that "psychiatrists should bend over backwards to avoid complicity, and the danger of becoming over-zealous lackeys".

Of comparable importance is Chapter IV: The Trial of John Hinkley. Hinkley, it will be remembered, attempted the assassination of President Reagen. His trial and the verdict, not guilty by reason of insanity, rocked public confidence in American psychiatry and in the American criminal justice system, although it seems clear that, as the law stood, the jury reached a just decision. Nevertheless, it was felt by the public at large that, due to the machinations of the psychiatrists, the would-be assassin of a popular President had got away with it. It would not be idle to compare Hinkley's trial with that of Sutcliffe, the Yorkshire Ripper, in 1981. It is exceedingly doubtful if the jury on this occasion reached a just decision, but the public's anxiety and lust for revenge was assuaged, and it was agreed, except by the majority of psychiatrists, that Sutcliffe had got his just deserts.

Dr Stone ends this chapter with a grim warning. He writes, "Psychiatry is held hostage by the psychiatrists who testify in courts whatever their standards and whatever the test of insanity may be... the reputation and credibility of our profession is in their hands...".

In chapters IV–VII Dr Stone paints a terrifying picture of the legal minefield in which mental health workers at all levels have to pick their way. So perilous has the situation become that, at least in the public mental hospital sector, to treat or not to treat has become a legal decision and not a psychiatric one. We may well ask how near we have come to matching this state of affairs in this country, and how much nearer will we come if certain of our civil libertarians continue to increase their influence on mental health legislation.

If I hesitate to recommend this book wholeheartedly it is only because the hazards of the practice of psychiatry are so painfully portrayed and so off-putting that many potential entrants to the field might adhere to the advice of an American Appeal Judge, Judge Aldisert: "If you are contemplating a position as an attendant in a mental hospital, seek another job!"

HENRY R. ROLLIN, *Emeritus Consultant, Horton Hospital, Epsom*

The Diagnosis and Treatment of Drug and Alcohol Abuse. Edited by SIDNEY COHEN and JAMES F. CALLAHAN. New York: The Haworth Press. 1986. Pp 305. $39.95.

This volume brings up to date previous monographs issued by the United States National Institute on Drug Abuse. It is a guide to practical issues in the recognition, assessment, and management of drug and alcohol abusers. It is designed for nurses and doctors and is very medically oriented, but could be read by psychologists, social workers, and lay counsellors wishing to understand the practical and medical aspects of managing these conditions.

It is clearly laid out, well indexed, and has a strong cover, a clear large typeface, and durable paper. It would survive well and be useful in a busy clinic or ward.

It is richer and fills more of a gap when dealing with drug abusers than with alcohol abusers, although it is unfortunate that in a book published in 1986 there was not more on cocaine and on the HTLV-III virus. Methadone maintenance treatment (which the Federal Drug Administration permits if an abuser has been dependent on heroin for two years) is treated favourably, although, given the format of the book, not debated in detail. There is a guide to the use of clonidine in opiate withdrawal. The future potential of naltrexone, the long-acting opiate antagonist, in preventing relapse is touched on: so long as naltrexone is taken regularly, the euphoric effect of opiates is blocked. Overdosage of commonly abused drugs is usefully dealt with.

The alcoholism sections are useful, but are not as rich in detail as the drug abuse sections. Whereas all manner of skin lesions and disorders are described in drug abusers, the injected conjunctivae and excessive skin capillarisation of the alcoholic are not mentioned. Hypertension is erroneously said not to occur in alcohol withdrawal.

The last 61 pages detail training resources in the United States, with names and addresses of trainers and lists of training materials. This is of little or no relevance to readers outside North America. There are other sections which make the book unlike a standard text, but which are more useful. Each part of the book is preceded by a true/false or MSQ set of questions, and you are invited to test yourself again after reading each section. This is a helpful aid to study. The model assessment interview is detailed and would well provide a basis for a clinic wishing to devise its own assessment schedule. It is suggested that the counsellor records subjective data: (a) "does he like the client?"; (b) "does the client scare him?"; (c) "is the client a hustler?"; (d) "is he a nice person?". As this might suggest, the level of psychological sophistication in the book is not high. Some important psychosocial aspects of drug and alcohol abuse are not mentioned at all, such as marital and sexual problems and the needs of the family.

Nevertheless, for the trainees in a Drug Abuse clinic, or at a Casualty Department or Infectious Diseases unit where drug abusers are frequent attenders, this would be a useful introduction. The well-endowed Department of Psychiatry Library could also consider buying a copy if it is lacking a textbook on the topic.

JONATHAN CHICK, *Consultant Psychiatrist, Royal Edinburgh Hospital*

Science and Service in Mental Retardation. Edited by JOSEPH M. BERG. London: Methuen. 1986. Pp 475. £45.00.

The International Association For The Scientific Study of Mental Deficiency was founded in 1964 and, among many other activities, has promoted a conference every three years. This book, produced commendably quickly, contains part of the proceedings of the conference co-sponsored by the World Health Organization and held in New Delhi in 1985. This venue provided the opportunity for the conference to relate current knowledge and practice to the services in the Third World. The Association commends the multidisciplinary approach and attempts to bring together research and practice in the vast area of primary prevention, ranging from biological studies, through the characteristics and needs of the handicapped person, to service development in all parts of the world.

The contents of the book have been sensibly restricted to 47 out of some 200 papers presented at the conference. The result is a range of interesting papers covering epidemiology, clinical and biological studies, behavioural and psychiatric aspects, educational considerations, preventive and therapeutic interventions, retardation in adulthood, and perspectives in developing countries. The editors are to be congratulated on the balance of the papers chosen, which demonstrates the growing points of the specialty. While biological research aimed at disease identification and primary prevention must continue, there is no doubt that people with a mental handicap will always be with us. There is evidence that services are becoming more sophisticated throughout the world and that the developing countries have the opportunity to avoid the tragic errors of service delivery made by those that are supposedly more advanced.

These triennial conferences and the subsequent publication are unique and mark the progress made on the international scene of our sub-speciality. Long may they continue to provide a universal knowledge base, a sense of purpose, and a chance to renew our dedication and commitment to people with a mental handicap throughout the world.

JOAN BICKNELL, *Professor of the Psychiatry of Mental Handicap, St George's Hospital Medical School, London*

Obsessive Compulsive Disorders: Theory and Management. Edited by MICHAEL A. JENIKE, LEE BAER and WILLIAM E. MINICHIELLO. Bristol: Wright. 1986. Pp 196. £16.00.

Sir Aubrey Lewis's concise, clear, and assertive writings on obsessional disorders provided a dependable guide and a standard for over 30 years. It is reasonable to expect new publications on this subject to add to or improve Lewis's account, and to incorporate the information gathered since the resurgence of interest that took place in the seventies. Many parts of this book are considerably less adequate than the writings by Lewis, some sections are misleading, and all but two chapters make little or no reference to recent research findings.

The book is divided into 11 chapters that are intended to cover aetiology, epidemiology, behaviour therapy, somatic treatments, psychotherapy, prognosis, related disorders, the biology of the disorder, and the management of the individual patient. Dr Jenike, the first-named and presumably the senior editor, wrote six of the eleven chapters and was co-author of two others.

After reading the first few chapters of the book it became evident that Lewis's work had either been forgotten or was being ignored. As there is no author index, it was necessary to make a count of the number of references to his work, and the total for the entire volume is two – both minor.

Most of the contributions are unsatisfactory. Jenike's chapter on aetiology consists of a brief examination of several possibilities, none of which are considered in detail. His concluding remarks contain the following statement:

> "The fact that OCD (obsessive-compulsive disorder) is refractory to non-behavioural psychotherapeutic manoeuvres but is responsive to certain medications and surgical techniques lends support to a neurologic hypothesis for OCD" (page 18).

Even if that statement were accurate, which is debatable, it does not follow that a neurological hypothesis would be supported. But in any event, the statement fails to consider the effects of behavioural methods of treatment and the theoretical consequences of this evidence. This omission is especially strange, as on page 60 of the same book Baer & Minichiello state that, "in general, these studies have found that 60% to 70% of patients with compulsive rituals were much improved after behavioural treatment", and on page 38, Rasmussen & Tsuang note that, "over the past 15 years, significant advances have been made in the behavioural and pharmacological treatment of OCD".

Jenike opens his chapter on psychotherapy with the admission that "traditional psychodynamic psychotherapy is not an effective treatment for patients with obsessive-compulsive disorder as defined in the DSM". Not easily dissuaded, he then proceeds to give ten pages of advice on how to conduct such psychotherapy. In this chapter, as elsewhere, the information and conceptual approach are out-of-date.

More seriously, Jenike's recommendation of psychosurgery may be misleading. In a chapter that repeats most of the old information, but fails to refer to the large volume by E. Valenstein (*The Psychosurgery Debate.* San Francisco: W. F. Freeman, 1980) devoted exclusively to psychosurgery, Jenike concludes that, "for the patient with disabling OCD, who fails to respond to more conservative treatment, psychosurgery is a viable option" (page 105). This conclusion is not justified by the older evidence, and the one recent study (Tippin, J. & Henn, M. (1982) *American Journal of Psychiatry*, **139**, 1601–1603) which is used to bolster his conclusion consists of no more than five highly selected cases which are incompletely and unsatisfactorily described and analysed.

The chapter on epidemiology by Rasmussen & Tsuang is sound and informative, as is the critical review of behaviour therapy written by Baer & Minichiello. The outcome of the ambitious epidemiological study referred to by Rasmussen is awaited with great interest. These two chapters deserve to be published in better company.

STANLEY RACHMAN, *Professor, University of British Columbia, Canada*

Drug-Induced Diseases in the Elderly. By F. I. CAIRD and P. J. W. SCOTT. Amsterdam: Elsevier Biomedical Press. 1986. Pp 210. US$70.25, Dfl. 190.00.

In no branch of medicine are adverse drug reactions (ADRs) more important than in (psycho-)geriatrics. In the late 1970s an estimated 12% of admissions to geriatric units in the UK were at least partly due to ADRs. The incidence in hospital and general practice is probably falling due to wider understanding of the problems and better education of doctors, but as the authors state, there is "no reason at all for complacency".

This book is sub-titled "*A critical survey of the literature*", which is not strictly true. A great deal of the literature has been read, no doubt with a critical eye, and reference lists are lengthy, but most of the text could not be described as a critical survey. In fact, it is much better and more useful than that. After some short, pithy introductory chapters on epidemiology, mechanisms, and management, the remaining three-quarters of the book deal with specific ADRs, first by systems (neuropsychiatric, gastro-intestinal, cardio-vascular, etc.) and then by main drug groups (psycho-pharmacological agents, anti-convulsants, etc.). Most ADRs are therefore covered twice, once from each standpoint.

The text is set out with exemplary clarity. Paragraphs are short and numbered for easy reference. Tables are numerous, easily understood, and give information at a glance. The index is comprehensive. Thus what we have here is an excellent reference dictionary on ADRs in the elderly, which I have already found useful in clinical practice. I should like to have recommended it for every medical library and (psycho-)geriatric ward in the country. However, I fear that the publishers have ruled this out by setting a price so unreasonably high as to go beyond most means in these straightened times.

ROBIN JACOBY, *Consultant Psychiatrist, The Bethlem Royal Hospital, Kent*

Behavioral Neurology: A Practical Approach. By HOWARD S. KIRSHNER. Edinburgh: Churchill Livingstone. 1986. Pp 230. £24.50.

What is behavioural neurology? It is a discipline which does not appear to exist in the UK, at least under this name. Apparently it is flourishing in the USA, and this is the second textbook in recent years to be published from that country with this title. The author tells us that behavioural neurology is "the study of the effects of brain disease on human behaviour and higher cortical functions. Behaviour, in this context, includes both specific, localised brain functions such as language, memory calculations, and visuospatial ability, and the more difficult to define qualities of intelligence, mood and personality". After a brief chapter on the neurological approach to mental state examination, more than half the book is taken up·with aphasias, alexias, agraphias, apraxias, agnosias, and disorders of the right hemisphere. There follows chapters on the frontal lobes, amnesias, dementia and ageing, delirium and acute confusional states, and finally behavioural aspects of epilepsy.

A comparison with the book on behavioural neurology by Pincus & Tucker reveals considerable discrepancies and uncertainties as to the scope of behavioural neurology in the USA. Pincus & Tucker include chapters on schizophrenia, depression, psychosis, movement disorders, sleep, limbic system, and violence, none of which are covered in Kirshner's book. Indeed, the great bulk of this monograph is a more detailed review of 'disorders of intellectual functioning' (using the Pincus & Tucker terminology) without specific consideration of organic brain syndromes in children, early childhood autism, or 'attention deficit disorder'. Some aspects of this volume are also covered in greater detail by Benson in a monograph in the same series on aphasia, alexia, and agraphia.

The author advises us that behavioural neurology should be distinguished from two related fields, neuropsychology and biological psychiatry. The former he defines as "the branch of psychology which deals with assessment of brain disease by standardised psychological tests". The latter is defined as "the study of physical or organic abnormalities underlying primary psychiatric diseases such as depression and schizophrenia, in which no primary brain abnormality is proved" (a view which is clearly not shared by Pincus & Tucker). There is in this book, as the author admits, much from the field of neuropsychology, which he regards as complementary to the subject of behavioural neurology.

We are told that the history of behavioural neurology has had two distinct phases. It began with the descriptions of the great 19th century neurologists. It lapsed in the early and middle years of the 20th century under the influence of psychological theories and religious beliefs. We are now in the second golden era of behavioural neurology, which began after World War II when the late Dr Norman Geschwind, as much as any individual, rediscovered the important descriptions of the 19th century behavioural neurologists and renewed the study of the higher cortical functions. Perhaps the author is describing a purely American phenomenon and he does not know that the 19th century clinical findings and descriptions, which were after all European, were not lost sight of or forgotten in Europe (although it must be admitted that there is a danger of this happening now in the UK).

This volume is indeed an update of the 19th century clinico-anatomical approach to selected aspects of neurology. It contains a liberal number of neuro-anatomical diagrams, modern CT scan pictures, and tables relating clinical symptoms to focal lesions. The main emphasis is diagnostic, with relatively few excursions into therapy. What is lacking is any 'functional' component to the picture, using the word in its 19th century neurological sense. For example, there is not an EEG tracing in sight, even in the chapter on behavioural aspects of epilepsy. Clinical practice so often reveals that, even with the help of the modern CT scanner, the strict relationship of clinical syndromes and symptoms to local lesions is not always so straightforward as this book suggests.

E. H. Reynolds, *Consultant Neurologist, Maudsley Hospital, London*

Transcultural Psychiatry. Edited by John L. Cox. Beckenham: Croom Helm. 1986. Pp 337. £29.50.

This is a multi-author text which sets out to be a contemporary critique of transcultural psychiatry. The book is divided into 18 chapters, and the various authors have in the main drawn on information not only from their clinical, research, or anthropological standpoints but from their intimate knowledge of the various socio-cultural groups described. The essential material includes: the epidemiology of mental illness across cultures; migration; family therapy across cultures; psychiatric services for ethnic minorities; depression in ethnic minorities; and politics and the impact of racism on mental illness. The book dispels the common myth that the mainstay of transcultural psychiatry is a cluster of culture-bound syndromes presenting in ethnic minorities (from far-away lands), often with bizarre or dramatic manifestations. The salient point is that no society is entirely homogenous and that there are equally important cultural determinants to the presentation and outcome of disease in, say, a first generation West Indian living in Britain as in an Irishman who has emigrated to England.

The significance of this is often inadequately explored or underestimated in the mental state in clinical practice. The difficulty in applying 'orthodox' descriptive psychopathology to individuals of varying cultural backgrounds is also illustrated. For instance, in the definition of a delusion (a false, unshakeable belief held against all evidence to the contrary, and also out of keeping with the patient's social and cultural background), how sure can one be in reliably eliciting this phenomenon without being *au fait* with every culture? A similar point is also made with regard to nosology.

Racism, prejudice, and the paucity of an adequate psychiatric service for ethnic minorities makes for sombre but imperative reading, and warns of the dangers in underestimating the level of distress caused by deprivation and isolation which pervades the life of many minority groups.

The multiplicity of contributors with their differing styles makes the book a little disjointed, and many readers may prefer to use it more as a source of references (with which the book is studded) than as a source of basic information. This, however, would be a pity, as on the whole the book is well written and has a definite clinical bias. It succeeds in providing an excellent review of essential aspects in transcultural psychiatry. As a result, most workers in psychiatry would benefit from reading this book, and it would no doubt stimulate in some an interest in medical anthropology.

B. A. Johnson, *Registrar in Psychiatry, The London Hospital (St Clement's)*

Genetic Risk. By Stephen Thomas. London: Penguin. 1986. Pp 182. £3.95

This book has been written by a layman, a one-time consumer of genetic counselling, for other consumers or potential consumers. It provides a clear and well set-out discussion of the basis of human genetics and the application of genetics in clinical practice. There are useful chapters on pre-natal testing, abortion, contraception, and sterilisation, as well as artificial reproduction. There is a well considered chapter, entitled 'Decisions', which describes the practical aspects, the ethical problems, and the potential benefits of genetic counselling. In the main the book deals with single gene disorders and chromosomal abnormalities, with relatively little on multifactorial conditions. It is therefore only of limited use to a reader whose specific aim is to obtain a straightforward guide to genetics as applied in psychiatry. However, it is well researched, is carefully and clearly written, and can be confidently recommended to those without a medical or biological background who wish to obtain a brief, balanced overview.

PETER MCGUFFIN, *Professor of Psychological Medicine, University of Wales, Cardiff*

Neurology and Neurobiology, Vol. 17: Two Hemispheres—One Brain. Functions of the Corpus Callosum. Edited by FRANCO LEPORE, MAURICE PTITO and HERBERT H. JASPER. New York: Alan R. Liss. 1986. Pp 565. £89.00.

This volume is one of a well-known series and contains the proceedings of a conference held in Montreal in 1984. It is well produced, adequately illustrated, and contains a series of chapters which span the fields of philosophy via anatomy to neuropsychology. I particularly enjoyed the introductory chapters by Sperry and Bogen, both of whom give overviews of the conceptual issues involved in considering the behavioural results of commissurotomy. To the casual observer, patients who undergo this procedure appear normal. How can it be that the result of severing some 200 million nerve fibres which join one half of the brain to the other is a splitting of consciousness which is only demonstrable using controlled lateralised testing? The results from such tests indicate that the subjects have a consciousness in each hemisphere and each show appropriate reactions to social events. This finding is expanded by the work of Jeeves, which describes work on acallosal patients. The puzzle of how separate consciousnesses are fused in normal people is the starting point for other chapters which aim to show that the corpus callosum is not just for holding the two hemispheres together.

The anatomy of the corpus callosum is particularly well served in historical perspective (Collonier) and in detailed reviews of the topography of commissural fibres. The relevance of callosal anatomy to the thorny problems of laterality in humans is discussed by Witleson in 'Wires of the mind'. Functions of the corpus callosum are dealt with in depth in the sections on electrophysiology, animal behaviour, and human neuropsychology.

The last section of the book contains a series of useful reviews critically assessing investigations using particular techniques (e.g. cerebral blood flow, visual masking) or theoretical approaches (e.g. complementary specialisation).

In summary, this is a useful book. The introduction will be of interest to any general reader intrigued by notions of brain and mind. There is enough detail in other sections to make this a handy reference work. Its price takes it beyond the reach of many who would profit from it, and probably ensures that it will only be found on library shelves.

GARETH W. ROBERTS, *Clinical Research Centre, Northwick Park Hospital*

Suicide. Edited by ALEC ROY. London: Williams & Wilkins. 1986. Pp 205. £27.00.

Suicide is statistically a relatively rare event which is difficult to predict even after intensive individual assessment, and the practical problems which beset research into it are no less formidable. Nevertheless, the assessment of a suicide risk and its prevention is an important aspect of day-to-day clinical practice. This volume is a welcome addition to the literature on the subject.

A dozen or so distinguished researchers into suicide have contributed as many chapters over a wide range of topics relevant to suicidal behaviour. Although there is inevitably a certain amount of redundancy of material from one chapter to another, each is closely linked with the wider literature which on the whole is commendably up-to-date. Topics range widely from epidemiological, genetic, and biological themes, through a systematic consideration of psychotic syndromes and physical illness, to issues concerned with management and prevention. Much of the material is thought-provoking, and the underlying approach of each author is discernible in each chapter: this adds to the authoritative quality of the volume as a whole. Much information is packed into the deceptively slim size and it is no quick read.

Those who need rapid access to reference material for teaching purposes will certainly find this book useful. It also deserves attention from anyone with a special interest in suicide and its prevention. Entirely written by psychiatrists, its emphasis is on medical and other clinical aspects of the problem. It is to be hoped that its second edition will also include more detailed consideration of the environmental and relationship factors which play such an important part in deciding whether or not a vulnerable individual will commit suicide.

H. G. MORGAN, *Professor of Mental Health, University of Bristol*

Contents of
THE AMERICAN JOURNAL OF PSYCHIATRY

Volume 144, Number 2 **February 1987**

Special Articles

127 Self-Portrayal by a Depressed Poet: A Contribution to the Clinical Biography of William Cowper. *Joachim-Ernst Meyer and Ruth Meyer*

THE BRITISH JOURNAL OF PSYCHIATRY

April 1987 Vol 150

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrist

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . .'

> DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.
>
> KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124**, 352–358.
>
> RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.
>
> SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

POSTDOCTORAL FELLOWSHIP

Clinical Psychiatric Research

1 Year, Stipend $40,000

The fellowship, available immediately, will primarily provide advanced training and hands-on experience in research into clinical psychopharmacology and psychopathology of schizophrenia.

Opportunity for contacts with analytical psychopharmacologists, biostatisticians, clinical neurophysiologists, molecular biologists at The Nathan Kline Institute for Psychiatric Research and New York University.

The Nathan Kline Institute, a major affiliate of New York University, is located in the suburbs 20 miles from New York City.

Requirements:
M.D. degree, 3 years training in clinical psychiatry, some ability in research.

Send C.V. to:
Dr. Michael Kohn, Nathan Kline Institute,
Orangeburg, New York 10962, U.S.A.

Disipal® Controls symptoms and elevates mood.

THE AGA KHAN UNIVERSITY

Faculty of Health Sciences
Medical College

The Aga Khan Medical College is now in its fourth year of operation. Its affiliated Aga Khan University Hospital has well equipped teaching and service laboratories and will have 721 beds when fully operational. The University and the University Hospital are autonomous privately funded institutions respectively committed to the provision of effective education and health services relevant to developing countries.

Applications are invited from candidates who meet the requirements for the positions of :

ASSISTANT PROFESSOR, DEPARTMENT OF PSYCHIATRY

Candidates applying for this position are required to have completed their postgraduate training in Psychiatry with specialty certification and must have three to five years of subsequent clinical experience

INSTRUCTOR, DEPARTMENT OF PSYCHIATRY

Candidates applying for this position must have MBBS and M.R.C. Psych (U.K.) or American Board in Psychiatry or equivalent qualifications.

Salary and benefits will be offered commensurate with qualifications, experience and level of responsibility Candidates intending to pursue a career in Pakistan will be preferred. Applications should include detailed résumé, bibliography and names and addresses of at least three referees familiar with recent work history. Reply to the Personnel Director, P.O. Box 3500, Stadium Road, Karachi-5, Pakistan.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine[1], trifluoperazine[2] and haloperidol[3] but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia[4]

sulpiride

Dolmatil™

IN SCHIZOPHRENIA

MENTAL HEALTH CARE

SQUIBB®

Prescribing Information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other Each tablet contains 200mg sulpiride. **Indications:** Acute and chronic schizophrenia **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended **Predominantly positive symptoms**· Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily **Predominantly negative symptoms** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily **Mixed positive and negative symptoms** 400mg–600mg twice daily The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment Clinical experience in children under 14 years of age is insufficient to permit specific recommendations **Contraindications:** Phaeochromocytoma **Warnings**· Extrapyramidal reactions principally akathisia have been reported in a small number of cases If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients in aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms Care should be exercised where hypomania is present Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy – anti-convulsant therapy should be continued unchanged Impaired renal function, as sulpiride is eliminated via the kidney Pregnancy – the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number**· PL 5299/0006 **Legal category:** POM **Basic NHS cost**· 63p per day at dose of 600mg daily **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141–149 Staines Road, Hounslow, Middlesex TW3 3JA •Trade Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL – Trade Mark of SESIF Authorised User Delagrange Ltd **References** 1 Harnryd C et al Acta Psychiatr Scand 1984;69 (Suppl 311) 7–30 2 Edwards J G et al Br J Psychiatry 1980, 137 522–529 3 Munk-Anderson E Acta Psychiatr Scand 1984, 69 (Suppl 311) 31–41 4 Schiff A A Brit Med J 1985, 291 (6506)· 1424

Annotation

Neuropsychiatry

D. ROGERS

The last 20 years have seen a rapidly growing interest in disorder of brain function in psychiatric illness but this is only the latest phase in a steady development of ideas over the last three centuries. Throughout this time, biological and psychological formulations of psychiatric disorder have co-existed and, at different periods, one or other has been the focus of attention. Thomas Willis, who coined the word 'neurology' 300 years ago, felt that psychiatric disorder represented brain disorder, but it was only during the nineteenth century, as understanding of brain function made its first real progress, that this opinion became more explicit and accepted. By the second half of the century, it was axiomatic that psychiatric disorder was synonymous with brain disorder (Griesinger, 1845; Maudsley, 1873; Ferrier, 1878); all that was lacking was the actual neurophysiological basis of mental disorder.

Ironically, as this neurophysiological knowledge then gradually accumulated, the focus of attention shifted to investigation of abnormal mental states divorced from cerebral function. Thus, as the first intimation of chemical mediation of nerve impulses (Elliot, 1904) and the concept of extrapyramidal motor disorder (Wilson, 1912) appeared, Bleuler (1911) put forward his psychological concept of schizophrenia. As the electroencephalogram was introduced (Berger, 1929) and the insights into neurotic and psychotic phenomena provided by epidemic encephalitis described (von Economo, 1931), the psychological approach pioneered by Freud, Adler, and Jung, which sought to construct causal explanations out of the stuff of subjective experience, was claimed to be more successful than the physiological approach (Hart, 1932). At the same time as the limbic system was being proposed as a cerebral basis for emotion (Papez, 1937), Lewis (1934), in his classic papers on depression, condemned the physiological and neurological conceptions of the previous generation of psychiatrists and the 'biological tendencies' of those contemporary psychiatrists who maintained an interest in the central nervous system.

Ey and his colleagues (1947), in the first extensive critical study of the relationship of neurology and psychiatry, concluded that this hinged on conflicting conceptualisations of the relationship of psychiatric disorder and the brain. For some, psychiatric disorders were disorders of the nervous system, neurologists specialising in disorders below the brainstem and psychiatrists in those above; this could be called the neurological paradigm. For others, psychiatric disorder was radically different from cerebral disorder, psychiatry having nothing in common with neurology; this could be called the psychological paradigm. These paradigms represent conceptually different approaches to understanding psychiatric disorder. Either approach is valid but they are mutually exclusive like the two different views of a Necker cube. The same psychiatric disorder can be viewed in terms of either paradigm. Individuals make their own decision as to which approach provides a more satisfying understanding of a particular disorder. Majority opinion is subject to an historical process. After the turn of the century, most psychiatrists favoured the psychological rather than the neurological paradigm, and most neurologists left the study of behavioural disorder to philosophy.

About 30 years ago, the neurological paradigm in psychiatry started to re-establish itself. Between 1950 and 1970, the main theory of the genesis of infantile psychosis changed from a psychogenic to a neurophysiological one (Kolvin *et al*, 1971). Anderson (1952) described a personal conversion from one paradigm to the other, and how the symptoms in adult patients with schizophrenia that she had previously conscientiously tried to interpret psychodynamically now appeared quite similar, if not identical, with known organically determined symptoms, as some had consistently maintained (Kleist, 1960). From this time the neurological paradigm became an increasingly orthodox position (Symonds, 1960; Hunter, 1973; Kiloh, 1982), and technological advance again stimulated interest in the investigation of major mental disorder. The rise of biological psychiatry was evidence of this new interest, although its concentration on biological processes managed to avoid the neurological implications of the change in approach. Neurologists developed a new interest in behaviour which grew to become 'behavioural neurology'. Some (Damasio, 1984) completely excluded psychiatry from participation in this new speciality, although others

(Stevens, 1982) pointed out that it was in fact another name for neuropsychiatry. The modern revival of neuropsychiatry is bringing psychiatry and neurology together again after a century of separation; 'we are back where Griesinger started' (Caine & Joynt, 1986).

Conceptions of neurological disorder have also evolved. Not all neurological disorder is constant and irreversible. Basal ganglia disorders typically fluctuate in severity and the extensor plantar response after an epileptic fit is fully reversible. Neurological features of psychiatric illness are typically variable in expression and can be completely reversible, including such 'hard' neurological signs as extensor plantar responses in schizophrenia (Claude *et al*, 1927). Neurological features fluctuate in severity with the severity of psychiatric features of both neurological and psychiatric disorder (Modai *et al*, 1985; Tucker & Silberfarb, 1978). Thus the more severe the psychiatric disorder the more neurological it will appear. Certain neurological disorders, for example oculogyric crises, basal ganglia diseases, epilepsy and spasmodic torticollis can be precipitated, exacerbated, improved or completely resolved by psychosocial factors (Delbeke & van Bogaert, 1928; Brenner *et al*, 1947, Fenwick, 1982; Jayne *et al*, 1984). There have long been suggestions that symptoms produced by physical trauma to certain areas of cerebral tissue might also arise from transient and reversible lesions in the same areas, including those produced by emotional trauma (Marinesco & Dragenesco, 1929; Vujic, 1952; Whitty, 1956). A proper neuropsychiatric assessment always considers the contribution of psychosocial factors.

The conceptual issues discussed above have important practical consequences. The terms 'organic' and 'functional' both have two distinct meanings. Organic can mean structural or it can mean physical in origin; functional can mean physiological or it can mean mental in origin. Two issues are involved: one is descriptive – the presence or absence of recognisable pathological change, and the other philosophical – the choice between the two paradigms for psychiatric disorder. These two issues are completely independent and bear no necessary relationship to each other. Ambivalent use of the terms organic and functional, however, allows this distinction to be blurred. Thus, the difference between organic and functional psychoses theoretically refers to their presumed physical or mental origin, but in practice hinges on the presence or absence of recognisable cerebral disorder. This means that in clinical and research investigations of functional psychosis, when the investigation reveals brain disorder in particular cases, these are excluded from the study (Johnstone *et al*, 1986*a*, *b*). It allows the same textbook (Pincus & Tucker, 1974) to accept minor neurological abnormalities as commonly found in schizophrenia (p. 108), but give the absence of major neurological deficits as one of the important criteria for its diagnosis (p. 86). It makes the preliminary elimination of organic states a requirement for psychiatric assessment with precise diagnostic instruments such as the Present State Examination (Wing *et al*, 1974) and Research Diagnostic Criteria (Spitzer *et al*, 1978), although the criteria for this important first step are not specified. These paradoxical positions have been consistently criticised (Gibbs, 1938; Ferraro, 1943; Stevens, 1982; Murray *et al*, 1985), but are still orthodox. A basically philosophical issue is interfering with empirical research, since the cases excluded from investigation are likely to be the very ones to throw most light on the cerebral basis of psychiatric disorder.

A neuropsychiatric approach is an approach to psychiatric disorder in general. It is not limited to psychiatric disorder associated with known cerebral disorder. With such an approach there is no absolute demarcation between neurological and psychiatric disorder and disorders can only be classified as neurological or psychiatric in terms of who manages them. Neurological examination and investigation is performed on patients with psychiatric disorder for the information it provides on the disorder and not only to define those cases needing referral to a neurologist. Abnormalities detected are no longer described as incidental or non-contributory. Neurological dysfunction is incorporated as a component of psychiatric syndromes. Medication is not divided into neurotropic and psychotropic. Needless to say, a neurological approach does not in any way preclude a caring or supportive approach to the patient, from either neurologist or psychiatrist.

In England and Wales there are currently ten times the number of consultant psychiatrists (including mental handicap) as consultant neurologists (DHSS, 1983). Most central nervous system disorder is managed by psychiatrists. Thirty years ago, neurology could lay claim to the study of the neural basis of all the psychological functions of man (Brain, 1958). Now, a neurological approach is becoming increasingly relevant to the practice of psychiatry. It is both permissible and desirable. However, even in some university centres, psychiatrists are not permitted to order essential neurological investigations on their out-patients because they are not considered competent enough by their non-psychiatric colleagues (Hays, 1985). In future, neuropsychiatry must form a major part of the training of psychiatrists.

Review Article

Amnesia:
Organic and Psychogenic

M. D. KOPELMAN

This paper describes the clinical features of selected examples of organic and psychogenic amnesia, and it discusses the nature of the dysfunction that these amnesias entail. The anterograde component of organic amnesia involves a severe impairment in acquiring (or learning) new information, rather than accelerated forgetting, and this may reflect an underlying limbic or neurochemical dysfunction. Retrograde amnesia has a basis which is (at least partially) independent of anterograde amnesia – in some patients, it appears to involve a failure to reconstruct past experience from contextual cues, and this may reflect a superimposed frontal dysfunction. Two types of confabulation are discussed, one of which ('provoked') is a normal response to poor memory, and the other ('spontaneous') appears to reflect incoherent, context-free retrieval, associated with more severe frontal pathology. It is argued that many cases of psychogenic amnesia may resemble organic amnesia, in that they result from an impaired acquisition of information at the time of initial input, perhaps thereby predisposing the subject to subsequent retrieval difficulties.

> The stream of thought flows on; but most of its segments fall into the bottomless abyss of oblivion. . . . Selection is the very keel on which our mental ship is built. And . . . its utility is obvious. If we remembered everything, we should on most occasions be as ill off as if we remembered nothing.
>
> (William James, *The Principles of Psychology*, 1890)

> We oftentimes find a disease quite strips the mind of all its ideas, and the flames of a fever in a few days calcine all those images to dust and confusion, which seemed to be as lasting as if graven in marble.
>
> (John Locke, *Essay concerning Human Understanding*, 1690)

In recent years, the truth of these two maxims has been demonstrated in Luria's brilliant case histories, which have illustrated the crippling consequences of an extraordinarily absorptive and retentive memory (Luria, 1969), as well as the devastating effects of a 'shattered' one (Luria, 1976). Memory plays a central organising and selective role in our mental life. Moreover, its anomalies of function were the starting point for psychoanalysis; its impairment is an early and common sign of organic dysfunction; and its disruption in dementia is one of the most prevalent and distressing of psychological disabilities. For these various reasons, the study of memory and amnesia should be of immense interest to the general psychiatrist.

Regrettably, progress in this topic has sometimes been impeded by the narrow perspectives of particular disciplines, and by their conflicting uses of terminology. Because of this, the present review will begin with a brief outline of the terminology to be employed here; and it will then consider the topic in four sections:

(1) clinical aspects of organic amnesia
(2) the nature of the deficits in organic amnesia
(3) the neuropathology of amnesia
(4) psychogenic amnesia.

The paper will summarise the principal features of selected examples of organic and psychogenic amnesia, and it will discuss the main theories which purport to account for these disorders in terms of the registration, retention, or retrieval of information. In addition, it will draw attention to resemblances between organic and psychogenic amnesia, in the hope that the extensive research on the nature of the former may also shed some light on the latter.

Terminology

Experimental psychologists distinguish between a *primary* (or *short-term*) memory of very limited capacity, which holds information for a few seconds only, and a *secondary* (or *long-term*) memory of much greater capacity and durability. *Secondary memory*, therefore, encompasses all material recalled beyond a period of a few seconds, and items within it may have occurred within the remote or recent past. *Remote* and *recent memory* tend to be very loosely defined, but generally refer to the relative *age* of particular memories; whereas *retrograde* and *post-traumatic amnesia* are precisely defined in terms of the *onset* of an injury or illness. *Retrograde amnesia* (RA) refers to memory loss for events occurring before the onset of a lesion, whilst *post-traumatic amnesia* (PTA) refers to memory loss for events following this, and, with respect to head trauma, it ends with the return of the continuous registration of 'personal' memories. *Anterograde amnesia* (AA) refers to an impairment in learning new material; it is commonly used synonymously with PTA, although, in traumatic cases, such an impairment may persist long after the termination of PTA.

There have been various attempts to investigate the subcomponents of primary and secondary memory. *Working memory* refers to a particular model of primary memory, distinguishing its subcomponents and emphasising its information-processing activity. Secondary memory has been considered in terms of *episodic* (personal) memory and *semantic* (conceptual) memory, or, alternatively, in terms of *conscious recollection* and memory for skills (*procedural* memory): these will be discussed below. Traditionally, primary and secondary memory were thought of as separate *stores* operating in series: nowadays, greater emphasis is placed upon the *processes* they entail, and some authorities argue that they operate in parallel rather than in series.

The present paper will use the term *psychogenic amnesia* to refer to all instances in which memory loss is presumed to have a psychological, rather than an organic, basis. This term allows for the facts that (i) *both* organic and psychogenic amnesia involve disordered 'function', and that (ii) some *combination* of conscious and unconscious ('hysterical') factors may precipitate a psychologically based amnesia.

The following two cases illustrate the way that some of these concepts will be used in the present paper.

A.B. is a 62-year-old Korsakoff patient whose Wernicke encephalopathy occurred in 1970, after many years of heavy drinking. He performs at a normal or near-normal level at tests of primary memory, such as digit span. He can find his way about the hospital (procedural memory), although he is unable to describe ('recollect') his route and he soon gets lost if he leaves the immediate vicinity. He shows severe impairment at tests of secondary memory which require him to learn new material (AA). He recalls virtually nothing about recent events, either in his personal experience (episodic memory) or requiring conceptual knowledge, such as the name of the present Prime Minister (semantic memory). He also performs very poorly on a remote memory test, which asks about news events from the late 1930s to the early 1980s – although there is relative sparing of memories preceding the mid-1950s. Obviously, both RA (pre-1970) and AA (post-1970) have contributed to this man's remote memory impairment.

By contrast, C.D. is a 24-year-old man who suffered a moderately severe concussion injury in a road traffic accident. He developed an RA of 10–15 minutes and a PTA of 24 hours. During the period of his PTA, his performance at tests of primary memory was impaired, but this recovered soon afterward. When reassessed some weeks after his accident, his recall of recent and remote events appeared completely intact except that his RA and PTA remained unchanged, i.e. there was a discrete gap in his episodic memory. He also showed a mild impairment on formal learning tests (AA).

Clinical aspects of organic amnesia

The amnesic states seen in clinical practice can be classified along two dimensions – organic *vs* psychogenic, and discrete (time-limited) episodes *vs* persistent memory impairment. Table I provides examples of amnesic disorders falling within the four quadrants of this classification. Obviously, there is some overspill between the quadrants: for example, head injury and hypoglycaemia often give rise to discrete amnesic 'gaps', but sometimes they may produce more persistent memory impairment as well. The clinical characteristics of selected examples of organic amnesia will be briefly discussed in the present section.

Lishman (1987) has described in detail the clinical assessment and investigation of organic amnesia. Some clinical tests of memory, e.g. the use of a

TABLE I
Amnesic states

Discrete episode	*Persistent impairment*
Organic	
Toxic confusional state	Drug toxicity
Head injury	Amnesic syndrome, specific
Epilepsy	Dementia, global
Alcoholic 'black-out'	
Hypoglycaemia	
Transient global amnesia	
Post-ECT	
Psychogenic	
Fugue states	Pseudodementia
Situation-specific e.g. for an offence	

memory and orientation scale and recall of a passage of prose, appear to be more discriminating than others (Kopelman, 1986*a*); and formal neuropsychological assessment is usually essential.

Head injury

Head injury is the classical instance of a discrete, organic amnesia. The familiar pattern of memory loss consists of a brief period of retrograde amnesia (RA), a longer period of post-traumatic amnesia (PTA), and islets of preserved memory within the amnesic gap (Russell & Nathan, 1946). Occasionally, PTA may occur without any RA, although this is more common in cases of penetrating lesions. Sometimes, there is a particularly vivid memory for images or sounds occurring immediately before the injury, on regaining consciousness, or during a 'lucid' interval between the injury and the onset of PTA.

As is well known, the duration of PTA is assumed to reflect the degree of underlying diffuse brain pathology. It is predictive of eventual cognitive outcome (Brooks, 1984), psychiatric outcome (Lishman, 1968), and social outcome (Russell & Smith, 1961), although these relationships are weaker than is often assumed. There appears to be a relationship with age such that older subjects tend to have a longer PTA and more serious deficits at a given PTA (Russell & Smith, 1961), whereas in subjects under 30 PTA is sometimes found to be less effective as a predictor of subsequent memory impairment (Brooks, 1972).

Following a mild head injury, a neurotic ('post-traumatic') syndrome sometimes ensues in which 'forgetfulness' is a prominent complaint. The aetiology of this syndrome remains controversial, but it is clear that the symptoms often persist long after the settlement of any compensation issues. In more severe head injury, the ability to learn new material is the slowest cognitive deficit to recover, and the pattern of residual memory deficit resembles, in many respects, that seen in the Korsakoff or 'amnesic' syndrome (Brooks, 1984; Baddeley *et al*, 1987; Merskey & Woodforde, 1972).

Alcoholic black-out

Goodwin *et al* (1969) described discrete episodes of 'memory loss for significant events' which occurred in 64% of a sample of 100 hospitalised alcoholics. These 'black-outs' were always associated with prolonged alcohol abuse and severe intoxication, and were of two types. In the 'fragmentary' type, the subject became aware of his memory loss only after being told about an event later: there were 'islets' of preserved memory, and the amnesia tended to shrink through time in a manner analogous to the RA of a head injury. In the 'en bloc' variety, the subject usually became aware of the memory loss on awakening from sleep with a sense of 'lost time': the amnesic gap had a definite starting point, islets of preserved memory were rare, and the memories were very seldom recovered. In a minority of cases, the subjects 'came round' while alert and awake, realising that they had no recollection of what they had been doing: sometimes they had travelled, paid cheques, stayed in hotels, in a similar manner to a 'fugue state'. Three subjects reported 'en bloc' black-outs lasting between 2 and 5 days. In addition, 'state-dependent' phenomena were reported by 61% of the patients who had black-outs: commonly, the subjects would hide money when drunk, be unable to find it when sober, and would retrieve it again when intoxicated. The authors cited a 47-year-old woman who wrote letters when drinking, was unable to decipher them when sober, and would resume writing as soon as she had had a few drinks: "It was like picking up the pencil where I had left off."

The diagnosis of an alcoholic black-out can be important in medico-legal cases in which a defendent may claim amnesia for his offence, as will be discussed below.

ECT

This is an iatrogenic form of 'discrete' amnesia, and the adverse effects of ECT on the recall of personal memories were noted from an early stage (e.g. Janis & Astrachan, 1951). In recent years, the pattern of the memory deficit has been carefully mapped out. Verbal memory appears to be particularly sensitive to disruption, and unilateral ECT to the non-dominant hemisphere produces considerably less memory impairment than bilateral ECT (Squire, 1977), making it important to identify the non-dominant hemisphere by a valid procedure (Kopelman, 1982). Squire and his colleagues have found that subjects tested within a few hours of ECT show a retrograde impairment for information from the preceding 1–3 years, a pronounced anterograde deficit on recall and recognition tests, and accelerated forgetting of newly learned information (Squire, 1977, 1981; Squire *et al*, 1984). Although these deficits have been attributed by some to cholinergic depletion, they are more widespread than would be expected on such a basis, and would seem more likely to be attributable to gross metabolic disruption.

Follow-up studies, 6–9 months after ECT, reveal that memory performance on objective tests returns to normal, apart from a persistent loss of material acquired within a few hours of the convulsions (Squire, 1977; Freeman *et al*, 1980; Squire & Slater, 1983; Frith *et al* 1983). However, complaints of memory impairment persist (Squire, 1977; Freeman *et al*, 1980; Frith *et al*, 1983), and are still evident after 3 years (Squire & Slater, 1983). Squire & Slater (1983) found that the complaints focus upon the period for which there has been an initial, authentic (retrograde and anterograde) amnesia. Freeman *et al* (1980) reported that the subjects who complain most do, in fact, perform poorer on objective tests than those who do not complain, but Squire & Slater (1983), using similar tests, did not find this. Squire & Slater (1983) and Frith *et al* (1983) both indicate that the 'complainers' are the patients who have recovered least well from their depression.

Korsakoff syndrome

The Korsakoff syndrome is the classical example of a 'persistent' organic amnesia. It is best defined as "an abnormal mental state in which memory and learning are affected out of all proportion to other cognitive functions in an otherwise alert and responsive patient" (Victor *et al*, 1971).

Lawson (1879) and Korsakoff (1889) both described profound amnesia occurring as a consequence of extensive alcohol abuse, but they also recognised that other factors could produce an identical syndrome. Although Korsakoff indicated that recent memories tend to be more severely affected than remote, he emphasised that the retrograde component to the amnesia is very variable and sometimes extends back many years or decades. Subsequent clinical and experimental studies have confirmed the extensiveness of the remote memory impairment, but tend to find that there is indeed a relative sparing of the most distant memories, whether tested in terms of the recognition or recall of famous faces and news events, or the recall of personal memories (Butters & Albert, 1982; Squire *et al*, 1984; Baddeley & Wilson, 1986).

Korsakoff (1889) also drew attention to the patients' disorientation in time and their inability to recall the temporal sequence of events. The disorientation in time can result in an under-estimation of the time spent in hospital (Moll, 1916) and of the patient's own age (Zangwill, 1953), rather similar to that described in some schizophrenic patients. The failure to recall the temporal context of events may contribute to confabulation, which often involves the inappropriate and jumbled recall of genuine events, rather than the fabrication of fictions (Korsakoff, 1889; Victor *et al*, 1971). "Telling of a trip she had made to Finland before her illness . . . [the patient] mixed into her story her recollections of the Crimea, and so it turned out that in Finland people always eat lamb and the inhabitants are Tartars" (Korsakoff, 1889).

It is commonly stated that both Wernicke and Korsakoff failed to recognise the relationship of their two syndromes (e.g. Victor *et al*, 1971). However, Korsakoff (1889) did in fact notice confusion, ataxia, nystagmus, and opthalmoplegia in some of his patients. Describing patients seen in an acute neurological service, Victor *et al* (1971) reported that Wernicke signs preceded the amnesia in 96% of Korsakoff cases; whereas the recorded prevalence in psychiatric series tends to be rather lower. Moll (1916) suggested that the disorder can have either an acute or an insidious onset; and recent studies have confirmed that the initial clinical manifestations of the disorder may range from acute coma (Torvik *et al*, 1982), through the classical acute Wernicke syndrome, to an insidious onset (Cutting, 1978*a*). Moreover, the characteristic neuropathology is identified in many cases at autopsy who have survived in the community without being diagnosed in life (Harper, 1983; Torvik *et al*, 1982). This latter finding provides some support for those who believe that the clinical Korsakoff syndrome may represent an extreme form of the memory impairment commonly found in non-Korsakoff alcoholics (e.g. Butters & Albert, 1982).

Alzheimer-type dementia

Memory impairment is a prominent early symptom in dementing patients, but, unlike the above disorders, it takes place in the context of widespread cortical atrophy and multiple cognitive deficits. Morris and Kopelman (1986) have suggested that the pattern of memory impairment in Alzheimer-type dementia can be viewed as the outcome of 'information-processing' deficits superimposed upon an amnesic syndrome; and there is evidence that this pattern may differ from that seen in normal aging (Huppert & Kopelman, 1987).

There is a profound impairment in learning new information but, surprisingly, the forgetting rate of 'acquired' information is normal in early cases, once adequate learning has been accomplished, a pattern which is consistent with that expected on the basis of cholinergic depletion (Kopelman, 1985*a*). There is also an extensive impairment of remote memory, although, to date, objective tests have failed to establish evidence of any relative sparing of the most distant memories (Wilson *et al*, 1981). Superimposed on this pattern is a substantial impairment at tests of primary memory, e.g. digit span (Miller, 1973; Kopelman, 1985*a*); and there may also be impairment in certain aspects of semantic memory, requiring knowledge of facts or concepts (Weingartner *et al*, 1983). Furthermore, the impact of these various memory deficits upon the patients' daily lives is likely to be potentiated by an interaction with the effect of their other cognitive defects. For example, the impairment of primary memory is most severe in younger patients, who have the most advanced neuropathology, and this deficit may exacerbate the effect of any subtle dysphasic difficulty (Kopelman, 1986*b*). Similarly, as discussed below, the combination of amnesia and severe frontal dysfunction may precipitate very florid confabulation in some cases.

Clinical trials of cholinergic 'replacement' therapy to alleviate the memory disorder in dementia have tended to be a little more successful than trials of other pharmacological agents, although all are disappointing. These studies have been reviewed in detail elsewhere (Hollander *et al*, 1986; Kopelman & Lishman, 1986; Kopelman, 1986*c*).

Confabulation

Berlyne (1972) distinguished between 'momentary' confabulation, which is fleeting and has to be provoked, and 'fantastic' confabulation which is sustained, wide-ranging, grandiose, and spontaneous. These might better be termed 'provoked' and 'spontaneous' confabulation as the former is seen only in response to questions probing the subject's memory, whereas the latter is readily evident in his or her everyday conversation.

Provoked confabulation is common in amnesic patients when given memory tests and may represent a normal response to a faulty memory; it may be related to the distortions and intrusions commonly produced by healthy subjects when they remember something poorly (Bartlett, 1932). In a series of 16 Alzheimer and 16 Korsakoff patients described elsewhere (Kopelman, 1985*a*,*b*), the present author obtained instances of provoked confabulation in seven Alzheimer and eight Korsakoff cases, usually in the immediate or delayed (45 minutes) recall of a prose passage. Moreover, when 17 healthy subjects were asked to recall this passage after a 1-week delay, eight subjects showed similar distortions or confabulations, e.g. in recalling a woman whose purse had been stolen in a high street, it was said that she was a thief who was stopped by the police, or that the episode took place near a railway station. (A paper reporting these data in more detail is in preparation.)

Spontaneous confabulation, on the other hand, is a pathological phenomenon, which may result from the superimposition of frontal lobe pathology on an organic amnesia. This suggestion was first made by Luria in 1976, and, subsequently, a number of other researchers have identified an association between confabulation and the presence of either frontal lobe pathology or evidence of frontal dysfunction (Stuss *et al*, 1978; Kapur & Coughlan, 1980; Baddeley & Wilson, 1986). According to Luria (1976), this kind of confabulation may sometimes involve the inappropriate recall of real memories, jumbled in temporal sequence (cf. Korsakoff, 1889; Victor *et al*, 1971), whereas Berlyne (1972) emphasised the fabrication of fictions: it seems likely that the latter can be grafted on to the former. Several authors have noted that the confabulations can be preoccupying, bizarre, and held with firm conviction, in which case they may be distinguishable from delusional memories only in that they occur in the context of an organic amnesia rather than a psychosis. Possibly because of the association with fairly severe frontal lobe pathology, spontaneous confabulation appears to be much commoner in the more advanced stages of Alzheimer's disease than in the chronic phase of Korsakoff's syndrome. In Berlyne's (1972) series, it occurred in eight out of 62 dementing patients, but in only one Korsakoff patient who was described as having had a frontal lobe syndrome following a head injury. In the present author's series, it was seen in only two cases, both of whom were Alzheimer patients.

Kapur and Coughlan (1980) described a 48-year-old building contractor who had an (anterior communicating) aneurysm clipped following a subarachnoid haemorrhage. CT scan showed a well-defined area of left frontal hypodensity. An initial right-sided weakness recovered rapidly, but he was left with a pronounced personality change including irritability, apathy, and sexual disinhibition. Performance at delayed recall and 'frontal' tests was poor, but he did surprisingly well at recognition tests. Confabulation was prominent and spontaneous: "He would claim . . . in the morning to have fictitious business appointments when in fact he was attending a day centre, would frequently dress for dinner in the evening in the mistaken belief that guests were coming . . . When questioned about holidays or outings over the past few days, he would again report events that bore no relation to actual happenings. When the correct version of events was brought to his attention, he would either seem puzzled . . . or place the confabulated event in another temporal context".

Nature of the deficits in organic amnesia

Neuropsychologists have devoted considerable attention to trying to identify the nature of the memory deficits in organic amnesia. With regard to anterograde amnesia, many theories have been propounded but they can be broadly classified under four main headings, corresponding to the stage or aspect of memory processes considered impaired. Some theories postulate deficits in the 'acquisition' processes occurring during and shortly after the initial 'registration' of information, whereas others propose impairments in subsequent 'retention' or 'retrieval'.

Faulty encoding

These theories propose that there is a deficit in the psychological processes involved in the initial 'registration' of information. In particular, it has been suggested that, whilst amnesic patients are able to 'encode' the direct, sensory properties of information, they have difficulty in 'processing' its more meaningful (semantic) qualities. For example, Korsakoff patients perform particularly badly at learning word pairs (e.g. hungry–thin) whose recall is normally facilitated by thinking of semantic links between the words (Cutting, 1978*b*). On the other hand, this does not seem to be true of all cases (Squire, 1982), and giving instructions or orienting tasks which encourage the extraction of meaning from a stimulus produces, at most, a relatively small enhancement in the amnesic patients' subsequent recall of that stimulus (Meudell *et al*, 1979; McDowall, 1981). It seems unlikely that a failure to encode semantic information is the fundamental deficit in amnesia, although it remains plausible that there exists some impairment in initial 'encoding' which is at present poorly defined and measured.

Faulty consolidation

A second type of hypothesis proposes that there is impairment in the physiological processes which are assumed to occur shortly after initial registration and to establish ('consolidate') information in memory into some relatively permanent form (e.g. Meudell *et al*, 1979; Moscovitch, 1982). These processes were traditionally thought to involve the 'transfer' of information from primary to secondary memory, operating during a time-period of something less than a minute. The hypothesis was suggested by the finding that primary memory (holding information for a few seconds) is relatively intact, in the presence of profound amnesia, in patients with hippocampal lesions, head injury, and in some studies of Korsakoff patients (e.g. Milner, 1966; Brooks, 1984; Kopelman, 1985*b*). In one particularly intriguing study, Lynch and Yarnell (1973) interviewed six concussed American footballers within 30 seconds of their injury and at intervals thereafter. Although they were initially able to give a lucid account of events occurring just before the blow, they subsequently developed a 'relatively complete' retrograde amnesia.

An attraction of consolidation theory is that the properties and time-course of action of the cholinergic neurotransmitter system might appear to make it an excellent 'candidate' as the physiological substrate of the process (see Kopelman, 1985*a*, 1986*c*). A problem is that such a rapid consolidation process cannot explain why a retrograde amnesia of more than a few seconds can occur; and Squire *et al* (1984) have recently postulated 'consolidation' lasting as long as two years to try to account for this difficulty (see below).

Accelerated forgetting

A third possibility focuses attention upon 'storage' (retention) rather than learning processes. In recent years, it has been suggested that patients who have hippocampal lesions show faster forgetting, even after material has been adequately learned (Huppert & Piercy, 1979; Squire, 1981). In one version of this theory, the accelerated forgetting appears to be viewed as being superimposed upon (and arising independently of) any 'acquisition' deficit (Huppert & Piercy, 1979); whereas, in another version, it is seen as a consequence of a faulty (and protracted) consolidation process (Squire *et al*, 1984).

There is some evidence that normal aging causes a slight increase in the forgetting rate of visuospatial information (Huppert & Kopelman, 1987), and that the gross metabolic disruption following ECT produces accelerated forgetting (Squire, 1981). However, there is surprisingly little evidence that structural lesions produce accelerated forgetting. Patients who have the Korsakoff syndrome, penetrating and non-penetrating head injury, and Alzheimer-type dementia have all been shown to exhibit a normal forgetting rate (relative to age-matched controls), once efforts have been taken to ensure that adequate initial learning has taken place (Huppert & Piercy, 1978; Squire, 1981; Kopelman, 1985*b*; Baddeley *et al*, 1987). It seems that the clinical impression of faster forgetting in such patients arises because information has never been adequately absorbed at initial input.

Faulty retrieval

Two types of retrieval hypothesis have been postulated. 'Pure' retrieval hypotheses postulate a retrieval deficit arising independently of any failure in 'acquisition' processes. For example, Warrington & Weiskrantz (1973) postulated that amnesic patients are unable to suppress inappropriate responses during recall or recognition tasks. They noted that amnesic patients sometimes respond erroneously to memory tests with what had been the correct replies to previous tests (even if these had not been recalled at the appropriate time); and, secondly, that the provision of retrieval cues (e.g. initial letters of words to be recalled) can improve their performance. On the other hand, it has been shown that healthy subjects also exhibit these phenomena when given recall tests at relatively long retention intervals (e.g. a week) – suggesting that they may be a consequence of poor memory, rather than its cause (e.g. Woods & Piercy, 1974). Moreover, restricting the number of choices in a recognition or cued recall test does not necessarily improve amnesics' performance, relative to controls, in the way that this hypothesis predicts that it should (Huppert & Piercy, 1976; Warrington & Weiskrantz, 1978).

A modified retrieval hypothesis stresses evidence that retrieval processes are dependent upon the nature of initial encoding, in terms of a network of cognitive and affective associations, and it suggests that retrieval deficits arise in consequence of initial encoding deficits. However, when couched in these terms, the distinction between an encoding and retrieval deficit becomes essentially linguistic (Squire, 1980).

Retrograde amnesia

In summary, the evidence reviewed above would seem to suggest that the deficit in anterograde amnesia occurs at the stage of memory 'acquisition,' although the precise nature of this fault, in terms of (psychological) encoding or (physiological) consolidation, remains to be specified. Accelerated forgetting does not seem to occur in cases of structural lesions, and any retrieval deficits appear to take place as a consequence of the initial 'acquisition' deficit.

Such an explanation fails to account for retrograde amnesia and for its temporal gradient, with relative sparing of more remote memories in, for example, the Korsakoff syndrome. However, various clinical studies have suggested that retrograde and anterograde amnesia may occur, and show improvement or deterioration, independently of each other (e.g. Goldberg *et al*, 1982; Kapur *et al*, 1986). Differing anatomical substrates for the two aspects of amnesia have been postulated, but there is very little agreement on which site produces retrograde amnesia.

At a psychological level, several factors have been implicated. Squire *et al* (1984) cited the occurrence of a relatively short (1–2 years) retrograde impairment in some head injury cases, post-ECT confusional states, and a bitemporal lobectomy patient, as evidence for disruption of a prolonged 'consolidation' process. Much more commonly, the length of retrograde amnesia in head injury is a few seconds or minutes only (Russell & Smith, 1961), and it certainly seems very plausible that such a short RA might result from a disrupted physiological process, such as 'consolidation'. However, the more extensive remote memory impairment in Korsakoff and Alzheimer cases requires a different explanation.

Butters & Albert (1982) demonstrated a loss of recent memories in chronic alcoholics, which they attributed to a progressive anterograde impairment during the period of heavy drinking. Korsakoff patients perform substantially worse than other alcoholics at remote memory tests, and Butters & Albert suggested that, superimposed on the alcoholics' loss of recent memories, Korsakoff patients exhibit a 'generalised' retrograde impairment, which has an abrupt onset at the time of the Wernicke encephalopathy. Alzheimer patients may manifest a similarly generalised retrograde loss, in which a relative sparing of the most remote memories may be more apparent than real (Wilson *et al*, 1981). It has been suggested that this generalised, retrograde loss consists of a 'general impairment in reconstructing past memories' (Squire *et al*, 1984); and, in this connection, it may be relevant that various authors have emphasised the role of contextual cues (e.g. time, order, place) in the 'reconstruction' (conjuring up) of past memories (e.g. Baddeley, 1982).

Memory for context

There is now evidence that Korsakoff patients and some (but not all) other amnesic patients have particular difficulty in recalling the context of information (Huppert & Piercy, 1976; Mayes *et al*, 1985). In studies of anterograde amnesia, they show a disproportionate difficulty in recalling the temporal sequence of events, the place where something was learned (spatial context), and the source of information even when the information itself has been recalled. In studies of retrograde amnesia, they exhibit problems in dating or ordering events.

There are problems of method in most of these studies, but evidence is accumulating that it is the presence of concomitant frontal lobe pathology in amnesia which may underlie the failure to recall the context of information (Squire, 1982; Mayes *et al*, 1985). Since some degree of frontal dysfunction is common in Korsakoff and Alzheimer patients, it seems reasonable to suppose that this failure to recall contextual information may contribute to their difficulty in retrieving from remote memory – a hypothesis currently being tested by the author. As mentioned above, frontal dysfunction and impaired recall of temporal context have also been implicated as factors producing 'spontaneous' confabulation: it seems plausible that spontaneous confabulation may reflect more extensive frontal lobe pathology, resulting in the extremely incoherent (context-free) retrieval of past memories and associations.

Memory without awareness

Whatever the fundamental deficit in organic amnesia, certain aspects of memory *do* appear to be relatively preserved in amnesia, and these appear to be those components which do not require conscious recollection of personal experiences. In the nineteenth century, James Mill, Henry Maudsley and William James had all emphasised that an essential component of memory is the "additional consciousness that we have thought or experienced (something) before" (James, 1890). However, at the turn of the century, Claparede (1911) demonstrated that "the feeling that (a memory) belongs to the person's experience can be absent in situations in which retention is evident". He cited a Korsakoff patient whose finger he pricked with a pin, and who avoided shaking Claparede's extended hand the next day without knowing why. This lady was able to learn her way around the hospital, e.g. to the bathroom, but was completely unable to describe her route.

Modern experiments have confirmed that severely amnesic subjects can show normal conditioning (Weiskrantz & Warrington, 1979), and can acquire and retain affective reactions despite their profound impairment of 'conscious recollection' (Johnson *et al*, 1985). They can also acquire and show retention in certain skills, e.g. performing jigsaw puzzles or reading back-to-front writing, in the absence of any recall or recognition of having performed the tasks before. In a particularly striking example, Starr & Phillips (1970) described a pianist who was taught a new piece of music but the next day had no recall of it: on being hummed the first few bars, he was able to continue playing the piece, although still unable to recall the name of the piece or that he had been taught it before. Such skill (or 'procedural') learning does not necessarily appear to depend upon well-established premorbid learning, and most researchers postulate that it depends upon a subsystem of memory independent of that which subserves 'conscious recollection' (Moscovitch, 1982; Squire *et al*, 1984).

Probably related is the 'priming' phenomenon, in which a learning episode has a transient, facilitative effect on the performance of a subsequent task. For example, viewing a series of words during a study session makes it especially likely that amnesic subjects will give those words in response to some subsequent test, even though their performance at a recognition test of those words may be severely impaired. Shimamura & Squire (1984) propose that priming involves the activation of 'pre-existing elements or processing structures', which, in turn, may be necessary for skill learning to develop.

A further suggestion, put forward in different ways by Gillespie (1937) and Tulving (1972), is that 'semantic memory' is selectively spared in organic amnesia, i.e. memory for facts, concepts, and language (as opposed to memory for personal experiences or events). Unfortunately, the status of semantic memory as an independent memory subsystem remains equivocal, because the tests used to examine it have usually required the recall of material which has been 'over-learned' premorbidly. Moreover, the concept of 'semantic memory' is itself something of a conglomerate, in that the memory system which subserves our use of language (commonly spared in amnesia) may well differ from that which enables us to name the present or past Prime Minister (characteristically affected in amnesia).

The neuropathology of amnesia

Neuroanatomy and neurophysiology

Table II lists the principal types of pathology which give rise to an amnesic syndrome. Consideration of these pathologies has led many authorities to postulate that two types of lesion are particularly likely to disrupt the formation of new memories: bilateral hippocampal lesions and diencephalic lesions.

TABLE II
Aetiology of the amnesic syndrome

Thiamine deficiency	—alcohol —malnutrition —malabsorption
Head injury	
Post-encephalitis	—e.g. herpes simplex
Anoxia	—e.g. CO poisoning
Vascular lesions	—e.g. thalamic infarction —subarachnoid haemorrhage
Tumour (third Ventricle)	
TB meningitis	
(Bilateral) temporal lobectomy	

Scoville & Milner (1957) reported moderate or severe amnesia in eight patients who had undergone bilateral temporal lobectomy for management of psychosis or epilepsy, the amnesia being most severe in three cases in whom the removal of the hippocampi was most extensive. No amnesia was seen in a case who had a unilateral operation only, nor in a case in whom the hippocampi were spared. One of the most severe cases (H.M.) has been described in detail (e.g. Milner, 1966). He had a retrograde component to his amnesia extending back 2 or 3 years before his operation, and a profound anterograde amnesia. More than a decade after his operation, he was unable to find his way to the home in which he had lived for several years; he performed the same crossword puzzle repetitively without showing practice effects; and he mourned afresh every time he learned that his uncle had died. However, his immediate memory span, his IQ, and his ability to hold conversation were all normal (Milner, 1966). Patients who have suffered a herpes simplex encephalitis sometimes manifest a similarly severe amnesia, and the neuropathology typically involves a profound necrosis of bilateral, medial temporal structures as well as some involvement of the orbitofrontal regions (Hierons *et al*, 1978). The hippocampi and the temporal lobes are, of course, particularly implicated in the neuropathology of Alzheimer's disease (Tomlinson & Corsellis, 1984); and the temporal poles are especially vulnerable to bilateral contusions in head injury (Teasdale & Mendelow, 1984).

Diencephalic involvement was first implicated from autopsy studies of Korsakoff cases. Malamud & Skillicorn (1956) and Victor *et al* (1971) noted that the pathology occurred in the paraventricular and peri-aqueductal grey matter, particularly in the mammillary bodies and medial-dorsal nucleus of the thalamus. Victor *et al* (1971) pointed out that all 24 of their cases, in whom the medial-dorsal nucleus of the thalamus was implicated, had a history of memory impairment (Korsakoff syndrome), whereas five cases in whom it was not affected had a history of Wernicke features only. By contrast, the mammillary bodies were implicated in all the Wernicke and Korsakoff cases examined. Amnesia in association with unilateral or bilateral involvement of the thalamic nuclei, with apparent *sparing* of the mamillary bodies, has been described in cases of tumour, trauma, and infarction (McEntee *et al*, 1976; Squire & Moore, 1979; Speedie & Heilman, 1982). However, Mair *et al* (1979) have described two amnesic cases whose autopsies showed lesions in the mammillary bodies and the midline of the thalamus, but *not* in the medial dorsal nuclei. Mair *et al* suggested that the lesions they described might 'disconnect' a critical circuit running between the temporal lobes and the frontal cortex.

A potential difficulty for the view that the diencephalon and hippocampi are critical in memory formation is that lesions of the fornix bundle, which transmits connecting fibres between them, do not always seem to produce amnesia in animals and man. However, the more recent animal studies suggest deficits consistent with those seen in human amnesia: namely, a relative sparing of primary memory and the learning of affective associations, together with a profound impairment of secondary memory as measured on recognition tests (Owen & Butler, 1981; Carr, 1982). A more serious problem, documented by Markowitsch (1984), is that lesions within the hippocampi and thalamic nuclei themselves do not always give rise to amnesia and, when they do, there is usually concomitant involvement of other nuclei. Whilst acknowledging that there may be 'nodal points' in the neural substrate of memory, Markowitsch argues that the thalamic nuclei and hippocampi do not represent discrete 'functional entities', but are embedded in complex neural circuits and 'neuronal assemblies'. Similarly, Mishkin (1978) has argued that *combined* lesions within the hippocampal (medial limbic) and amygdaloid (basolateral limbic) circuits are required to produce severe amnesia; and it seems plausible to suppose that neurotransmitter depletion within these circuits, which contain cholinergic pathways, may be critical in producing amnesia. The dorsomedial thalamus and medial temporal lobes are the anatomical locations ('nodal points') where these two circuits converge, and are, therefore, particularly vulnerable to the effect of discrete, structural lesions (Speedie & Heilman, 1982).

Neurochemistry

Recent attention has focused upon the neurochemistry of amnesia. In the Korsakoff syndrome, the role of thiamine deficiency was confirmed by the De Wardener & Lennox (1947) study of prisoners of war in South East Asia; and, more recently, Blass & Gibson (1977) have postulated a hereditary abnormality of transketolase metabolism which predisposes some alcoholics to this disorder. However, this latter study was based on only four cases, and other studies indicate wide variability in transketolase activity amongst Korsakoff and other alcoholics (Leigh *et al*, 1981).

In Alzheimer's disease, three sources of evidence suggest that cholinergic depletion contributes to the memory disorder:

(a) neuropathological studies demonstrating reduction in cholinergic enzymes and synthesis
(b) pharmacological studies examining the effect of cholinergic 'blockade' in healthy subjects
(c) clinical trials administering cholinergic agents to Alzheimer patients.

These studies have been reviewed in detail elsewhere (Kopelman, 1986*c*), and it seems likely that cholinergic depletion accounts for some, but not all, of the memory deficits seen in Alzheimer-type dementia. A small study has suggested that there may also be depletion of cholinergic neurons in Korsakoff's syndrome (Arendt *et al*, 1983), and the pattern of the anterograde memory deficit in this disorder would indeed be consistent with such an observation: however, there is insufficient neuropathological evidence to place any great weight on this hypothesis as yet.

The role of other neurotransmitter systems in memory and dementia remains to be elucidated. An impairment of the ascending noradrenergic pathways in Korsakoff's syndrome has been implicated by McEntee *et al* (1984), but their results have not been replicated (Martin *et al*, 1984). Moreover, animal studies implicate the adrenergic system in mechanisms mediating attention and arousal, and trials of vasopressin, which modulates adrenergic activity, indicate an effect on arousal and mood rather than memory (Kopelman & Lishman, 1986).

Psychogenic amnesia

Diagnosis and phenomenology

Table I includes psychologically based amnesias, giving fugue states and situation-specific memory loss as examples of 'discrete' amnesias, and depressive pseudodementia as a more persistent impairment. In both discrete and persistent amnesia, the differentiation of psychogenic from organic causation can be surprisingly difficult. In the discrete type, the diagnosis usually relies on such features as the rate and circumstances of the onset, loss of personal identity (rare in organic amnesia except in advanced dementia), and whether new learning is affected (often spared in psychogenic amnesia, although not necessarily so). In the persistent type, the past and family history, the results of physical investigations, the current pattern of deficit, and the patient's response to it, all provide important clues, but the diagnostic problem can remain perplexing.

The phenomenology of psychogenic amnesia often bears interesting resemblances to organic amnesia. For example, there may be islets or fragments of preserved memory within the amnesic gap. A woman, who was due to meet her husband to discuss divorce, recalled that she was 'supposed to meet someone' (Kanzer, 1939). A young man, who slipped into a fugue following his grandfather's funeral, recalled a cluster of details from the year (1979) which he described (after recovery) as having been the happiest of his life (Schachter *et al*, 1982). The subject may adopt a detached attitude to these memory fragments, describing them as 'strange and unfamiliar' (Coriat, 1907). In many cases, semantic knowledge remains intact, e.g. foreign languages and the names of streets, towns, and famous people (Kanzer, 1939; Schachter *et al*, 1982), whereas in others it is also implicated (Coriat, 1907; Abeles & Schilder, 1935; Kanzer, 1939). Similarly, performance at verbal learning tests has been reported as unaffected (Abeles & Schilder, 1935), mildly impaired (Schachter *et al*, 1982), or more severely impaired (Gudjonsson & Taylor, 1985). Memory for skills is often preserved (e.g. Coriat, 1907), but in the Padola case (Bradford & Smith, 1979) retention of a rudimentary knowledge of aerodynamics and of other skills (e.g. solving jigsaw puzzles) was taken as evidence against an organic amnesia – an interpretation in conflict with the recent findings regarding the relative preservation of 'procedural' memory, reviewed above. Sometimes, memory retrieval may be facilitated by chance cues in the environment (e.g. Abeles & Schilder, 1935; Schachter *et al*, 1982) but deliberate cueing is often unsuccessful (Coriat, 1907; Kanzer, 1939), and the results of amytal abreaction are very variable.

Fugue states

'Fugue states' refer to a syndrome characterised by the abrupt onset of a loss of personal ('episodic') memory and of the sense of personal identity, associated with a period of wandering. The episode usually resolves within a few hours or days, after which the subject is left with a residual amnesic gap for the period of the fugue. Fugue states are rare, but their study has helped to elucidate the factors predisposing to psychogenic amnesia. These are listed in Table III.

There is always a severe precipitating stress, and fugues are reported much more commonly in wartime (Sargant & Slater, 1941). However, they also occur following marital or emotional discord or at times of financial difficulty. A history of depressed mood just before the onset of the fugue is virtually always present, including those cases in which there is some other, formal psychiatric diagnosis (Berrington *et al*, 1956). Occasionally, the fugue may even represent a 'flight from suicide' (Stengel, 1941). For example, Abeles & Schilder (1935) described a

TABLE III

Psychogenic amnesia: factors predisposing to fugue states

1. Precipitating stress e.g.	—marital discord	(Kanzer, 1939)
	—financial problems	(Kanzer, 1939)
	—offending	(Wilson *et al*, 1950)
	—war stress	(Sargant & Slater, 1941; Parfitt & Gall, 1944)
2. Depressed mood		(Kanzer, 1939; Stengel, 1941; Berrington *et al*, 1956)
3. Suicide attempts		(Stengel, 1941; Berrington *et al*, 1956)
4. Past history of head injury		(Abeles and Schilder, 1939; Berrington *et al*, 1956)
5. Past history of alcohol abuse		(Kanzer, 1939; Berrington *et al*, 1956)
6. Epilepsy		(Stengel, 1941)
7. Other neurosis		(Sargant & Slater, 1941)
8. Other organic disorder		(Kennedy & Neville, 1957)
9. Tendency to lie		(Stengel, 1941; Wilson *et al*, 1950; Berrington *et al*, 1956)

woman who deserted her husband for another man: after a week she determined to return to her family but, as she descended the Underground stairway, she was contemplating suicide. "Instead amnesia developed", the authors tersely reported. Stengel (1941) claimed that suicide never occurs during a fugue, but may take place as the subject emerges from the fugue. A past history of an organic amnesia is also common, arising, for example, from a head injury, an alcholic black-out, or from epilepsy. Berrington *et al* (1956) reported that 16 of their 37 cases had previously experienced a severe head injury, and a further three cases head injury of uncertain severity. On the other hand, epilepsy is reported less commonly than is generally supposed, Stengel giving the highest figure (10%). In summary, it appears that some subjects, who have experienced an earlier organic amnesia, are predisposed to developing a psychogenic memory loss, in the presence of depressed mood and a severe precipitating stress. On the other hand, several authors have remarked that these patients tend to be rather unreliable personalities with either a tendency to lie or a legal motive for wishing to have a fugue state substantiated.

E.F. was a 46-year-old man who described 12 to 15 episodes of 'going blank' during the previous 5 years. He said that these episodes lasted 2 to 36 hours, and that, on 'coming round', his feet were often sore, he was a long way from home, and he had no idea of the time or what had been happening during the previous hours. For example, he found himself on one occasion near the Thames, 10 miles from his home, with his clothes sopping wet. There was a history of epilepsy since he was 19, ECT and bilateral leucotomy at 33, major cardiac surgery, recurrent depression, and two serious suicide attempts. He had recently married for the third time: his wife was many years younger than himself and was pregnant. Marital difficulties were suspected, but were vehemently denied by both partners. Mr E.F. asked for a psychiatric report after being charged with driving whilst disqualified, without any insurance, and whilst under the influence of alcohol: his defence was that he had been in a fugue state.

Amnesia for offending

A common form of psychogenic amnesia with important implications is that claimed for a criminal offence. Most commonly, this has been described in association with homicide, in which it is claimed in 30–40% of cases (Table IV). A study in Broadmoor Hospital (Hopwood & Snell, 1933) and another in Brixton remand prison (Taylor & Kopelman, 1984) showed that amnesia also occurs in other violent crimes, although less commonly. In these studies, amnesia was found rarely or not at all in non-violent crime: this may have reflected the locations of the studies, but there is evidence that in violent crime recall by victims and eyewitnesses is also impaired. Taylor & Kopelman (1984) found that amnesia for an offence occurs in three types of circumstance:

(a) homicide cases in which the victim is closely related to the offender (a lover, wife, or family member), and the offence is unpremeditated and takes place in a state of high emotional arousal

TABLE IV

Homicide studies

	n	*% Amnesic*
Leitch (1948)	51	31
Guttmacher (1955)	36	33
O'Connell (1960)	50	40
Bradford & Smith (1979)	30	47
Taylor & Kopelman (1984)	34	26
Parwatikar *et al* (1985)[1]	105	23

[1] Pre-trial evaluations only; rate for convicted homicides not given.

(b) chronic alcohol abusers who commit a crime when severely intoxicated and whose victims are much less commonly related to them
(c) a small number of schizophrenic patients who commit criminal damage when floridly psychotic.

G.H. was a 40-year-old man, who had been born in Egypt, and was Jewish by religion. He had lived in England for 20 years, and was married to a 33-year-old Englishwoman. There was a son aged 9 and a daughter aged 3. The wife was having an affair with a musician, and G.H. was being treated for depression as an out-patient at a teaching hospital. He was taking an antidepressant and a benzodiazepine. On the day of the offence, the couple had a furious row during which G.H. threatened to kill the musician. His wife shared a bedroom with her daughter, and the last thing G.H. remembered was going to kiss the child goodnight. He reported that he could not remember what happened after that until the police arrived, but that he had been told that he phoned the police himself. He was charged with the murder of his wife by stabbing.

Depression and pseudodementia

A more persistent, psychologically based memory impairment is that occurring in a depressive pseudodementia, the clinical features of which have been described elsewhere. Memory impairment appears to be common in depression, although in the majority of cases it is relatively mild and poorly correlated with the severity of the depression (e.g. Kopelman, 1986*a*). The nature of the impairment in those cases which masquerade as 'dementia' is unclear, but one suggestion is that the disorder involves the more 'effortful' aspects of memory processes, and is closely associated with deficits in attention, motivation, and drive (Cohen *et al*, 1982). Affective disorder also gives rise to some particularly interesting state-dependent phenomena: depressives show a relative facility in recalling unpleasant events (Lishman, 1972; Lloyd & Lishman, 1975); this increased accessibility of unpleasant memories has a diurnal variation (Clark & Teasdale, 1982); and patients with mood swings show superior performance at memory tests if mood is consistent between learning and recall than if the mood changes (Weingartner *et al*, 1977).

Mechanisms in psychogenic amnesia

What mechanisms underlie psychogenic amnesia? One possibility is that many instances of psychogenic amnesia may result from faulty encoding of information at initial input (Kopelman, 1985*a*) and that deficits in retrieval may arise in consequence of this. In support of this view, it should be noted that psychogenic amnesia commonly occurs in states of abnormal mood or extreme arousal, in which normal cognitive processing might well be compromised. Fugues arise in the context of depressed mood and severe stress; amnesia for offences in situations of extreme emotional arousal, severe intoxication, or florid psychosis; and memory disorder in depression in association with impaired attention and motivation. This view, emphasising a disturbance in memory 'acquisition', suggests that the impairment in psychogenic amnesia mimics that in organic amnesia—of which there is so often an earlier history.

A second possibility is, of course, that psychogenic amnesia is an example of 'motivated forgetting' or repression. There is a considerable literature purporting to test the 'repression hypothesis' by showing that subjects tend to recall 'pleasant' events more readily than 'unpleasant' (e.g. Meltzer, 1930) and that this phenomenon cannot be accounted for by the relative affective intensity of the memories (Master *et al*, 1983). Although Freud (1915/17) wrote that "it is an undoubted fact that disagreeable impressions are easily forgotten", this kind of experimental study has often been criticised on the grounds that it fails to take account of the role of 'antagonistic impulses' in engendering repression—"an attempt at flight by the ego from libido which is felt as danger" (Freud, 1915/17). Experimental tests of repression in this sense tend to rely on very crude laboratory analogues, but Erdelyi & Goldberg (1979) have reviewed a number of concepts in contemporary cognitive psychology which appear to resemble repression. In this connection, the recent observations in organic amnesia of memory without awareness, and especially of preserved affective reactions in the presence of profound amnesia, are particularly intriguing.

A third possibility, strongly advocated by Bower (1981), is a (primary) retrieval deficit. Bower suggested that the 'discrete' psychogenic amnesias may reflect mood-state dependent phenomena, similar to those described in depression. According to this view, the experiences of a 'dissociative state' would be retrieved if the subject could be restored to the same subjective state in which they originally occurred. Fugue states and amnesia for offences are both associated with depressed mood and extreme states of arousal (Berrington *et al*, 1956; Taylor & Kopelman, 1984); and the latter are also associated with heavy abuse of alcohol in which state-dependent phenomena have commonly been described (Goodwin *et al*, 1969). Against this view, the state-dependent phenomena seen in laboratory experiments tend to be small and undramatic; mood disorder and alcohol abuse are common, whereas psychogenic amnesia is rare; and the only direct test of the hypothesis has failed to support it (Wolf, 1980).

Conclusion

This review has attempted to summarise the clinical features and the pattern of the memory dysfunction in selected examples of organic and psychogenic amnesia. It has also surveyed various theories which purport to explain the nature of the dysfunction.

It appears that the anterograde amnesia produced by structural lesions, including the widespread neuropathology of Alzheimer's disease, involves a severe impairment in acquiring (or learning) new information, and any retrieval deficits arise as a consequence of this. Contrary to clinical impression, the forgetting rate of new information is not accelerated, once adequate learning has been accomplished – although elderly people do show somewhat poorer retention of visuospatial material than younger subjects, and the metabolic disruption which follows ECT may produce accelerated forgetting. The precise deficit in psychological 'encoding' or physiological 'consolidation', which underlies this acquisition (or learning) deficit, remains to be elucidated. However, the simultaneous implication of two limbic circuits has been postulated as critical for the occurrence of anterograde amnesia, and it is known that these pathways contain cholinergic fibres. Future research is likely to clarify further the role of neurotransmitter depletion in producing amnesia.

Both psychological and pathophysiological evidence suggest the partial independence of the retrograde and anterograde components of amnesia. Retrograde amnesia may result from a number of factors, including a failure to make use of contextual cues (with regard to time, order, place, and source) in 'reconstructing' past experience. There is controversy as to where the critical lesions lie which produce retrograde amnesia, but there is evidence that frontal lesions disrupt the recall of contextual information. Moreover, two types of confabulation have been postulated, one of which ('provoked') may be a normal response to poor memory, but the other ('spontaneous') is characterised by the extremely incoherent (context-free) retrieval of memories and associations, and appears to reflect more extensive frontal pathology.

Finally, it has been postulated that many instances of psychogenic amnesia may resemble organic in that they result from the impaired acquisition of information at initial input, perhaps thereby predisposing the subject to subsequent retrieval difficulties in consequence of this. Such a view does not exclude the role of other possible mechanisms: organic amnesia provides a model for 'memory without awareness', and state-dependent phenomena may occur as occasional instances of retrieval difficulty.

Acknowledgements

The author is grateful to Professor W. A. Lishman and Dr T. Brugha for reading an earlier draft of this manuscript, to Dr P. Taylor for permission to cite one of her cases, and to Mrs M. Fisher for patiently typing the manuscript. The author is supported by a Wellcome Trust Lectureship.

Lecture

Temperament, Personality and Personality Disorder

M. RUTTER

It is now over 2000 years since Hippocrates put forward his idea that there were four body 'humours', each associated with a characteristic personality style: black bile with melancholic; blood with sanguine; yellow bile with choleric; and phlegm with phlegmatic (Mora, 1980). The proposition that human beings are constitutionally different in ways that shape their personality style caught on with the lay public. Indeed the notion of body humours determined the very words that we use to describe such styles. Yet the view has not had such a smooth journey in scientific circles. There is a surprising lack of uniformity in both concept and terminology, as is all too evident in the controversies surrounding the terms 'temperament', 'personality' and 'personality disorder'.

Paradoxically, personality psychology went out of fashion just at the time that the study of temperament was becoming firmly established. But the recent upsurge of research and of writing on temperament has not brought general agreement. Kagan *et al* (1987) see temperament in terms of those behavioural styles that have a strong biological basis; somewhat similarly Buss & Plomin (1986) defined temperament as inherited personality traits present in early childhood. By contrast, Bates (1980) suggested that much of temperament lay in parental percepts rather than child behaviour; Mischel (1968) argued that situational influences were so strong that the role of personality traits could be ignored; Stevenson-Hinde & Hinde (1986) accepted that there is an individual component to behaviour but pointed out that most behaviour as observed is a property of social interactions rather than just one person; and Graham & Stevenson (1986) maintained that temperament represents only subclinical manifestations of psychiatric disorder. Where does the truth lie? What value have these concepts for clinical practice if their meaning and basis is in such dispute? My purpose in this paper is to attempt some clarification of the rather complex mesh of ideas that fall under the general rubric of temperament, personality and personality disorder. In so doing, I shall seek to provide tentative answers to these difficult questions and, more hesitantly, I shall suggest some possible ways forward.

Temperament

The modern study of child temperament can be said to have begun with the New York Longitudinal Study initiated in the 1950s by Thomas *et al* (Thomas *et al*, 1963; Thomas & Chess, 1977; Chess & Thomas, 1984). The themes of current interest in temperament (Plomin, 1983) reflect those emphasised in that pioneering investigation. These include a focus on: 1) individual differences in development rather than normative trends; 2) the child as an active agent who shapes his own environment as well as being influenced by his circumstances; 3) possible neurobiological bases for behaviour, including genetic influences; and 4) socioemotional, rather than cognitive, aspects of development. Of course, their work should not be seen in isolation. It had its roots in Pavlov's (1927) typology of nervous systems, in Sheldon's (1942) study of body types and temperament, in Lacey & Lacey's (1958*a,b*) psychophysiological investigations and in Gesell's (1937) earlier studies of children's behavioural attributes, to mention but a few examples.

Before considering some of the controversial issues surrounding the concept of temperament, it is important to draw attention to some of the many matters that are no longer controversial because there is ample supporting empirical evidence. First, it is abundantly clear that individual children differ markedly from one another in a host of different ways that can be measured with reasonable reliability (Buss & Plomin, 1975; Berger, 1985; Dunn, 1980; Campos *et al*, 1983). This has been shown, for example, with features as varied as activity level, autonomic reactivity, behavioural inhibition, and sociability. Second, it has been well demonstrated that these differences *matter* in terms of their implications for later development and for psychiatric risk.

As the psychopathological importance of temperament rests on that point it may be as well to spell out some of the main findings. To begin with, it has been found that interview measures of temperament predict the later development of emotional and

Based on the Maudsley Lecture to the Royal College of Psychiatrists Autumn Quarterly Meeting on 30 October 1986.

behavioural disorders in both 'normal' (Rutter *et al*, 1964; Thomas & Chess, 1977; Dunn & Kendrick, 1982; Kagan *et al*, 1987) and high risk samples (Graham *et al*, 1973; Wolkind & De Salis, 1982). Similar findings derive from studies using questionnaire measures (Bates *et al*, 1985; Maziade *et al*, 1985); these have also shown an association between 'difficult' temperamental features and a higher rate of accidents, sleep difficulties and of infantile colic (Huttunden & Nyman, 1982; Carey, 1986). There are good reasons for accepting the validity of these findings. Thus, some of the associations between temperament and disorder have spanned quite long time periods; 5 years in the study by Maziade *et al* (1985). Dunn & Kendrick (1982) found that temperamental characteristics were more strongly associated with an *increase* in emotional disturbance following the birth of a sibling than with emotional disturbance at the time of the temperamental assessment prebirth. Also, Graham *et al* (1973; Rutter, 1978) found that temperamental features (measured by parental interview) predicted behavioural deviance at school a year later. In other words, the children's temperament has been found to predict *changes* of behaviour in different contexts at a later date.

The third topic that is no longer controversial is relevant to the matter of psychiatric risk; namely that children's temperamental features influence the ways in which *other* people respond to them. It may suffice to give just a few examples of findings in this area. Thus, Lee & Bates (1985) found that temperamentally difficult infants elicited more confrontations with their mothers as well as a greater tendency for these to result in conflict. We (Rutter, 1978) found that children with adverse temperamental features were more likely to be the target of parental criticism. Stevenson-Hinde & Hinde (1986) noted that children with more negative mood were more likely to have mothers who were irritable and teachers who were reactively hostile. It might be suggested that these associations reflected the impact of others on the child rather than the reverse. Of course, effects are likely to be bidirectional but several sets of data show the importance of child effects. First, this is evident from clinical studies in which beneficial drug effects on children's hyperactivity have been followed by changes in parental behaviour (Barkley, 1981). Second, it has been demonstrated by experimental investigations in which children have been trained to behave in contrasting ways (Brunk & Henggeler, 1984). Third, it is implicit in the differences in parental behaviour associated with organically determined child handicaps (Cross *et al*, 1985).

All of this adds up to a strong case for the clinical importance of individual differences in children's temperamental attributes. However, it is necessary to go on to consider just what is this temperament that has clinical implications. The first point to underline is that, necessarily, temperamental characteristics are abstractions, rather than directly observable discrete behaviours (Rutter *et al*, 1964). This is so for several somewhat different reasons. Most measures of temperament rely on someone's ratings of the children's behaviour. Inevitably, such ratings are bound to be influenced by errors and biases in the perceptions and attributions of the person making the rating. There is good reason to suppose that such biases may be present. For instance, it has been found that adults, when presented with a wrongly labelled, ambiguously dressed crying infant, are more likely to attribute anger if told that the infant is a boy and fear if a girl (Condry & Condry, 1976; Haviland & Malatesta, 1981). Nevertheless, the relatively good agreement between ratings and directly observed discrete behaviours (Bates, 1986; Dunn & Kendrick, 1980) are reassuring that the measures reflect far more than biased perception. Indeed, Bates (1980) who first raised the bias issue with respect to the measurement of 'difficult' temperament has now concluded that temperament measures reflect both objective and subjective factors (Bates & Bayles, 1984).

A further problem is that observations and ratings have to be based on the situations in which the child has been present with the rater or observer. This is relevant because it is known that people's behaviour is influenced by the situations in which they find themselves (Mischel, 1979; Rutter & Giller, 1983). Behaviour as observed is bound to reflect *both* personal traits and situation-specific reactions. As an extension of the same point, behaviour in a social context (and most temperamental features are ones that are evident in social situations) is bound to reflect the properties of that context, including the temperamental traits of the *other* person as well as influences stemming from the history of previous interactions (Asher, 1983; Dodge, 1980). As I have noted already, temperament is an abstraction, not an observable variable. Of course, there are ways and means of getting closer to that abstraction. The use of multiple measuring devices and multiple situations provides a good means of overcoming all three sources of measurement distortion (Epstein, 1979, 1983). Moreover, structural equation modelling is a statistical procedure that enables one to study 'latent' variables (Duncan-Jones *et al*, 1986). The requirement simply is to specify just what is conceptualised as the latent variable. Thus, one could specify that it is that aspect of the behaviour that is pervasive over situations and consistent over time, once measurement errors have been excluded.

Therein lies the difficulty, however. At first it seems obvious that some definition of that sort must be what one wants. But is it? Let us take emotional reactivity as an example of a temperamental attribute that is included by virtually all researchers and which shows both substantial heritability and stability over time (Buss & Plomin, 1975). Suomi's (1983) studies of rhesus monkeys show clearly that individual differences in autonomic reactivity remain moderately consistent over the period from infancy to puberty, but *only* when measured in stressful situations. In other words, it has required the 'press' of particular situations to bring out an important temperamental trait. It would be seriously misleading to suppose that personal traits have to be pervasive over all situations.

Kagan's human data (Kagan *et al*, 1986, 1987; Reznick *et al*, 1986) bring out two other crucial points. First, the behavioural manifestations of the same trait change over the course of development. Behavioural inhibition in an infant may be evident in the seeking of proximity to mother, but in a school-age child by a particular style of social interaction and a cautious approach to new tasks. Also the situations required to elicit inhibition change as the tasks that are meaningful to the child also alter with developmental progression. The very process of development makes it unlikely that an underlying predisposition will be expressed in the same way throughout the whole of childhood (Campos *et al*, 1983). Moreover, the finding of a similar factor structure at different ages does not mean that the behaviours have the same meaning, as the data on type A behaviours illustrate (Steinberg, 1986).

Second, composites or constellations of behaviour may be more meaningful than single dimensions considered individually. This is *not* just a matter of broad measures being better than narrow ones or of factors being superior to the components of the factor. Rather, it is an indication that in some circumstances, the association of two behaviours may change their meaning. For example, Kagan *et al* (1987) found that their heart rate measures (treated in dimensional terms) added nothing to the variance accounted for by their behavioural measure of inhibition. But, the subgroup of children with both behavioural inhibition *and* a high stable heart rate were strikingly different from the remainder. Magnusson (1987) noted the same with respect to the role of autonomic measures in relation to aggressivity. However, it should not be thought that the function necessarily resides in the combination of physiological and behavioural measures. Magnusson (1987) found that it also applied to the combination of the two behavioural measures of restlessness and aggressivity.

Where do these considerations leave us? Two related points need to be discussed: 1) what sort of concept do we want to be covered by the term 'temperament'?; and 2) depending on the answer to that question, which traits or qualities should be included within the concept? Of course, that question can only be answered by considering which qualities (and why) should *not* be included.

It is most appropriate to start with the views that suggest that temperament should not be separately conceptualised at all; rather it should be seen as a mini-disorder (Stevenson & Graham, 1982; Graham & Stevenson, 1986). The main rationale for this argument is that the factor structure of behavioural deviance in the general population closely parallels that in clinical groups, that most child psychiatric disorders represent quantitative rather than qualitative departures from normality, and that some of the items in temperamental scales sound like lesser variants of those in psychiatric measures (high activity level or high emotional reactivity would be examples). The value of studying the behavioural transitions from normality to abnormality can certainly be accepted (Rutter, 1986*a*; 1987*a*) but still the equation of temperament with psychiatric disorder must be rejected. First, extremes of temperamental traits do not in themselves constitute disorder. Second, most of the symptoms of child psychiatric disorder are not part of temperamental concepts (this would be so, for example, with antisocial behaviour, specific phobias, encopresis, or feelings of guilt or hopelessness). Third, the patterns of correlations with *change* in behaviour rather than with current disorder (see above) do not fit easily with the hypothesis. Fourth, the suggestion bypasses the evidence on the indirect path by which temperament may lead to disorder via influences on other people's reactions. Fifth, the notion fails to take account of the repeated finding that the effects of temperament may vary by sex. For example, Buss (1981) found that high activity was associated with positive interactions between fathers and sons but negative interactions between fathers and daughters. Conversely, Stevenson-Hinde & Hinde (1986) found that shyness in boys was associated with largely negative interpersonal interactions whereas in girls the correlates were largely positive. It seems that the extreme of a trait often does not lead directly to psychopathology, rather its effects are dependent on the social meaning that is given to the behaviour. Finally, the importance of temperament does not lie just in psychiatric risk; moreover the same trait may carry both positive and negative implications according to circumstances. For example, high activity proved protective to infants raised in a poor institution (Schaffer, 1966) and a 'difficult' temperament was protective to Masai infants during the East African famine (De Vries, 1984) - presumably in both cases because they demanded and received more attention and/or food. In other situations, however, high activity and a difficult temperament are psychiatric risk factors. It is not helpful to view temperament as subclinical psychiatric disorder; that constitutes an unacceptable broadening of the concept of disorder and fails to account for key empirical findings. The issue, however, is one to which I must return when discussing personality disorder.

The more usual concept of temperament is exemplified by Buss & Plomin's (1986) suggestion, following the tradition of Allport (1937), that it forms a subclass of personality traits that emerge early in life and which show high heritability. Previously, stability over time had also been regarded as an essential feature (Buss & Plomin, 1975; Plomin, 1983). Like McCall (1986) I find that definition equally unsatisfactory. Much of behaviour has a substantial genetic component, appears early and shows a reasonable degree of consistency over time, at least after infancy (and temperamental traits correlate very weakly from infancy to middle or later childhood). Moreover, as Plomin (1986) has pointed out elsewhere, heritability for most characteristics tends to rise with age, typically being very low in the early infancy period. Also, it is evident that traits that are genetically distinct may lead to a single phenotype as a result of environmental effects (Martin *et al*, 1979). The definition both requires too much and too little. Its demands are too high in expecting pervasiveness over situations and stability over time. As already noted, some traits require particular environments in order that they be manifest. Also, it must be expected that behaviour will change with development. I've already commented on the fact that the manifestations of behavioural inhibition do so. Its requirements with respect to heritability are unhelpful in being non-discriminating. It is not suggested that temperament is insusceptible to environmental influences; indeed no human characteristic is. Thus, height is a characteristic with very high heritability but yet the effects of nutrition are considerable (Tizard, 1975). Moreover, which human behaviour does *not* have a substantial genetic component? That does not seem to differentiate temperament in theory or in practice; empirically the heritability of temperamental traits is not particularly high in comparison with that of other behaviours. The key requirement is to decide how to separate temperament from other aspects of personality or of human function more generally.

The New York group argued that temperament represented the *how* of behaviour, that is the style as distinct from the *why* or motivational component and the *what* of content or capacity. As Graham & Stevenson (1986) noted, the how-what differentiation is not easy to apply in practice as people's behavioural styles lead them to choose one activity over another (the highly active child is more likely to be found on the football field or up a tree than in the library!). Nevertheless, the distinctions seem helpful in excluding from temperament behaviours that are defined in terms of content (thus emotional reactivity is included but specific fears are not) or of motivation or cognitive components (so that, negative mood is allowable but helplessness or depression is not). There is also an implicit focus on simple stylistic, non-motivational, non-cognitive features rather than complex behavioural tendencies. Activity level is included but obsessionality, generosity and suspiciousness are not.

Many theorists have also suggested that there should be a fairly direct connection with neurobiological processes. For example, Kagan *et al* (1987) suggest that their characteristic of behavioural inhibition is a function of a low threshold of responsivity in limbic and hypothalamic structures. In support, they point to the systematic associations with autonomic reactivity and cortisol levels. While this theoretical approach has not been typical of researchers in the field of child temperament, it has been characteristic of many personality theorists in the adult field. Moreover, it is striking that they tend to focus on much the same set of traits. Thus Buss & Plomin (1986) argue for three main temperamental traits: emotionality, activity and sociability, with uncertainty over a possible fourth, impulsivity. The first letters of the traits form the acronym EASI. While not identical, these appear closely comparable to Eysenck's (1967, 1982) neuroticism, extraversion and psychoticism; to Tellegen's (1985) negative and positive emotionality and constraint; to Gray's (1983) behavioural inhibition, impulsivity and fight/flight; and Cloninger's (1987) harm avoidance, novelty seeking and reward dependence. Cloninger (1987) has recently extensively reviewed the evidence on the neurobiological correlates of these traits and argued that variation in each dimension is strongly related to activity in a specific central monoaminergic pathway: harm avoidance with high serontonergic activity, novelty seeking with low basal dopaminergic activity and reward dependence with low basal noradrenergic activity. There will be debate on both the specific ways the traits are defined and on the specific neurobiological correlates. Nevertheless, it can be accepted that a good case has been made out for some kind of correlates, and for a small set of traits that could reasonably be regarded as temperamental in terms of the concepts discussed here. Furthermore, there seem to be no good reasons for regarding them as part of temperament in childhood but personality in adult life.

Several further issues require to be addressed, however. First, there is the question of whether the traits are best conceptualised in dimensional or categorical terms. Both Kagan *et al* (1987) and Magnusson (1987) have noted that at least some traits may be better dealt with in terms of physio-behavioural composites that are qualitatively distinct rather than a continuum. The matter has been too little explored up to now for any decision on the matter. What may be said is that we would be unwise unquestionably to assume that traits have to be dimensional.

The second major issue concerns what needs to be left out of temperament if the traits are to be conceptualised as simple, non-motivational, non-cognitive stylistic characteristics. I have already noted that this approach rules out most of the personality traits that appear in adult psychiatric classifications - such as schizoid, paranoid, histrionic and obsessional. However, also it raises questions about some characteristics that have played a prominent part in child temperament research. For example, should 'difficultness' be accepted as a temperamental feature? As already discussed, it has predictive validity but is it temperament? The term is unfortunate as it suggests that the concept is defined in terms of other people's reactions. However, that is misleading because, in fact, it is based on a constellation of child behaviours. It remains uncertain how it fits into the concept of temperament. If it can be defined in terms of a composite of simple behavioural styles, if that composite has substantial neurobiological correlates, and if there is substantial consistency over time perhaps it should be classed as a temperamental trait. The fact that it is a composite should not be a reason for exclusion. However, if its unity lies only or mainly in terms of other people's reactions that would seem to rule it out. The evidence is not enough to enable any decision (but see Korn, 1984).

The second trait that raises queries is aggressivity; in this case because most temperamental researchers leave it out rather than because it is included. Of course, it sounds as if motivational components are inherent but are they? Is it a derivative of the temperament traits noted already or is it a trait in its own right? If stability over time is used as a criterion for temperament, aggresivity must rank as a serious contender, as Olweus' (1979) review of the evidence indicates. Buss & Plomin (1975) ruled it out first of all on the lack of evidence for high heritability. However, it is not that there are data showing a low genetic component, rather there is little evidence one way or the other. However, such evidence as there is shows substantial heritability (Rushton *et al*, 1986). Buss & Plomin (1975) also argue that aggressiveness can be explained in terms of the combination of three temperamental features: activity, emotionality and impulsivity. If that were so, it would be a reason for rejecting aggressivity as a simple, stylistic temperamental attribute but, once more the necessary evidence is lacking.

Where does that leave the concept of temperament? We may conclude that there are strong grounds for assuming the validity of the general notion that there are simple, non-motivational, non-cognitive, stylistic characteristics that represent meaningful ways of describing individual differences between people. For the most part, such differences appear early in childhood, show substantial stability over time after the pre-school years (although the particular behavioural manifestations may change), represent predictable modes of response (although these may require particular situations to bring them out), and possibly have fairly direct neurobiological correlates. As used in this way, the term temperament seems as applicable to adult traits as to child characteristics. There is continuing debate over the best way of conceptualising such basic traits but there is general agreement that some variant on the features of emotionality, activity and sociability is needed. There may be other traits (such as impulsivity or aggressivity) and also it may be that some traits are better viewed in categorical terms rather than dimensional ones. Finally, it is possible that some behavioural composites should be included. The 'difficultness' composite remains a contender but there is continuing uncertainty on the unity of the concept as a biological construct. It should be added that, of course, there are many aspects of human individuality that are of considerable clinical and developmental interest but yet which can not be included in temperament. For example, it has been shown that names and physical appearance have psychological significance for people's own behaviour and other people's reaction to them (Rutter, 1977).

Personality

This point raises the broader issue of how personality differs from temperament. Hall & Lindzey (1978) defined personality as . . . "that which gives order and congruence to all the different kinds of behaviour in which the individual engages". Thus, like Sroufe (1979) they placed emphasis on integrative and organising functions and, by implication, on cognitive and motivational as well as dispositional components. It is these non-behavioural aspects that provide the clearest differentiation from temperament. Both agree in their focus on consistency in styles of behaviour, but personality differs in its inclusion of coherences that stem from attitudinal features, from patterns of thought, and from motivational factors as well as from simple dispositional attributes. Personality differs, also, in its concern with meaningful patterns of behaviour that may be evident in a *lack* of behavioural generalisation across situations. For example, Dunn & Kendrick (1982) found that girls who had an intense, warm playful relationship with their mothers were more likely to have a poor relationship with their siblings. Instead of a generalisation of warm relationships, jealousy led to an *inverse* association. Somewhat similarly, Sroufe *et al* (1985) argued that maternal seductiveness provided the organising function for an extreme form of markedly different reactions to sons and daughters. It is evident that there is much more to personality development than just the increasing stabilisation of generalised temperamental traits. However, this 'more' stems from the role of non-behavioural components and not simply from the force of environmental influences. There is no reason to suppose that temperament is immune from environmental shaping; equally, there is every reason to assume that heritable factors play some part in the shaping of attitudes and expectations as well as behavioural traits (Scarr & Kidd, 1983). Indeed, the various components of personality, at least as usually measured, differ surprisingly little in the extent to which they are heritable (Loehlin & Nichols, 1976; Plomin, 1986).

If we accept the need for a concept of personality that is much broader than a collection of temperamental traits, it is necessary to go on to ask how different aspects of personality are best dealt with. Allport (1937), one of the most influential personality theorists, referred to dynamic organisation, a phrase that emphasised both an active mental role and also the importance of developmental changes. Personality, in a sense, is the patterning that each person, as a thinking being, develops as a way of dealing with the traits with which he is endowed, the social contexts that he encounters, and the experiences he has received. For Allport, adult personality encompassed attitudes to the self (including elements such as acceptance, humour and insight), a style of relating to others, projections into the future (as evident in hoping and planning) and an implicit philosophy of life. His ideas have much in common with contemporary theorising on the development of self-concepts (Harter, 1983). Murray (Murray *et al*, 1938; Murray & Kluckhohn, 1953) similarly conceived of personality as an organising and integrating force, a force that exhibited both coherence and flux, and which grew out of life experiences as well as basic needs. As he put it, the history of the personality is the personality.

These general notions may be accepted as reasonable guiding principles but, in themselves, they lack specificity and predictive power. Various theoretical approaches have sought to provide such specificity. Psychoanalysis constitutes the key example, of course. It opened our eyes to the richness of the workings of the human mind, to the crucial importance of the meanings attached to experiences, and to the role of intrapsychic processes. Many of these ideas have become part of the currency of contemporary theories of personality functioning (Rutter, 1986*b*, 1987*b*). But, equally, many of the key tenets of psychoanalysis have had to be abandoned and others stand in need of radical overhaul (Eagle, 1984; Dare, 1985). It is doubtful whether, as a theory of personality, it is very helpful today. Some would argue for the utility of types of defence mechanisms as a means of classifying personality (Vaillant, 1977, 1983) but the evidence seems unconvicing. The maturity of defences are most strongly correlated with IQ and feelings of adequacy and there is major overlap with general measures of functioning. That people do indeed employ coping mechanisms (of which defences are a variety) in dealing with intrapsychic and interpersonal problems is not in doubt (Rutter, 1981; Moos, 1986); also it is likely that the coping process may play a part in both the onset and course of psychological disturbances following stress or adversity (Parker *et al*, 1986). What is much more uncertain is whether particular coping styles constitute a stable and pervasive aspect of personality functioning and whether they provide a useful means of classifying personality types or processes.

Probably three main approaches receive most attention now: 1) concepts of attachment and relationships; 2) cognitive processing; and 3) personality traits. Humans are social animals and it is clear that social relationships play a crucial role in most activities. The loss of a love relationship constitutes a powerful stressor throughout the lifespan and the presence of close confiding relationships provide important emotional support at all ages (Wolkind & Rutter, 1985). In recent years, stimulated especially by Hinde's (1979; Hinde & Stevenson-Hinde 1986) writings, and by the study of peer relationships in childhood (Hartup, 1983; Hartup & Rubin, 1986) there has been interest in frameworks to describe relationships. It has been argued that studying the origins of personality and the origins of social relations is one and the same task (Sroufe & Fleeson, 1986). Particular attention has been paid to the role of early parent-child attachments in the development of later relationships (Bretherton & Waters, 1985). It is not suggested, of course, that relationships should be viewed as a consistent personality trait. The same individual may have quite different relationships with different people; relationships show reciprocity and complementarity as well as generalisation. Nevertheless, it has been suggested that relationships are in some sense internalised and carried forward in ways that influence later relationships. Sroufe & Fleeson (1986) argued that this influence may arise through several routes, including: 1) the internal organisation of needs, attitudes, beliefs and styles of coping – that is the features that give rise to coherence of personality functioning; 2) expectations about relationships; and 3) understanding of relationships and skills in social encounters. Most attention has been paid to the categorisation of early attachment relationships according to types of security and insecurity. There is now a body of evidence showing that the security classification in infancy is associated with predictable patterns of peer relationships over the next few years and, less certainly, with consequences reaching very much further ahead (Bretherton & Waters, 1985). In part these continuities are likely to reflect environmental consistencies over the childhood years but, at least in the case of severely constrained attachment opportunities as in an institutional up-bringing, this does not constitute the whole explanation (Rutter, 1987*c*). Hodges & Tizard (1987*a,b*) found that late adopted children still maintained a distinctive social style at 16 years that seemed to be a function of institutional caretaking in the early years, in spite of a radical change in environment.

The mechanisms involved in these continuities in relationship are not fully understood. The concept of an 'internal working model' of relationships has been put forward as an explanatory variable (Bowlby, 1969/82; Bretherton & Waters, 1985). The general idea is that children derive a set of expectations about their own relationship capacities and about other people's response to their social overtures and interactions, these expectations being created on the basis of their early parent–child attachments. Thus, to some extent, children shape their later relationships as a result of cognitive concepts derived from earlier relationships. But, in turn, later relationships serve to modify the working model. That is, it is supposed that there is both coherence and fluidity; a substantial degree of consistency but not a rigidity or fixity of functioning. The ideas are important and intuitively plausible but, as yet, largely untested.

The hypotheses link closely with the second main approach to personality functioning, namely cognitive processing (Rutter, 1987*b*). The central concept is that personality involves, amongst other things, a set of cognitions about ourselves, our relationships, and our interactions with the environment. These cognitions constitute the self-system (Harter, 1983, 1986). We see ourselves as having a coherence of functioning that is related to our concept about what sort of people we are. The counterpart to our self-image is our tendency to respond to others on the basis of their reputations or our perceptions of what sort of person they are. There is evidence that we do indeed respond to such percepts and not just to people's immediate behaviours; similarly it has been shown that our allocated social roles influence our self concepts which in turn influence our behaviour (Rutter, 1987*b*).

Cognitive sets are thought to play a major role in how people respond to potentially negative life experiences but it is uncertain just which aspect of the self is most crucial in that connection. It may be self-esteem (itself a multi-faceted concept – Harter, 1986), or self-efficacy or social problem-solving skills. Probably in varying degrees all play a part. There are effects on people's appraisal of life experiences, on their mental reaction to them, and on their action to deal with the situation. These self concepts are not seen as static traits. Rather attention has focused on how feelings of self worth develop, how the constituent parts of the self concept become integrated and how changes occur.

Cognitive processes have been postulated as having a particularly important role in the genesis and perpetuation of depression. Seligman has emphasised the importance of feelings of learned helplessness (Abahamson *et al*, 1978; Peterson & Seligman, 1984); Beck (1967) the role of a negative triad of feelings about the self, the immediate life-situation and the future; and Brown & Harris (1978), too, have given the cognitive styles of helplessness and hopelessness a key place in their concepts of how vulnerability factors cause reactions to loss events to lead to depression. There are many unanswered questions regarding these theories (Bebbington, 1985; Brewin, 1985) but there is some evidence in support of the suggestion that low self-esteem may operate as the mediating variable linking early adverse experiences with a later vulnerability to depression (Brown *et al*, 1986; Ingham *et al*, 1986); also the ideas have been useful in formulating effective cognitive therapies for depression (Brewin, 1985; Mathews, 1986).

One of the key issues concerns the relationship between these cognitive sets and temperamental variables. To what extent, for example, does neuroticism predispose to learned helplessness? Insofar as the two are related, does helplessness constitute the mechanism by which the temperamental feature predisposes to emotional disorder, or are the cognitive features no more than epiphenomena for a trait that leads more directly to disorder? We do not know. The different approaches to personality have remained regrettably separate from each other.

The last approach to mention is that based on personality traits. There are many traits that have been considered over the years, covering virtually the whole range of adjectives that could be applied to people. Altruism, empathy and nurturance (Rushton *et al*, 1986) constitute examples of apparently positive attributes; suspiciousness, abasement and rebelliousness (Ahern *et al*, 1982) of those at the negative pole. Some traits, however, are more obviously derived from theoretical constructs. Sensation-seeking (Quay, 1977; Fulker *et al*, 1980), internal locus of control (Rotter, 1975; Miller & Rose, 1982), and femininity (Rowe, 1982; Huston, 1983) constitute examples of this kind. It is difficult to know how to evaluate the usefulness of this heterogeneous mixture of labels. Many of them have been found to have a substantial genetic component (see refs above) and many show moderate stability over time after early childhood (Moss & Susman, 1980). However, these qualities do not tell us much that is useful about personality functioning. In particular, traits reflect a static concept that does not provide for an understanding of developmental change or of dynamic processes (Pervin, 1985).

Nevertheless, three developmental findings warrant mention. First, several longitudinal studies have shown *heterotypic* continuity (Kagan, 1971; Moss & Susman, 1980; Campos *et al*, 1983), meaning that the overt character of behaviour changes over time while individual differences remain stable. For example, passivity in early childhood predicted non-competitiveness in adult life in the Fels study (Kagan & Moss, 1962). Similarly, indirect competitiveness in childhood was related to adult achievement orientation and physical adventurousness to adult sexual behaviour (Ryder, 1967). The notion of heterotypic continuity is an important one but unfortunately at present it lacks a coherent theoretical framework and it is difficult to know how to apply it to clinical issues. Second, it seems that the extent to which personality functioning remains stable over time may be itself a useful feature to consider. Block (1971) found that individuals who changed differed from those who did not, in being less relaxed, less effective people in greater conflict with societal values. Again, the notion seems potentially valuable but we lack the data upon which to build a set of expectations regarding the meaning and predictability of temporal instability in personality functioning. Third, it is evident that genetic contributions to personality development need to be viewed in fluid rather than fixed terms (Plomin, 1986). Not only is it likely that several different sorts of gene-environment interaction operate (Kendler & Eaves, 1986), but also it seems that genetic effects are amplified during development, that to an important extent people create their own environments, so that nature shapes nurture (Scarr & McCartney, 1983), and that the strongest environmental effects are those that impinge differently on different children in the same family (Plomin & Daniels, 1987). This is a field of growing interest and importance.

Finally, following Schneider (1958) there are those traits that derive from psychiatric concepts; such as obsessionality, paranoid qualities and hysterical features (Presley & Walton, 1973; Tyrer & Alexander, 1979; Mann *et al*, 1981). These overlap with the more general neuroticism characteristic and evidence on the relative contribution of genetic and environmental influences to the supposedly more specific traits is contradictory and inconclusive (Torgersen, 1980; Clifford *et al*, 1984). As these traits are central to traditional psychiatric concepts of personality disorder, they are more appropriately discussed under that rubric.

Personality disorder

The concept of personality disorder has had a very chequered history in psychiatry (Lewis, 1974; Millon 1981; Widiger & Frances, 1985; Frances & Widiger, 1986) and the literature is full of disputes on this or that aspect of the topic. Nevertheless, most psychiatrists have found it necessary to make use of this diagnostic category, even if they have done so in widely disparate ways. The three unifying features have been: 1) an onset in childhood or adolescence; 2) longstanding persistence over time without marked remission or relapses; and 3) abnormalities that seem to constitute a basic aspect of the individual's usual functioning. Perhaps four broad trends in the approach to personality disorder may be discerned. First, there is the traditional psychiatric approach in which particular personality types are linked with specific forms of mental illness. In their rather different ways, Kretschner and Schneider were both pioneers of this approach, which has given rise to terms such as schizoid, schizotypal and anankastic or obsessional personality disorders. Second, personality disorders have been defined in terms of some postulated psychological deficit. Prichard's (1835) diagnosis of 'moral insanity' based on a perversion of moral feelings was the forerunner here. Cleckley's (1964) focus on an inability to learn from experience or to exhibit remorse, and Bowlby's (1946) concentration on an inability to form close affectionate ties are in the same tradition. Third, the disorder may be seen solely in terms of social deviance or incompetence, as with Robins' (1966) use of 'sociopathic personality', which was defined as a generalised persistent failure to conform to societal norms. Fourthly, there are the psychodynamic approaches in which the concept is defined in terms of some hypothesised psychodynamic aetiological mechanism. Alexander's (1930) character neurosis, the psychoanalytical oral and anal character types (Fenichel, 1945) and, more recently, Kernberg's (1967) concept of 'borderline personality disorders' are all in that tradition.

The two main 'official' classification systems, the World Health Organisation's (1978) ICD-9 and the American Psychiatric Association's (1980) DSM-III do not follow any approach consistently; rather they contain a somewhat uneasy mixture of several different paradigms (Shepherd & Sartorius, 1974; Siever & Klar, 1986). Both ICD-9 and DSM-III are similar in their general requirement that there be deeply ingrained maladaptive patterns that have been present since adolescence and which have given rise to personal distress or social impairment. However, they differ somewhat in their approach to sub-classification. ICD-9 mostly follows the traditional psychiatric system of basing the types on extremes of particular traits such as paranoid or obsessional qualities. DSM-III employs three clusters (Vaillant & Perry, 1980; Millon, 1981; Siever & Klar, 1986). The first is based on odd eccentric behaviour (the paranoid, schizoid and schizotypal varieties); the second on dramatic, erratic or emotional behaviour (the histrionic, narcissistic, antisocial and borderline varieties); and the third on anxious or fearful behaviour (the avoidant, dependent, compulsive and passive-aggressive types).

Most British research measures have followed the WHO style in supposing that personality disorder derives from the individual's being extreme on particular traits, although the traits assessed have not been synonymous with those in ICD-9 (Walton & Presley, 1973; Tyrer & Alexander, 1979; Mann *et al*, 1981). North American measures are rather more varied and differ in their focus on broader aspects of social functioning and on specific psychological abnormalities, particularly those of the types required for the diagnosis of schizotypal or borderline conditions (Reich, 1985). Taken together in conjunction with the studies relying on less standardised clinical assessments of personality disorder, they provide a body of data that allows examination of some of the main postulates of the various approaches to personality disorder.

On the positive side, it is evident from the few available studies that the overall diagnosis of personality disorder has satisfactory reliability and reasonable predictive validity (Merikangas & Weissman, 1986). Thus, in our 4-year follow-up study of a representative sample of newly referred adults with children below the age of 15 years, we found that those with a personality disorder differed from the rest of the group in being much more likely to have continuing symptoms with social impairment (Rutter & Quinton, 1984*a*). This worse outcome was *not* just a function of duration of symptoms as duration did not relate to outcome in those without a personality disorder (Rutter, 1977; Rutter & Quinton, 1984*a*). Other investigations, too, have shown that personality disorders tend to be persistent over the course of years (Sund, 1973; Tyrer *et al*, 1983*a*). Drake & Vaillant (1985) and Robins (1986, 1987) have shown the childhood origins of personality disorder and the associated social impairment (but low rate of contact with psychiatric services) in adult life.

On the negative side, however, the findings fail to support the trait based approach to personality disorder. The reliability and temporal stability of most trait-defined subtypes has been found to be quite poor (Mann *et al*, 1981; Tyrer *et al*, 1983*b*) and it is common to find that individual patients meet the criteria for several supposedly distinct subtypes (Boyd *et al*, 1984; Siever & Klar, 1986). Follow-up studies of patients with neurotic disorders have similarly shown fluctuating patterns of symptomatology (Greer & Cawley, 1966) and there is only a relatively weak association between specific personality traits and the type of neurotic disorder (Snaith *et al*, 1971; Tyrer *et al*, 1983*b*). It may be useful to assess those personality traits that are associated with an increased predisposition to neurotic disorder (such as obsessionality and emotionality) but these are probably best dealt with in dimensional rather than categorical terms and they do not seem to provide the best approach to personality *disorder*. Evidence is lacking that personality disorder derives from the person being extreme on some particular trait and it seems unlikely that this is the case.

Undoubtedly, the best evidence on the coherence of a subtype is that for antisocial personality disorder. As Robins has shown in her own impeccable follow-up studies, as well as in her review of the literature (Robins, 1978; 1987), almost always it has its origins in childhood conduct disturbance, it is associated with widespread social impairment, and it shows substantial persistence over time. Even so, it is a questionable diagnostic entity. In the first place, it is partially defined in terms of social deviance. This is particularly unsatisfactory from a forensic point of view as Barbara Wootton (1959) pointed out so clearly years ago; because the same behaviours (i.e. antisocial acts) are being used to define the crime and the psychiatric condition (i.e. the personality disorder) said to account for it. However, more importantly, the psychiatric findings do not justify the use of antisocial behaviour as the defining criterion for the personality disorder in adult life. Conduct disturbance in childhood leads onto both antisocial *and* inadequate or dependent type personality disorders, more often the former in males and the latter in females (Quinton *et al*, 1984; Zeitlin, 1986). Indeed, in women emotional and somatisation problems are a common sequel to conduct disorders in childhood (Robins, 1986). Both antisocial *and* other types of personality disorders in parents predispose to conduct disorder in the children (Rutter & Quinton, 1984*a*). Furthermore, family history studies show that antisocial personality disorders and somatisation disorders are associated, again with male and female preponderance respectively (Crowe, 1983; Guze *et al*, 1986). It seems possible that the unifying feature may turn out to be a widespread and pervasive abnormality in social relationships rather than antisocial acts or dependent behaviour or somatic complaints.

ICD-9 has a category for affective personality disorder characterised by mood swings (WHO, 1978) and the category of 'asthenic' personality (meaning anxiety proneness and inability to cope with stress) has been widely employed in European studies in the past (Goldberg, 1983). DSM-III has a somewhat similar category 'dysthymic disorder' but, in contrast, it is classified with affective, rather than personality, disorders (APA, 1980). Longitudinal data have confirmed that such personality features are indeed associated with a substantially increased risk of psychiatric disorder (Hagnell, 1966; Tolle, 1968). However, what is much less clear is how to differentiate these supposed personality disorders from remitting and relapsing affective conditions. Follow-up studies of psychiatric patients show that the pattern of fluctuating recurrance of symptoms is common (Greer & Cawley, 1966; Rutter & Quinton, 1984*a*; Bronisch *et al*, 1985). Sometimes the recurrence amounts to a clinically handicapping disorder and sometimes it does not. The presence of mild depressive symptoms at one point predicts the development of a major affective disorder at some later date (Weissman *et al*, 1986); this appears to be so in childhood as well as in adult life (Kovacs *et al*, 1984*a,b*). Also it is evident that people's responses to personality questionnaires fluctuate markedly according to whether or not they are currently suffering from an affective disorder (Coppen & Metcalfe, 1965; Liebowitz *et al*, 1979; Hirschfeld *et al*, 1983). The same difficulty in differentiating personality features from chronic or recurrent disorders applies in lesser degree to interview measures (Tyrer *et al*, 1983*a,b*). The conclusion seems to be that these subclinical manifestations of dysthymia or cyclothymia are real enough but that they are better dealt with in terms of mild affective disorders rather than separated into a different personality disorder category. That is indeed what has happened to the diagnosis in the draft guidelines for ICD-10.

The category of borderline personality disorder has given rise to a substantial literature in recent years but without resolution of its nosological status (Siever & Klar, 1986; Docherty *et al*, 1986). It is defined primarily in terms of an instability in both mood and interpersonal relationships but it overlaps considerably with the DSM-III categories of narcissistic and histrionic personality disorders, and investigators have differed considerably in the criteria upon which they have placed emphasis. It seems clear enough that there are individuals who have unstable intense personal relationships; who tend to be exploitative and impulsive; and who show marked affective instability, often with recurrent suicidal attempts. Moreover, such characteristics tend to persist over time. Despite its rather misleading title, there seems to be little or no genetic or predispositional association with schizophrenia. Two main questions arise. First, are there good reasons for making this a distinct category that differs from other personality disorder characterised by chronic and widespread relationship difficulties? The data to provide a definitive answer do not exist but perhaps there is more to be said for 'lumping' that 'splitting' at this point. Second, what is the nature of the association with affective conditions? There is no doubt that individuals with borderline disorders have an increased rate of affective disturbance but, on the whole, family data suggest that the two sets of conditions are likely to be genetically distinct (Loranger *et al*, 1982; Pope *et al*, 1983).

Schizotypal personality disorder differs most strikingly from the other subtypes in its emphasis on both odd eccentric behaviour and abnormalities of cognition and perception, with suspiciousness, ideas of reference and paranoid feelings, as well as poor social relationships. Although twin data have been equivocal (Torgerson, 1984) family data have been consistent in showing a relatively strong association with schizophrenia (Kendler *et al*, 1981, 1984; Baron *et al*, 1983). Clinical follow-up also shows that there is substantial overlap with schizophrenia (McGlashan, 1986) and it seems preferable to group schizotypal conditions with schizophrenia rather than with personality disorder. That move is proposed in the draft guidelines for ICD-10.

The situation is comparable, but less clear, with respect to paranoid personality disorders. They, too, show a familial association with schizophrenia (Stephens *et al*, 1975; Kendler & Gruenberg, 1984). However, recent data from Kendler *et al* (1981) suggest a stronger association with delusional states than with schizophrenia. It remains uncertain quite where paranoid personality disorders should be placed in any psychiatric classification scheme.

Finally, there is the issue of how to define and where to place schizoid personality disorder. In spite of its name, no association with schizophrenia was found in the Danish Adoption studies (Kety *et al*, 1975). However, it was defined rather broadly in that investigation. Wolff's (Chick *et al*, 1979; Wolff & Barlow, 1979; Wolff & Chick, 1980) criteria for schizoid disorder of childhood overlap greatly with those for the adult personality disorder in their emphasis on specific abnormalities of empathy and social relatedness. Her findings show many similarities between schizoid disorder and childhood autism, as well as with Asperger's syndrome (Wing, 1981); her follow-up also demonstrated that strong persistence of the clinical pattern. On the whole, the connections with autism seem much more striking than those with schizophrenia (although in both Wolff's and Wing's series a few individuals developed schizophrenia-like disorders). The problem of possible links with both autism and schizophrenia probably stems from the inherent difficulties in differentiating schizoid from schizotypal disorders; in reality it is likely that the former links with autism and the latter with schizophrenia but that the two sometimes get confused. The best means of differentiation have yet to be established but perhaps the schizoid pattern (better termed Asperger's syndrome) should place weight on the early appearance of the pattern, the stereotyped interests, and the lack of empathy; in contrast, the schizotypal pattern may be best characterised by the paranoid, suspicious qualities and the eccentric incongruous behaviour.

The literature on personality disorder is far from satisfactory in numerous respects, most strikingly in the divergent definitions, concepts, and measures. Accordingly, it is not possible to draw any firm conclusions that are likely to receive general assent. Indeed, it is striking that different groups are moving in disparate, often opposite, directions. Thus, the second draft of DSM-III R retains the 11 personality disorder categories in DSM-III and adds two more, sadistic and masochistic or self-defeating. As already noted, the draft for ICD-10 has removed two categories (cyclothymia and schizotypal) from the personality disorder section to other sections. On the other hand, it has created a whole new set of codes for 'personality trait accentuation', which differ from personality disorders only in terms of severity and pervasiveness.

As I have tried to indicate, research findings emphasise both the heterogeneity of the overall personality disorder category and the substantial overlap between the supposedly separate subcategories. It seems desirable to remove those that fit more easily into other sections of the classification, as the ICD-10 draft has done with cyclothymia and schizothymia. The draft guidelines for ICD-10 also groups Asperger's syndrome with autistic conditions, which seems equally justifiable. On the other hand, it retains a separate category for schizoid personality disorders in adult life that are not schizotypal. Whether that is necessary remains to be seen. It is unclear what to do with paranoid personality disorders.

I see little justification for the retention of trait-defined personality disorders. The traits may well be useful descriptors but it seems that they are better dealt with in dimensional not categorical terms.

Rather than split the remaining personality disorder categories, for reasons already discussed, I would group together those that DSM-III termed the 'dramatic' cluster – namely the borderline, antisocial, histrionic and narcissistic varieties, perhaps with the addition of somatisation disorder (although that is less certain). The characteristic that seems to define them all is a pervasive persistent abnormality in maintaining social relationships. The abnormality differs from that in the schizoid and schizotypal varieties in that there is no lack of interest in relationships; moreover it is likely that the early childhood pattern is also different. Of course, it is highly desirable to provide a more precise description of the nature of the relationship difficulty but that requires data not available at present. There is evidence for both genetic (Crowe, 1983) and environmental (Rutter & Quinton, 1984*b*) determinants and, at present, it is quite uncertain whether those with a strong heritable component differ from the remainder, or whether some other subdivision is required. But, for the moment, one overall category defined in terms of relationship abnormalities seems preferable to multiple subcategories without clear boundaries between them.

Conclusions

The terms temperament, personality and personality disorder have often been used interchangeably or, alternatively, they have been viewed in sequential fashion with one leading to the next, so that personality disorders represent the extremes of genetically determined temperamental traits together with the added effect of environmental shaping of personality during the years of development. Although hallowed by time, the concept is mistaken in my view. There is, indeed, a need for all three terms but they refer to rather different phenomena and rather different processes. It is suggested that temperament is best viewed in terms of a relatively small number of simple, non-motivational, non-cognitive, stylistic features of which emotionality, activity and sociability are the best validated. It is possible that these characteristics have fairly direct neurobiological correlates but this has yet to be demonstrated. By contrast, personality refers to the coherence of functioning that derives from how people react to their given attributes, how they think about themselves, and how they put these together into some form of conceptual whole. There is no one way of measuring personality. Some aspects may be dealt with in terms of dimensional traits such as obsessionality but others are best thought of in terms of processes involving cognitive, emotional and social mechanisms. Personality disorders, as traditionally conceived, include several categories that are most appropriately considered as variants of conditions such as affective disorder, autism and schizophrenia. However, there remains a substantial group of disorders that are characterised by a persistent, pervasive abnormality in social relationships and social functioning generally. These personality disorders are clinically important in terms of both their incidence and their chronicity. They deserve much greater attention than they have received in the past.

The Dexamethasone Suppression Test in Depression

A WORLD HEALTH ORGANIZATION COLLABORATIVE STUDY

The response to the dexamethasone suppression test (DST) was examined in 543 patients suffering from major depressive illness and 246 healthy controls, from 13 research centres, representing 12 different countries, in a World Health Organization Collaborative Study. In almost all the centres, the post-dexamethasone plasma cortisol concentration was significantly higher in the patients than in the controls. Although there is variation between centres, this abnormal response to the DST was shown to be frequent in patients from widely different geographical areas.

The dexamethasone suppression test (DST) has been reported to be abnormal in many but not all investigations in depressive patients. The proportion of patients showing an abnormal response has varied greatly between different centres (Carroll *et al*, 1982).

In order to study the incidence of this abnormal response, the World Health Organization initiated in 1981 a multicentre prospective investigation of DST response in patients from 13 research centres. Since it was unlikely that 13 research centres would use the same technique to measure plasma cortisol concentration, it was decided that all samples would be sent to one laboratory (Epsom) for the estimation of cortisol and for the collation of the clinical details of the patients.

Method

Thirteen research centres from Europe, Africa, Asia and North America took part in the study. These centres were located in Basle, Brussels, Budapest, Casablanca, Copenhagen, Epsom, Irvine, Lucknow, Moscow, Munich, Nagasaki, Sapporo and Utrecht.

Dexamethasone suppression test

One mg of dexamethasone (Oradexon–Organon®) was administered to all patients at 23h00 (except for the patients from the Epsom centre who received the dexamethasone at 20h00). Blood samples were collected into heparin tubes from the patients between 15h00 and 16h00 the following day; the plasma was obtained by centrifugation; it was stored at −20°C until a sufficient number of samples had been acquired for transport in dry ice by air to the laboratory at the Epsom Centre. Cortisol was estimated using a radioimmunoassay technique (Amerlex®). The samples from Epsom were assayed using a radioimmunoassay kit produced by CIS International. It has already been reported that there is an excellent agreement between these two kits (Wood *et al*, 1983).

The results of the cortisol assays are expressed for each centre in two ways (a) as the mean post-dexamethasone plasma cortisol concentration and (b) as the percentage of abnormal responses. A post-dexamethasone cortisol level of <50 ng/ml was taken as a normal response; an abnormal response was taken as $\geqslant 50$ ng/ml of cortisol. The scientific officer who estimated the cortisol levels was unaware of the clinical details of the patients.

Classification and rating of patients

All patients from each centre fulfilled the Research Diagnostic Criteria (RDC) for major depressive disorder (Spitzer *et al*, 1978) and these were taken as the criteria for entry into the study. They were consecutively admitted to the study without any other pre-selection. The patients were classified according to the International Classification of Diseases - 9th Revision (ICD-9) (World Health Organization, 1978) and the Newcastle Diagnostic Scale (Carney *et al*, 1965). The severity of the patients' depressive symptoms was assessed using the Hamilton Rating Scale for Depression (HRS-D) (Hamilton, 1967).

Before the start of the study, a researcher responsible for the implementation of the study from each centre attended a training session in Basle to become familiar with the procedures of the research protocol and assessment instruments. This training was followed up by a reliability rating exercise to obtain the levels of inter-rater agreement on the clinical rating of patients on the Newcastle Scale.

Information was provided as to whether the patient was an in-patient or out-patient, his age, sex, any recent or chronic physical illness and any medication received in the 2 weeks prior to the administration of dexamethasone.

Control groups

During the early stages of the investigation it became apparent that the small number of abnormal responses previously reported in a healthy population might also vary from country to country and all investigators were therefore asked, if possible, to supply post-dexamethasone plasma from normal controls.

Means were compared using a *t*-test, with a Satterthwaite's modification where appropriate.

Results

Plasma samples for cortisol analysis were received from 562 patients. All except 31 were in-patients at the time of the test. Nineteen patients had to be omitted from the study: two because their concomitant medication was thought to have affected the DST, three because of a severe physical illness, three because of incomplete clinical data and 11 because their diagnosis did not conform to the RDC criteria for major depressive disorder. Plasma was also received and assayed for cortisol from 246 controls.

Table I indicates the number of patients in each of the research centres who participated in the study, the sex distribution, the mean age, HRS-D and Newcastle scores.

Most centres (all except Basle, Irvine, Moscow and Utrecht) collected and sent post-dexamethasone plasma samples from healthy controls, 246, altogether.

Table II indicates the mean post-dexamethasone plasma cortisol concentration of patients and controls. When the centre included controls in the study, the statistical comparison has been made between the patient and the control groups within the centre. Since some centres did not provide controls, a statistical comparison has also been made between the patients and the total ($n=246$) control group. In seven out of nine centres in which comparison

†Patients significantly different ($P<0.02$) from all controls

was possible, the mean post-dexamethasone plasma cortisol concentration of the patients was significantly higher than the mean of the control group. In 12 out of 13 centres, the mean post-dexamethasone plasma cortisol concentration of the patients was higher than the mean of the total control group.

Table II also indicates the percentage of abnormal responses to dexamethasone administration in patients and controls, using the 50 ng/ml cut-off point.

Since previous reports indicated a relationship between the endogenous nature of the illness and an abnormal DST response (Coppen *et al*, 1983) it was decided to check whether this relationship was still evident in such a large group of depressed patients. The result of the inter-rater reliability of Newcastle Scale scoring, prior to the onset of this study, was considered satisfactory. However, only five centres provided a large enough number of patients in each of the two categories of endogenous (Newcastle score ⩾6) and non-endogenous (Newcastle score ⩽5) illness. Four of these five centres had a higher mean post-dexamethasone plasma cortisol concentration in the endogenous patients than in the non-endogenous patients, but the difference was only statistically significant in the Epsom and Brussels centres. In these two centres the mean post DST plasma concentrations were respectively 66 and 62 for the non-endogenous patients and 120 and 114 for the endogenous.

All patients had been classified according to ICD-9. The depressive patients in category 296 (who come nearest to the definition 'endogenous') were compared to patients in all other categories of depression. Means for the ICD 296 groups were not significantly different from the means of the other ICD categories of depression except in the case of the Epsom centre where ICD 296 had a significantly higher mean (109.8 ng/ml) than the others (66.0 ng/ml).

There was no significant difference in the mean post-dexamethasone cortisol concentration or in the proportion of abnormal responders between groups of in-patients and out-patients in those centres which contained both.

Discussion

These results support the view that post-dexamethasone plasma cortisol concentration is higher among depressive patients than among controls. There is, however, variation between the centres with the highest mean plasma cortisol concentration (116.5 ng/ml) and the lowest mean (22.5 ng/ml). This variation is also evident in the percentage of abnormal responses (71% to 15%) among the patients.

Two Japanese centres had a low mean post-dexamethasone plasma concentration. However, the means for their control groups are also very low. This indicates that it is important for any centre undertaking a DST comparison to seek controls locally. It also points to the inappropriate nature of a universal cut-off point to define an abnormal DST response.

In general, the controls were younger than the patients; this does not account for the difference in DST response. When subsamples of younger patients were matched for age with controls from the same centre, the difference in DST response remained as marked as for the older group.

The results of this collaborative study point to the wide incidence of abnormal DST responses among depressive patients. They do not contribute to the question of the specificity of that response. They also do not indicate whether normal or abnormal DST responses are related to particular subgroups of depressive patients. The association between an abnormal DST response and an endogenous type of depression (as defined by the Newcastle classification) finds support in a similar study reported by the Copenhagen Centre (Dam *et al*, 1985) of 91 depressive patients tested in a similar way but not included in the present investigation: 50% of the endogenous and only 30% of the non-endogenous patients gave an abnormal response to the DST.

Sex distribution, age and severity of the illness were examined but did not account for the differences in post-dexamethasone cortisol concentration between the centres. Other factors such as ethnic features, psychopathological characteristics, geographical location, climate, etc. probably influenced the results of the DST. A more detailed analysis of the data is already under way.

Conclusion

Most of the healthy control population samples from various countries responded normally to the DST. A significantly larger proportion of patients suffering from major depressive illness failed to respond normally and the present findings confirm that an abnormal DST response is one of the more robust biological characteristics of that illness.

Whether this subgroup of patients with an abnormal DST response represents a homogeneous category with regard to treatment or to other clinical and biological characteristics remains to be demonstrated by further research.

Acknowledgement

The investigators wish to thank other members of the country teams who participated in this project. In addition, we are grateful to C. Steiner, E. Szadoczky, M. Nagy, H. Fujita, who assisted in the conduct of the study and to Royal Air Maroc, Ciba Geigy, Switzerland, and Organon Laboratories Ltd, UK for their generous help.

The Structure of Depressive Symptoms in the Elderly

W. R. GOOD, I. VLACHONIKOLIS, P. GRIFFITHS and R. A. GRIFFITHS

In a structured sample of 100 male and 100 female minimally impaired patients, aged 60 years and over, females were more depressed. Varimax factor analysis demonstrated four factor groupings which have clinical relevance – Depression, Anxiety, Cognitive impairment, and Psychosomatic disorder; their relative importance is different in males and females. Analysis of variance of the scores of clusters generated by cluster analysis demonstrated four groups of subjects – normal, mildly depressed, moderately depressed with borderline dementia and disability, and severely depressed with moderate dementia and frank disability. In the mildly and moderately depressed, symptoms of anxiety predominated.

Depression may refer to mood, symptoms, syndromes or disease (Calloway, 1982) and patients may be labelled 'depressed' as a result of changes in any of these categories. The classification of depressive illness is confused (Kendall, 1976), but there is general agreement on a basic division into Types A and B. Type A ('psychotic'/'endogenous') denotes severe depression with diurnal variation of mood, guilt, retardation, severe insomnia and loss of insight. Type B ('neurotic'/'reactive') denotes milder illnesses, prone to fluctuation and lacking the characteristic features of Type A. In describing the symptoms of a community, it is not necessary to make the *a priori* assumption that Type A/B classification is either hierarchical or dichotomous.

The prevalence of clinical diagnosis of depression is increased in the elderly, but the increase of prevalence of depressive symptoms is disproportionately greater. Of 'normal' (functionally normal for age) people aged over 65 years, 44% had a Self-rating Depression Scale (SDS) score above the SDS criterion for depression. It was concluded that "the normal elderly patient may feel depressed . . . but not enough to show measurable changes" in functional performance (Zung, 1967, 1972). This suggests that depressive symptoms may be more common in the elderly, even in the absence of clinical depression, but no symptomatic structure has been described in the normal elderly, comparable to that seen in the depressed.

If the difference between the normal and the depressed is one of intrinsic type, i.e. if the division is dichotomous, mutually comparable symptomatic structures could not be expected. However, if this difference is merely one of degree, i.e. if the division is hierarchical, then it should be possible to identify a symptomatic structure common to both.

Some community studies of 'depression' have described heterogenous samples which include patients with depressive illness, those with depressive syndrome in the absence of disease, those with depressive symptoms only, and those with simple altered mood. It has been concluded (Finestone & Blazer, 1982) that, while some elderly patients experience late-life dysphoria (dejection, despondency or unhappiness) in the absence of frank disease, their symptoms do not render them unable to maintain their usual activities and they do not require acute medical intervention.

Factor analysis of depressive symptoms describes patterns of association between them. On the basis of factor scores, it may be possible to allocate to diagnostic groups those patients who show highly polarised factor scores, but the majority of mildly or moderately impaired patients cannot easily be allocated on this basis. However, factor analysis is inappropriate for eliciting clinical syndromes which may be more appropriately described by discriminant function analysis (Hamilton, 1960).

Factor analysis has since been used widely to characterise groups of associated symptoms (Kiloh & Garside, 1963; Carney *et al*, 1965; Mowbray, 1972; Gurland *et al*, 1976; Giambra, 1977; Pull *et al*, 1979; Overall, 1980), which may or may not correspond to clinical entities. Most of the studies have demonstrated a Factor One, which corresponds to Hamilton's General Factor of Depressive Illness, and which is commensurate with overall severity of symptoms. Some have further demonstrated a second factor, which may describe the dichotomy between Type A and Type B depression, but allocation of patients to diagnostic groups outside this simple dichotomy is equivocal.

Mowbray (1972) based his analysis on a consideration of principal components and pointed out that Factor One is unipolar, in contrast to all further factors, which are bipolar. It is inherent to the technique of principal component analysis (PCA) that Factor One is unipolar and others bipolar, and that all variables have a complexity greater than 1 (Kim, 1975). In other words, every variable loads onto more than one factor, and further comment on the nature of underlying phenomena cannot be based on this differentiation. In PCA, differences in the form of a factor do not necessarily imply differences in form in the underlying dimension. (The concept of polarity of factors seen in factor analytical studies should not be confused with unipolar and bipolar clinical concepts of depressive illness.)

Hamilton (1960) provided a rotated factor matrix "For the interest of those factorists who have a taste for . . . simple structures". In Varimax rotation, "The clustering or patterning of . . . variables into . . . groups is more obvious after the rotation than before, even though the relative position or configuration of the variables remains unchanged. In the unrotated solution, every variable is accounted for by two (*or more*) significant common factors, while in the rotated solution each variable is accounted for by a single significant common factor. Therefore, the rotated factor loadings are conceptually simpler than the unrotated ones" (Kim, 1975). It is conceptually simpler to adopt a method of analysis which ascribes each variable to only one factor.

Hamilton presents an orthogonal rotation which presupposes that all factors, and therefore dimensions, are independent of each other. When multiple dimensions are orthogonal, "variation along each is independent. Description of position on one such dimension says nothing as to position on any of the others and has very different implications from membership of one of a set of mutually exclusive groups" (Paykel, 1971).

While factor analysis can distinguish between hierarchical and dichotomous models of depressive symptoms, it cannot differentiate dimensional (quantitative) and categorical (qualitative) mechanisms within these models (Eysenck, 1970). Factor analysis describes the inter-relationship of symptoms in a sample; it does not demonstrate interrelationships of subjects or allow their division into groups.

Cluster analysis provides methods of allocating subjects, on the basis of their factor scores, to groups which are independent of previous classification. The similarity of individuals within groups, and the difference between groups, is maximised, and this provides optimal categorisation of subjects. Cluster analysis has been used for the classification of depressed patients (Paykel, 1971) and of the mentally ill in general (Everitt *et al*, 1971); detailed reviews of clustering techniques may be found in Cormack (1971) and Everitt (1974).

Method

A study was made in 1979 of 200 elderly patients in the community (Griffiths *et al*, 1987); 100 males and 100 females were selected to provide 20 men and 20 women in each quinquennium from 60 to 79 years and a similar group aged 80 years and over. All these patients were assessed for depression and dementia using a modification of the Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960) and the Mental Test Score (MTS) (Hodkinson, 1973). The HDRS was modified to produce a semi-structured interviewer-assisted questionnaire (Griffiths *et al*, 1987) to standardise the assessment (available on application to authors).

The 200 'good' subjects included 51 whose HDRS was 14 or more, (our criterion for 'depression') and/or who had an MTS of 28 or less, (our criterion for 'dementia').

Factor analysis was performed on all 200 subjects and also separately on males and females.

Subjects were allocated to groups by cluster analysis of their rotated factor scores; differences in factor score profiles between groups were tested by analyses of variance.

Statistical techniques

The grouping of HDRS elements was assessed initially by PCA, with iteration, of the Pearson correlation matrix. Those factors having an eigenvalue greater than 1 were subjected to Varimax rotation; variable loadings were selected to maximise individual eigenvalues.

The significant critical value of each item loading in the Varimax-rotated factor matrices was calculated according to the method of Burt and Banks (Child, 1970). To guard against over-optimistic inclusion of marginal loadings, intentionally strict critical values were selected, corresponding to a probability $P<0.001$.

Subjects were allocated severally to clusters, on the basis of their HDRS item scores, by three different methods of cluster analysis: Ward's (1963), *k*-means (MacQueen, 1966) and the Normix method (Wolfe, 1965, 1967, 1970). The first two methods require similarity coefficients, and as such the Euclidean distances were specified; they make different initial assumptions of the structure of the data. The third method assumes a mixture of multivariate normal distributions with unequal covariance matrices, and uses the method of maximum likelihood to estimate the parameters. The subjects are then assigned to the cluster for which the probability of belonging is highest. These three methods are sufficiently dissimilar to test the validity of the resulting clusters.

F ratios were calculated by one-way analysis of variance (ANOVA) with each factor in turn as the dependent variable, and the cluster as independent. Multiple analysis of variance (MANOVA) was performed between the cluster as the independent variable, and all factors simultaneously as dependent variables. The association between sex and cluster was tested using χ^2. A two-way ANOVA was performed for each factor as the dependent variable, with sex and cluster as independent variables.

A one-way ANOVA was performed for each of the variables HDRS, MTS, usual activities score (UA) (Griffiths *et al*, 1987) and age as dependent variables, and the cluster as independent. Where a significant difference was observed, the relationships between the clusters for these variables was determined by Newman–Keuls test (Armitage, 1971).

Computing techniques

Data were analysed on an ICL 2988 computer. Factor analysis and analyses of variance were derived from the Statistical Package for the Social Sciences (SPSS II [Nie *et al*, 1975]) and the SPSS Update 7–9 (Nie & Hull, 1981), and were performed by subprograms 'Factor' and 'ANOVA'. Cluster analyses were derived from the statistical package CLUSTAN (Wishart, 1978) and were performed by subprogram 'Ward', '*k*-means' and 'Normix'. The χ^2 tests were performed manually. The Newman–Keuls tests were performed by the SNK routine of the SPSS subprogram 'Oneway'.

Results

Depression and dementia here refer to categories defined according to criteria established for rating scales (Griffiths *et al*, 1987) and not to clinical diagnoses. The criterion for depression was HDRS>13, and that for dementia, MTS<29. The numbers of subjects in each group are shown in Table I.

The severity of depression depends on the number of depressive symptoms and on the severity of each of those symptoms; the HDRS total score depends on the number of items answered positively, and on the degree of impairment revealed by each positive item.

PCA of the elements of the HDRS revealed three items which produced unrelated factors, i.e. they produced factors which were unique to themselves and derived no loading from other items; these items occurred on 1% or less of responses and were items 19, 20, and 21 (Griffiths *et al*, 1987) which are 'Depersonalisation and derealisation', 'Ideas of reference and persecution' and 'Obsessional ideas and behaviour'. Therefore, these items were excluded by us from repeat PCA and subsequent analysis, as they were by Hamilton (1960). In addition, item 14, 'Disturbance of libido', had been eliminated before data collection. Further individual deletion of items of the HDRS did not alter the number or pattern of principal components with an eigenvalue greater than 1; therefore, this 17-item scale was subjected to further analysis. The 17-item scale, so derived, corresponds to that on which Hamilton (1960) based his analysis, except that item 18, 'Diurnal variation', was not excluded by us.

Factor analysis

Separate PCA with iteration of the correlation matrices of the HDRS for all 200 'good' patients and for females only demonstrates four factors, which account for 60.7 and 62.6% of total variance respectively. In males only, six factors are seen, which account for 68.7% of the variance; but the last two factors here account for only 9.6% of the variance and have very low factor loadings. Therefore, it was decided to retain only the first four factors: their interpretation is equivocal and bears little relationship to clinical syndromes, although they are not dissimilar to those of Hamilton (1960), Mowbray (1972) and others. All these principal components have a complexity of greater than 1, and thus describe elements of more than one underlying dimension.

Varimax rotation produces an equally scattered distribution, although minimising the bipolarity seen in the unrotated matrix, and demonstrates factor groupings which resemble clinical syndromes (Table II). Variables having a less than critical loading (i.e. less than 0.23, which corresponds to a probability $P<0.001$) by the method of Burt and Banks (Child, 1970) are excluded from consideration in Table II. Primary loadings are shown in normal type; secondary loadings are in italics.

The four factors thus produced for the whole group, for females and for males, are similar in composition, although their order of emergence is different, and they differ in importance between the sexes. We have designated these four factors Anxiety, Depression, Cognitive impairment, and Psychosomatic disorder.

Factor A is a well-defined anxiety factor, common in all aspects to both sexes. Factor B, the depression factor, is first in order for the females, with high loadings, whereas

	13 General somatic	0.508		*0.257*		0.649	
	16 Weight loss	0.412		0.394		0.402	
	17 Loss of insight	*0.368*		*0.307*		*0.458*	
	18 Psychic anxiety	*0.260*		*0.261*		*0.368*	

Primary loadings are shown in normal type; secondary loadings are shown in italics. Non-significant loadings are shown in brackets.

TABLE III
Mean values of factors A, B, C and D by sex

Factor	*Sex*	*N*	*Mean*	*s.e.*	*t-value*	*d.f.*	*Significant difference between males and females*
A	Males	100	−0.242	0.077	−4.18	198	<0.01
	Females	100	0.242	0.087			
B	Males	100	−0.170	0.045	−2.79	198	<0.01
	Females	100	0.170	0.113			
C	Males	100	−0.075	0.076	−1.22	198	NS
	Females	100	0.075	0.097			
D	Males	100	−0.123	0.059	−2.17	198	<0.05
	Females	100	0.123	0.097			

for the males it is slower to emerge, and with low loadings on Agitation and Psychic anxiety. Factor C, Cognitive impairment, is first to emerge for the males, but is only fourth for the females, having low loadings on Guilt and Diurnal variation. Factor D, Psychosomatic disorder, is more apparent in females than in males, in whom low loadings are seen for Work and interests and Somatic anxiety.

Females scored more highly on every factor than did males (Table III). This is significant for all factors except factor C, Cognitive impairment.

Cluster analysis

The three methods used each produced a clear four-cluster solution. The clusters generated by Ward's method and by the *k*-means method were identical; those generated by the Normix method were slightly different, in that a total of 30 subjects were allocated differently among the first two clusters of the first two solutions. Therefore the solution produced by the first two methods was adopted for subsequent analysis, and the mean values for each factor, by cluster, are shown in Table IV.

TABLE IV

Mean values of factors A, B, C and D by cluster (Ward's and k-means solutions) (standard deviations in brackets)

Cluster	*n*	*Factor A*	*Factor B*	*Factor C*	*Factor D*
1	110	−0.59	−0.24	−0.10	−0.19
		(0.38)	(0.28)	(0.60)	(0.46)
2	55	0.75	−0.01	−0.49	−0.12
		(0.59)	(0.65)	(0.34)	(0.64)
3	27	0.64	0.25	0.87	0.46
		(0.81)	(1.44)	(1.25)	(1.24)
4	8	0.82	2.49	1.79	1.89
		(0.90)	(1.27)	(0.91)	(0.90)
F-value		97.843	39.072	42.370	27.928
d.f.		3,196	3,196	3,196	3,196
P		<0.01	<0.01	<0.01	<0.01

The four cluster mean values were significantly different for every factor. Examining all four factors simultaneously, i.e. forming a vector of dependent variables, MANOVA produced a Wilks' lambda of 0.0522 (d.f. 4, 3, 196) and *F* value of 87.43 (d.f. 12, 510); this was highly significant ($P<0.00001$), and the factor structure thus shows highly significant clustering.

Cluster 1, the largest, has negative mean values for every factor, an indication that it is composed mainly of unimpaired subjects. Cluster 2 has a high positive mean for factor A, Anxiety, and negative values for the other factors. Cluster 3 has high positive means for factors A and C, Anxiety and Cognitive impairment. Cluster 4 has high positive means for all four factors, and comprises eight subjects, all females.

TABLE V

Sex composition of the four clusters (Ward's and k-means solutions)

	Cluster 1	*Cluster 2*	*Cluster 3*	*Cluster 4*	*Total*
Males	68	23	9	0	100
Females	42	32	18	8	100
Total	110	55	27	8	200

The sex composition of the four clusters is seen in Table V. There is a significant association between sex and cluster ($\chi^2_{(3)}=18.6$, $P<0.001$); female subjects are found in higher proportion than males in clusters 2, 3 and 4, but in lower proportion in cluster 1.

The results of two-way ANOVA for each factor as the dependent variable, and sex and cluster as independent variables, are presented. The cluster effect on every factor is highly significant, but the sex effect is not significant for factors A and B.

For factors B and C, there is significant cluster by sex interaction. Cell means for these factors are shown in Table VI. Clusters 3 and 4 (composed of females only) are the only clusters in which there is a significant difference between the sexes. The clusters differ in respect to HDRS, MTS and UA score (Griffiths *et al*, 1987) (Table VII). The MTS is expressed as dMTS, the value obtained by subtracting the MTS value from the maximum obtainable (34), so that the direction of increasing impairment is maintained in all three test variables. Increased values of UA indicate increased disability.

TABLE VI

Mean values of factors B and C by sex and cluster

	Cluster 1	*Cluster 2*	*Cluster 3*	*Cluster 4*
Factor B[1]				
Males	−0.21	−0.00	−0.26	0.00
Females	−0.28	−0.01	0.50	2.49
Factor C[2]				
Males	−0.17	−0.49	1.68	0.00
Females	0.01	−0.49	0.46	1.79

1. $s^2=0.479$, based on 193 d.f.
2. $s^2=0.429$, based on 193 d.f.

Each cluster is significantly different from all others with respect to HDRS score; this might have been expected, since the clusters were generated using the HDRS scores. The clusters do not differ significantly in respect of age. However, for both UA and dMTS, clusters 3 and 4 differ significantly from each other and from clusters 1 and 2 combined.

TABLE VII
Analysis of variance of HDRS, MTS, UA and age in four clusters

	Cluster				
	1 *n=110* *(68m, 42f)*	*2* *n=55* *(23m, 32f)*	*3* *n=27* *(9m, 18f)*	*4* *n=8* *(0m, 8f)*	*ANOVA F-value Significance (P)*
HDRS±s.d.	2.9±1.8	9.1±2.5	14.2±3.4	27.6±3.0	436.0,
(range)	(0–8)	(6–16)	(8–22)	(24–33)	<0.001
dMTS±s.d.	3.0±2.5	2.6±2.2	5.4±4.7	9.9±6.9	17.3,
(range)	(0–11)	(0–8)	(0–16)	(3–17)	<0.001
UA±s.d.	3.5±4.1	3.8±4.3	7.2±4.9	12.3±2.9	15.3,
(range)	(0–18)	(0–21)	(0–20)	(9–16)	<0.001
Age±s.d.	72.2±7.2	70.0±7.2	73.8±5.9	73.1±6.0	2.1,
(range)	(60–87)	(60–88)	(65–85)	(68–83)	>0.1
					d.f. 3196

All clusters are significantly different for each variable (Newman–Keuls test, $P<0.01$), except where they are bracketed together (NS)

Discussion

In the elderly population, depressive symptoms are disproportionately more prevalent than clinical diagnoses (Zung, 1967), and clinical diagnosis is subject to considerable error (Cooper *et al*, 1972). The clinical diagnosis of depression depends on the presence and severity of the symptoms of a definitive syndrome plus the physical, psychological and social disabilities manifest.

In their attempts to characterise depression by PCA, previous authors have identified a 'General factor of depressive illness' which correlates well with total score and resembles Type A ('psychotic'/'endogenous') depression. Subsequent factors are less amenable to interpretation; PCA trivialises all factors except Factor 1, by maximising the variance loaded on to that factor. Subsequent factors have a complexity greater than unity; factors overlap, and individual factors do not, in practice, represent unique underlying syndromes. In factors subsequent to Factor 1, there is a duality, with high positive and high negative saturation, which misleadingly suggests bipolarity of the syndromes they attempt to describe.

Varimax rotation distributes the accountable variance and the item allocation to a factor more evenly across the factor field. The duality engendered by the presence of significant negative saturation in PCA is largely eliminated by the Varimax method; the negative loadings are trivial, implying the absence, in these results, of a true bipolarity in factor groupings. PCA factor groupings in this study approximate to those of previous authors, despite the complexity of the grouping matrix.

Our Varimax technique produces a simpler structure, and the factor groupings derived by this technique have obvious clinical interpretation. The four factors A (Anxiety), B (Depression), C (Cognitive impairment), and D (Psychosomatic disorder) are relevant to the classification of affective disorders in the elderly. However, the Anxiety factor contains a significant loading for depression. The Depression factor contains a significant loading for hypochondriasis – particularly relevant in the elderly. Although the Cognitive impairment factor is derived from the HDRS scores, all subjects with high scores for this factor also had impaired mentation, as measured by the MTS. The Psychosomatic disorder factor is relevant to depression in the elderly (Post, 1965), and we observed that high scores on this factor were frequently associated with high scores on the Depression factor.

The females in our sample account for 65% of the depressive symptoms reported and 88% of the defined Depressed patients. In females, the Depression factor accounts for the greatest part of the explained variance (61.8%), followed by Psychosomatic disorder (15.7%), Anxiety (12.6%) and Cognitive impairment (9.9%). In males, Cognitive impairment is most important (47.7%), followed by Anxiety (21.4%), Depression (16.5%) and Psychosomatic disorder (14.4%).

It has been suggested (Oltman *et al*, 1980) that the types of depression in the elderly may differ by sex; in a sample in which depressive symptoms are apparently twice as prevalent in females as in males (Griffiths *et al*, 1987), it is surprising that the pattern and structure of factors is not radically different, although their relative importance is changed.

Although diurnal variation has been accepted as a characteristic of some types of depression, it does not assume a fixed position in this factor field, and was excluded by Hamilton (1960). The HDRS does not distinguish between morning and evening dysphoria in the item score.

Work and interests in both males and females is associated with the factor with highest correlation with total score. In females, this is the Depression factor, while in males the association is with Cognitive impairment. This may be related to different changes in patterns of life events in males and females on retirement.

Although we do not present separate results for our subset of 149 'normal' subjects, (MTS > 28, HDRS < 14), the factor structure produced by separate analysis of this subset is essentially similar to that for the whole sample.

Community studies of depression, using factor analytical techniques, identify both patients with depressive illness and other patients with less severe syndromes of late-life dysphoria (Blazer & Williams, 1980; Finestone & Blazer, 1982). Our study demonstrates clinically relevant factors which are identifiable components of depression in the elderly community.

In our data, the patterns of association of depressive symptoms into factors are similar in the 'normal' and 'depressed' groups, which suggests that the threshold of depression as a clinical syndrome is not an intrinsic dichotomy. However, to test this, it would be necessary to perform factor analysis on larger groups for each HDRS score. Having established the association between the items of the HDRS, we attempted by cluster analysis to identify coherent groups of subjects, on the basis of their factor scores. The various techniques of cluster analysis (Cormack, 1971; Everitt, 1974) attempt to construct clusters whose members are as similar as possible and differ from the members of other clusters. The most serious criticism of cluster analysis lies in the difficulty of establishing the validity or significance of derived clusters, especially in the absence of objective external criteria. However, by adopting three different clustering techniques, which make different assumptions of the structure of the data, we hoped to provide some measure of validation.

All three clustering methods produced a clear four-cluster solution; the results of Ward's method and the *k*-means method were identical, while the Normix results showed some small differences, but largely agreed with the other two methods. The four clusters which emerged were characterised as Normal, Anxious, Anxious and cognitively impaired and Impaired on all factors. However, a closer examination of factor A (Anxiety) shows that it contains a significant secondary loading for depression; thus, the cluster we have here characterised as Anxious might more properly be described as anxious and mildly depressed. Consideration of the mean rating scale scores of each cluster (Table VII) confirms their classification as normal, mildly depressed, moderately depressed with borderline dementia and disability, and severely depressed with moderate dementia and frank disability.

Thus, the clusters may be retrospectively justified as having direct relevance to the clinical classification of psychiatric disorder in the elderly community. This technique provides clear differentiation of the severely impaired, while indicating two borderline groups of subjects—those with dysphoric symptoms only, and those with depression and disability, warranting clinical diagnosis, but in whom the primary disorder was not clear.

DSM-III Personality Disorder Clusters in Three Populations

J. REICH and W. DOUGLAS THOMPSON

DSM-III personality disorder clusters had not previously been tested for their ability to distinguish between different population groups. A major obstacle – different demographic characteristics of different populations – was overcome by using logistic regression. Three out-patient psychiatric referral groups (chronic pain, disability applicants and competency to stand trial) provided subjects; adjustments were made for age, race, sex and education. The groups were significantly different in the adjusted prevalence of DSM-III personality disorder clusters. Clinical association between personality disorder and drug or alcohol abuse was again confirmed.

The third edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-III) (American Psychiatric Association, 1980) represents a major leap forward in the methodology of American psychiatry. Its major innovation is in standardising and specifying the inclusion and exclusion criteria for each psychiatric disorder, which were field-tested for reliability. This helps rectify the problem that arises when psychiatrists use the same diagnostic label to refer to different patients, or different labels to refer to similar patients. Another innovation was the use of several axes to diagnose different types of disorders or information. The first axis is used to diagnose clinical syndromes such as affective disorders, schizophrenia, anxiety disorders and life circumstance problems; the second to diagnose personality and some specific developmental disorders; the third, physical disorders; the fourth, severity of psychosocial stressors; and the fifth, highest level of adaptive functioning for the past year.

One of the great values of DSM-III is that, by defining specifically the inclusion and exclusion criteria of the various disorders, the association between them can often be determined accurately. This allows empirical evidence to demonstrate important clinical associations, and perhaps guide the way for future revisions of diagnoses. Frances *et al* (1984) demonstrated considerable overlap of the various DSM-III personality disorders, which raises the possibility of developing a clustering scheme of these disorders in order to classify them more economically.

A potential clustering which has much apparent validity is described in DSM-III. The first group consists of the paranoid, schizoid and schizotypal personality disorders – the asocial personality type. The second group consists of the histrionic, narcissistic, antisocial and borderline disorders – the flamboyant personality type. The third group consists of the avoidant, dependent, compulsive and passive-aggressive disorders – the anxious personality type. However, in spite of their apparent validity, little empirical work has been performed to validate these clusters.

This report examines the association of the presence or absence of a personality disorder with seven Axis I psychiatric diagnostic categories (mental retardation, organic brain syndrome, affective disorder, schizophrenia, alcohol abuse, drug abuse and a combined drug or alcohol abuse category). It also provides a test of validity for the DSM-III personality types by determining whether they can differentiate three different groups of patients.

Method

Subjects were from three population groups: one concerning competence to stand trial ($n = 390$), one with chronic pain ($n = 43$) and one of applicants for disability benefits ($n = 55$). All analyses were adjusted for age, race, sex and level of education and have been reported in detail elsewhere (Reich *et al*, 1983; Reich, 1985*b*; Reich & Wells, 1985). These populations are representative of previously described groups of a similar nature (Devine & Merskey, 1965; Merskey, 1965; Cooke, 1968; Henn *et al*, 1977; Sikorski & Benedek, 1977); Bluestone & Mellela, 1978; Bluestone & Baskin, 1981).

The forensic group consisted of 390 defendants, referred for evaluation of competency to stand trial at the Yale–New Haven Psychiatric Court Clinic in 1980–1982. Each person was included only once for data collection; if any was referred more than once, only the most recent information was used, but such cases were very few. All were given a semistructured, standardised interview, to ascertain psychiatric diagnosis and other forensic variables. Data were gathered from those previously precoded from the case records. This population was 83.3%

male, 53.8% white and 36.2% black; the average age was 30.8 years, and the average years of education 10.2. To establish reliability, a blind review of the records was performed by one of the authors (J. R.) on 27 cases, with which he was not familiar, for the diagnosis of organic brain syndrome, affective disorder, schizophrenia, mental retardation, presence or absence of a personality disorder, alcohol abuse and drug abuse. An overall kappa of 0.69 was achieved.

The pain group consisted of 43 patients seen by J. R. in 1980–1981 as psychiatric consultant to the University of California, Davis Pain Board. All had an extensive review of records and were given a semistructured interview to elicit a DSM-III diagnosis and information relating to pain. Every patient seen by the board during that period was included. This population was 35% male, 88% white and 7% black; the average age was 43.2 years and the average length of education 12.9 years. Reliability for both Axes I and II was achieved by case review by a senior clinician (Reich *et al*, 1983), with 96% agreement on Axis I and II disorders.

The disability group consists of 55 patients referred to J. R. in 1983, for psychiatric evaluation for receiving social security disability (SSI). The medical records of many were available prior to the interview. All received the same semistructured interview to determine a DSM-III diagnosis and information relating to the disability. All were from the New Haven (Connecticut) metropolitan area. The population was 53% male, 63% white and 21.8% black; the average age was 44.6 years, and the average length of education 10.5 years. Reliability of psychiatric diagnoses was tested by review of medical records and 90% agreement was reached on the primary diagnosis for seven categories (organic brain syndrome, mental retardation, schizophrenia, affective disorder, specific personality disorders, alcohol abuse and drug abuse). As the diagnoses in the disability group were checked by a psychiatrist with a large data base at his disposal, it was felt that bias resulting from secondary gain was controlled adequately.

The diagnoses were all made by DSM-III criteria, using semistructured interview instruments of similar design, which collected information about the diagnosis, and relevant to the special interest (pain, disability or competency to stand trial). The two instruments for the pain and disability groups were designed by J. R., who also performed all the interviews for these groups; he also participated in some forensic interviews and, by studying the instrument and records review, was able to conclude that its results were equivalent to the other instruments, in terms of DSM-III diagnosis. The interview instrument was designed to diagnose both Axis I and II syndromes by DSM-III criteria. Questions relevant to major psychiatric diagnostic groups (e.g. schizophrenia, affective disorder, anxiety, organic brain syndrome, mental retardation, drug or alcohol abuse) were asked, and from these answers specific Axis I diagnoses were arrived at, using DSM-III criteria. After the Axis I disorders were diagnosed, questions were asked about occupational, interpersonal and social functioning and legal difficulty; if necessary, additional questions were asked to diagnose a DSM-III-defined personality disorder definitively. All diagnoses (Axes I and II) were by specific DSM-III diagnoses, and only later grouped together in categories for ease of analysis. The diagnoses for both Axes I and II were reviewed either by a senior clinician (pain group) or by review of records (disability group), with agreement greater than 90%. As there were no comprehensive standardised instruments for measuring Axis II at the time, this represented the state of the art for DSM-III personality disorder diagnoses by clinicians. The forensic group was diagnosed by a different instrument, which asked specific questions about certain symptoms such as depression and psychoticism to aid an Axis I diagnosis, and also questions that would assist an Axis II diagnosis (legal problems, drug usage, impulsivity, ability to relate appropriately to people etc.). All forensic diagnoses were by DSM-III criteria and were also reviewed by a senior clinician. Material from case records was also used to aid in the diagnoses of all groups.

The two semistructured interviews differed in the following ways. The J. R. instrument was designed to help diagnose specific DSM-III diagnostic categories, while the forensic instrument elicited extensive symptom information, which the clinician could then use in his diagnosis of DSM-III disorders. Both provided extensive information on symptoms, with the J. R. instrument organising it into diagnostic categories and the forensic instrument organising it into symptom groups, but as both resulted in DSM-III diagnoses, the end result was the same.

At the time of collection of the data, there was no plan for a personality cluster analysis (which was decided later by the nature of the clinical material); thus, in this respect, all raters were blind. The patients were placed in one of the three personality clusters if they had any diagnosis DSM-III personality disorder; those with such a disorder were placed in only one group. In the few cases where there was more than one personality disorder, patients were placed in the personality cluster which best reflected their most severe symptoms.

Using logistic regression (similar to linear regression), two sets of odds ratios and their associated significance levels were calculated. The first was the association between having any personality disorder and seven Axis I psychiatric diagnostic categories (mental retardation, organic brain syndrome, affective disorder, schizophrenia, drug abuse, alcohol abuse and a combined drug or alcohol abuse category). The second was the ability of a personality disorder, or presence or absence of a personality type (asocial, flamboyant or anxious), to differentiate between the three source groups (forensic, pain and disability). In all analyses, age, race, sex and education were adjusted for, in order to control for confounding. Unfortunately, the sample size was too small to allow an analysis of association between personality disorder types and Axis I diagnosis. The logistic regression program used for these analyses was PROC LOGIST (SAS Institute, 1980).

To reduce the type I (false positive) error that occurs when running multiple tests, the odds ratios for personality disorders and Axis I category were run adjusting for other Axis I disorders, in essence making it one test. It is reported as individual odds ratios for ease of presentation. Similarly only four (instead of 12) analyses were run for the association of personality disorder types and different populations. As the pairwise comparisons gave identical results, they are reported in pairs, again for ease of presentation.

An odds ratio is the proportion of an event in one population, compared with the occurrence of the same event in a second population (for example, if a borderline personality disorder occurs in 10% of population A and 5% of population B, then the A:B odds ratio for borderline personality would be 2. If A should be less than B (say 5 *vs* 10%) then the odds ratio would be less than 1 (in this case 0.5). In general, the higher the odds ratio, or the closer to 0 it is, the greater the chance that it will be significant. However, when the sample size is very small, the logistic regression program may generate a large odds ratio which does not achieve significance.

Results

The unadjusted percentages of seven major Axis I diagnostic groups, where a personality disorder diagnosis was also made, were: mental retardation 10.5, organic brain syndrome 5.3, affective disorder 19.6, schizophrenia 4.1, drug abuse 28.2, alcohol abuse 15.2 and drug or alcohol abuse 22.2. The odds ratios for presence of a personality disorder for each of these categories were: mental retardation 2.1, organic brain syndrome 0.0, affective disorder 0.9, schizophrenia 0.2 ($P<0.001$), drug abuse 2.1, alcohol abuse 1.0 and drug or alcohol abuse 2.1 ($P<0.05$). These odds ratios were adjusted for age, race, sex, group of origin, education and other Axis I disorders. Only two associations were significant: schizophrenia diagnoses had a decreased risk of having an associated diagnosed personality disorder diagnosis, with an odds ratio of 0.18 ($P<0.001$), while the combined drug or alcohol abuse category had a significantly increased chance of having an additional personality disorder diagnosis with an odds ratio of 2.06 ($P<0.05$). Table I gives the unadjusted percentages of total personality disorders and personality disorder types that occurred in each of the three study groups. Table II shows the odds ratios for the various pairwise comparisons of the three study groups for total personality disorders and the personality disorder types. These odds ratios (ORs) were adjusted for age, race, sex and education. Total personality disorders discriminated successfully the disability from the forensic group (OR = 3.19, $P<0.05$) and the pain from the forensic group (OR = 4.25, $P<0.001$). The asocial personality type distinguished successfully the disability from the forensic group (OR = 6.58, $P<0.05$) and the flamboyant personality type distinguished successfully the pain from the forensic group (OR = 2.86, $P<0.05$). Finally, the anxious personality type distinguished successfully both the pain from the forensic group (OR = 12.2, $P<0.001$) and the disability from the pain group (OR = 0.13, $P<0.05$).

TABLE I

Percentages of personality disorders and personality disorder subtypes by group (n = 488)

Diagnostic variable	*Forensic group n = 390*	*Pain group n = 43*	*Disability group n = 55*
Total personality disorders	11.8	37.2	22.2
Personality disorder subgroup A (asocial)	0.8	2.3	5.5
Personality disorder subgroup B (flamboyant)	8.0	20.9	10.9
Personality disorder subgroup C (anxious)	3.1	14.0	5.5

TABLE II

Odds ratios for group comparisons by total number of personality disorders and personality subtypes (odds ratios adjusted for age, race, sex and education) (n = 488)

Diagnostic variable	*Disability vs forensic*	*Pain vs forensic*	*Disability vs pain*
Total personality disorders	3.2*	4.3**	0.5
Personality subgroup A (asocial)	6.6*	1.2	2.6
Personality subgroup B (flamboyant)	2.5	2.9*	0.7
Personality subgroup C (anxious)	2.2	12.2**	0.1*

*$P<0.05$; **$P<0.001$.

Discussion

The finding of a significant association between drug or alcohol abuse and the presence of a concurrent personality disorder is consistent with clinical observation and other recent findings (Koenigsberg *et al*, 1985). Several research workers, using different techniques, have noted either an excess of personality disorders or specific personality traits in alcohol or drug abusers (Henn *et al*, 1977; Craig, 1979*a*,*b*). This finding supports clinical judgement that detoxifying a drug abuser often reveals a second diagnosis of personality disorder. The questions as to which personality disorders are more likely to be present in drug abusers and whether there is a difference in the personality disorders that are related to drug and alcohol abuse constitute important areas of future research.

The low frequency of personality disorders among schizophrenics has several possible interpretations. There may be simply less personality disorders to diagnose, but it is more likely that the diagnosis of schizophrenia subsumes many symptoms which might otherwise be used to make a diagnosis of personality disorder. The DSM-III in these cases often excludes such a diagnosis. This explanation would also be consistent with the hypothesised close relationship between schizophrenia and certain personality disorders (Kendler & Gruenberg, 1982; Baron *et al*, 1983; Lowing *et al*, 1983; Kendler *et al*, 1984).

The finding that total personality disorders can distinguish between the forensic and the pain and disability groups (the former having less personality disorders) is interesting in two respects. It demonstrates that the frequency of personality disorders differs across patient subgroups as well as across Axis I categories, and how differences across Axis I diagnoses can interact with personality disorder differences across groups. For example, since schizophrenics are diagnosed as having personality disorders less often, and since the forensic group contains a relative excess of schizophrenics, one would expect group differences among the forensic group and the other groups on the frequency of personality disorders. Both the research question as to why these groups differ and the clinical question as to how this difference would affect treatment approaches require further work.

To some extent, the significant findings between the personality subgroups are consistent with what we know about these patient populations. As those in the disability group are to some extent looking for a way to opt out of the competitive demands of daily life, we would expect to see more asocial personality types in this group than in the forensic group, whose members are interactive enough to get arrested. For the same reason, it is not unexpected that there are less anxious personality types in the disability than in the pain group. Those in the disability group are withdrawing from contact, in contrast with the pain group who still seek it, but it is not immediately clear why the latter should have an excess of flamboyant and anxious personality types, relative to the forensic group.

What is of some interest is that the personality subtypes were able to distinguish all three patient populations, even when adjusted for age, sex, race and education. This gives evidence for the validity of the grouping system.

There is evidence to support the DSM-III personality disorder types. In the asocial type, Kendler *et al* (1984) used a family history method and were able to show a relationship between a family history of schizophrenia and the schizophrenic spectrum (schizoid and schizotypal) personality disorders. This was replicated by Lowing *et al* (1983) using DSM-III criteria, while Kendler *et al* (1982), using similar methods were also able to demonstrate a relationship between paranoid personality disorder and schizophrenic spectrum disorder. Baron *et al* (1983) further demonstrated a possible genetic-familial link between schizotypal personality disorder and a family history of schizophrenia.

There is also evidence supporting the creation of a flamboyant type. Akiskal *et al* (1977) reported that some patients with a diagnosis of cyclothymic disorder are often diagnosed as personality disorders of the flamboyant type, while McNamara *et al* (1984) and Akiskal *et al* (1985) have documented similarities between REM latencies in the borderline group and in those with affective disorders. It appears that a subgroup of antisocial personalities are related to the affective disorders (Reich, 1985*a*), while the anxious personality disorders may well be related to Akiskal's (1983) concept of subaffective dysthymic group, in addition to having apparent validity and clinical overlap.

Work by Tyrer (Tyrer & Alexander, 1979; Tyrer *et al*, 1979, 1983), who approached the measurement of personality from a different perspective (measuring personality traits and then factor analysing for categories of personality disorders), yields categories which are not inconsistent with the DSM-III groupings. Their sociopathic type has similarities to the DSM-III flamboyant type, their schizoid type to the asocial type and their passive-dependence to the anxious type, while their final grouping of anakastic has similarities to the DSM-III compulsive personality disorder. These similarities also lend evidence to the validity of the DSM-III groupings of the personality disorder.

In summary, there is evidence that the frequency of occurrence of DSM-III personality disorders may differ among the groups meeting the criteria for various Axis I categories. There is also evidence supporting the validity of the DSM-III method of subtyping the personality disorders. The clinical implications of these findings are largely in the necessity of treating symptoms of personality disorders in many drug and alcohol abusers. Further research investigation into DSM-III personality clusters appears warranted.

Improving the Quality of Care on Psychiatric Hospital Rehabilitation Wards
A Controlled Evaluation

A. LAVENDER

This study attempted to use feedback from the Model Standards Questionnaires (a series designed to measure the quality of care) to improve care on a psychiatric hospital's rehabilitation wards. Both a controlled and quasi-experimental design were used. The controlled design provided evidence that feedback from the Questionnaire concerned with the Individual Programmes of Treatment and Care led to improvements in these practices but not for the remaining three questionnaires. The quasi-experimental design indicated that the significant generalised improvement in care, over all questionnaires, was most likely due to the feedback.

In the field of psychiatric rehabilitation much has been written about the need to develop methods of ensuring a high quality of care for clients in need of long-term care (DHSS, 1979; Shepherd, 1984). However, as Lavender (1985) points out there is no published scale which evaluates the broad range of conditions and practices that are important in the rehabilitation process (Watts & Bennett, 1983).

A number of studies have measured some of these conditions and practices. Morris (1969) developed measures of the physical environment and community contact, King *et al* (1972) of the physical environment and management practices and Wing & Brown (1970) of a number of aspects of the social environment (i.e. level of restrictiveness, number of personal possessions and amount of time doing nothing). More recently, Wykes *et al* (1982) devised measures of the management practices (Hostel Hospital Practices Profile) and level of community involvement and Garety & Morris (1984) [developing Richardson's (1977) work] of hostel management practices. The difficulty with these scales is that they only assess selected areas of practice and/or were devised for use in non-psychiatric settings, such as institutions for the mentally handicapped.

Given these difficulties, it proved necessary to devise a more comprehensive scale. Lavender (1985) describes the development of such a measure, the Model Standards Questionnaires. These questionnaires measured five aspects of the environment – (1) Staff Resources, (2) Physical Resources, (3) Management Practices, (4) Contact with the Community Practices, and (5) Treatment Practices. The present study was an attempt to use the information gathered from these questionnaires to improve the quality of care on the rehabilitation wards of a psychiatric hospital.

It is evident there are different ways of providing feedback about the performance of ward staff. Herold & Greller (1977) distinguish between five forms of feedback – (1) Negative, (2) Positive, (3) Negative from Hierarchy, (4) Positive from hierarchy, (5) From self. Andrask *et al* (1981) reviewed the behavioural methods that have been used to improve work performance and suggest that although instructions appear to be an ineffective method of feedback, if the instructions are clear and specific their effectiveness is increased (Iwata *et al*, 1977; Burg *et al*, 1979).

Further, a number of studies have shown social praise to be an effective method of improving staff level of interaction with patients (Montegar *et al*, 1977). Additionally, the work of Prue *et al* (1980) suggests that the effectiveness of feedback, whether from an individual or a ward can be enhanced if it is made public. Thus for this study a number of methods of providing feedback were used including social praise for high quality practices, specific instructions about how to improve low quality practice and finally a combination of private (to the ward team) and public (to the ward's senior nurses and rehabilitation committee) feedback.

Much of the literature concerned with interventions within institutions has involved descriptions about how and why such interventions succeed or fail (Georgiades & Phillimore, 1975; Towell & Dartington, 1976). This work, although somewhat anecdotal, is useful in providing practical advice to the researcher/change agent. Georgiades

& Phillimore (1975) record some of the ways institutions resist change and note how hospitals "like dragons eat hero innovators for breakfast". Similarly, Towell & Dartington (1976) point out that the publication and availability of guidance provided by Government Reports and research literature "should be a valuable stimulus for change but past experience suggests that such documents by themselves are likely to have only a diffuse and limited impact in many settings where improvement might be desirable". Given the inherent difficulties it was apparent that the manner in which the intervention was undertaken required careful consideration.

Thus from this anecdotal body of knowledge, a number of practical pieces of advice were drawn. Firstly, in order to maximise the impact of the intervention it was necessary to gain influence on the basis of 'expertise and ability' rather than formal power. Secondly, in order for the change agents to manage the institution's resistance and maintain high morale, it was important to establish a cohesive 'change agent team'. Thirdly, to maximise the impact of the intervention it was necessary to utilise the limited channels of authority to which the Rehabilitation Team (change agents) had access, an approach described as 'top down' by Towell & Dartington (1976). Finally, in order to harness the commitment of ward staff (essential if ward practices were to be changed), it was important to involve them actively in each stage of the project - an approach described by Towell & Dartington (1976) as 'bottom up'.

This paper describes an evaluation of an intervention designed to improve the quality of care in a group of 12 psychiatric hospital rehabilitation wards. This intervention was based on the Model Standards Questionnaires (Lavender, 1985) and consisted of specific recommendations (feedback) to the ward team about how the quality of care provided could be improved. The intervention was carried out by members of the hospital's Rehabilitation Committee following a request from management to investigate the quality of care provided on the hospital's rehabilitation wards.

The evaluation used two methodologies - the first, a controlled design to investigate whether the wards changed on questionnaires about which they received feedback but not on the other questionnaires. Thus in this part of the evaluation half the wards received feedback and half the wards did not receive feedback about each questionnaire. The second was a quasi experimental design (Cook & Campbell, 1979) to investigate whether the feedback lead to a more generalised change in ward practice. This was achieved by (a) comparing pre- and post-feedback scores on all wards, and (b) investigating whether other important ward variables (e.g. staff/patient ratios) changed in a way likely to account for any generalised changes in practice. If not it is a reasonable supposition that changes in practices can be attributed to the provision of feedback.

Method

Setting

The settings for both studies were 12 rehabilitation (medium- to long-stay) wards in a large psychiatric hospital (900 beds). For each ward the number of patients ranged between 21 and 30, the percentage of patients with a length of stay of 1 year or more ranged between 10 and 100 and the average nurse/patient ratio ranged from 1:5.6 to 1:10.8.

Measures and procedures

For the purposes of this study three of the five Model Standards Questionnaires were used. The data concerned with the reliability and validity of these questionnaires have been reported elsewhere (Lavender, 1985) but indicated that the measures were both reliable and valid. The three questionnaires used in this study are described in more detail below.

Individual programmes of treatment and care

This questionnaire consisted of 10 items assessing the extent to which patients on the ward/unit were engaged in particular therapeutic/training activities and the frequency with which these programmes were reviewed. The therapeutic/training activities included those designed to improve patients personal hygiene, domestic, social, occupational and leisure skills. Scoring involved a 1-10 rating based on the percentage of patients engaged in each area of training. An example of one of the items is given below.

3.(i) How many patients can do all the following: (a) cook two different main meals, (b) use a launderette, (c) use a Hoover or carpet sweeper, (d) buy at least three items from a shop and know how much change they should have.

Number ....

3.(ii) Could you please list the training activities that exist on and off the ward for teaching home management skills (cooking, cleaning, washing, laundry, shopping, budgeting) and the names of patients who have been actively engaged in such training in the last four weeks.

Ward management practices

This questionnaire included 25 items and assessed the extent to which management practices allowed patients to act autonomously, had their own personal possessions and minimised the social distance between patients and staff. Two items from the Questionnaire are given below to illustrate the format used.

6.(i) How many patients are allowed to operate the T.V. controls?

Number ......

24. How many patients have leisure possessions of their own? For example, books, records, musical instruments, radios, games etc.

Men *Women*

Number ...... Number ......

Scoring involved a 1.5 rating based on a unique set of criteria for each item but with clear markers at each point. For example, from item 9 (Visiting Hours) the average daily visiting hours is computed and scored using the following rating criterion: 1. 1-3 hours per day; 2. 4-6 hours; 3. 7-9 hours; 4. 10-12 hours; 5. 13 hours or more.

Community contact practices

This questionnaire included 13 items and assessed the extent to which patients had contacted with community-based facilities in the previous 4 weeks. No attempt was made to assess the extent of contact with family or friends from the community as this would have been less a measure of the quality of care provided and more a measure of a residents' community support. Scoring involved a 1-10 rating based on the percentage of patients engaged in each particular type of community contact.

Interviewer training procedure

The interviewer training procedure included the following steps: (1) reading through the questionnaires; (2) reading through the Scoring Manual; (3) reading through the Training Manual (the Training Manual was developed to clarify the items and provide advice to the interviewer for dealing with difficult or ambiguous responses), and (4) a discussion of each item with a trained interviewer before and after completing a training interview.

Interview procedure

The interview involved two interviewers attending the multidisciplinary meeting where the questionnaires were administered. The interviewers were two members of the Rehabilitation Committee which included a psychiatrist, psychologist, occupational therapist, nursing officer, sister and social worker. The interviewers included members of the ward's multiprofessional team which minimally included a consultant psychiatrist, social worker, two charge nurses/sisters, a staff nurse, student nurse and psychologist (if attached to the ward team). The interview was conducted by only one of the interviewers whilst the other remained silent and merely completed the questionnaire. The main interviewer took care to explain the purpose of the Questionnaires and the reason for the second silent interviewer (i.e. "to check that both interviewers recorded the same and therefore reliable information"). When completing the Physical Environment Questionnaire the main interviewer carried out the assessment by direct observation and measurement with the assistance and/or accompaniment of a nurse. The reliability interviewer recorded observations independently. Following the administration of the questionnaires, the interviewers rated the questionnaires independently using the Scoring Manual. The data presented in this paper are from the main interviewer.

Design

The 12 wards included all the medium- to long-stay rehabilitation wards in the hospital, thus they were not a group of specially selected rehabilitation wards. The basic design of the study was that following the first administration of the questionnaires the individual wards were given feedback about their current performance. For the purposes of the design the Ward Management Practices Questionnaire was divided into two - Part I (11 items) and Part II (11 items). Feedback was not given about three items in this scale because it was considered beyond the power of the ward team to immediately introduce the appropriate change.

The feedback consisted of a series of specific recommendations about whether the ward should continue or change the specific practices referred to by the individual items in the questionnaire. The feedback was given in two forms, firstly, in an interview between selected members of the Rehabilitation Committee and the ward's multidisciplinary team where the recommendations were discussed in detail. Secondly, in the form of a typed Model Standards Feedback Report which will be described in detail later. Nine months after the receipt of this first Feedback Report the Questionnaires were administered for a second time. The questionnaires were scored and the pre- and post-intervention scores compared.

The evaluation used two methodologies:

(a) *A controlled design* in which control was achieved by arranging that half the wards received feedback and half the wards did not receive feedback about each questionnaire. Thus each ward received feedback about two questionnaires and had feedback withheld for two questionnaires. The decision about which wards received feedback about which questionnaires was made using a random number assignment procedure.

(b) *A quasi experimental design* to investigate whether the feedback led to a generalised change in ward practice. This was achieved by (i) comparing pre- and post-intervention scores and (ii) measuring other important ward variables to investigate whether they could account for any generalised changes in practice. The other ward variables included nurse/patient ratio, involvement of other professional staff, number of patients on each ward, percentage of patients over 60 and the physical environment.

Results

Following a detailed analysis of the properties of the data (normality of distribution, equality of variance and level of measurement) it was considered appropriate to use parametric statistics. The results from the controlled and quasi-experimental design are presented separately.

Controlled design

Two methods of analysis were used, firstly, analysis of variance of gain scores and secondly, t-tests. The analysis of variance of gain scores assessed the significance of the difference or change in performance from pre- to post-intervention. These results proved insignificant for all questionnaires indicating that there was not a significantly greater improvement in the experimental (i.e. wards receiving feedback) than the control group. This method of analysis clearly provides the most conservative statistical estimate of the intervention effect.

The second form of statistical analysis was used to test whether there was a significant change when pre- and post-intervention scores were compared in the experimental and control group separately. This analysis (Table I) revealed that in the experimental group there was a significant increase in scores on the Individual Programmes of Treatment and Care Questionnaire ($t = 3.76$, $P < 0.01$) but not on the remaining questionnaires.

TABLE I

Experimental group analysis of pre- vs post-intervention data

Questionnaire	*t-Value*	*Probability*	*Significance*
1	3.706	<0.01	Significant
2	1.691	>0.05	Not significant
3	1.871	>0.05	Not significant
4	1.476	>0.05	Not significant

Quasi experimental design

In order to test whether there had been a generalised change in practice following the feedback intervention the pre- and post-intervention scores for the whole group were compared. These analyses confirmed that for all questionnaires there was a significant increase between pre- and post-intervention (Table II).

TABLE II

Experimental and control groups combined data comparison of pre- and post-intervention scores

Questionnaire	*t-Value*	*Probability*	*Significance*
1	2.296	<0.05	Significant
2	2.094	<0.05	Significant
3	2.551	<0.05	Significant
4	2.070	<0.05	Significant

The second part of the design involved an attempt to estimate whether this generalised change was due to changes in other important ward variables. Data were collected and analysed about five variables:

(i) *Nurse/patient ratios* were calculated from the data collected on the Policies, Planning, Monitoring of Progress and Staffing Levels Questionnaire (PPMSQ). In all cases although data were gathered only for the week prior to the interview, the nursing figures given were said to be the same as usual. These data were used to test whether there was a change in the nurse/patient ratio. The results of the analysis are presented in Table III and indicate that no significant change occurred and therefore it appears unlikely that this variable caused the generalised change in the questionnaire scores.

TABLE III

Statistical evaluation of changes in ward demographic variables between pre- and post-interventions

Variable	*Related t-Value*	*d.f.*	*Significance*
Nurse/patient ratio	0.8693	11	NS
Other professional staff	0.4528	11	NS
Patient numbers	0.3652	11	NS
Percentage patients over 60	0.3405	11	NS

(ii) *Other professional staff involvement.* Data concerning the time spent by other professional staff (doctors, psychologists, social workers, occupational therapists, etc.) on the ward or directly involved in work connected with the ward were collected on the Policies, Planning, Management and Staffing Levels Questionnaire (see Lavender, 1985). These data were used to test whether there was any change in the level of involvement of other professional staff between pre- and post-intervention. However, once again the statistical analysis presented in Table III revealed no significant change in the amount of professional staff involvement between pre- and post-intervention. This mitigates against this variable being an important cause of the observed changes in practice.

(iii) *Number of patients* on each ward was recorded on the Ward Information Sheet. Comparison of the number of patients on each ward between pre- and post-intervention was undertaken and as can be seen from Table III no significant changes were recorded.

(iv) *Percentage of patients over 60* was calculated from the data collected on the Ward Information Sheet. Again as Table III indicates there was no significant change in the percentage of patients over 60 between pre- and post-intervention.

(v) *The physical environment.* The fifth Model Standards Questionnaire measured the quality of the physical environment. Comparative analysis of this data revealed no significant difference between pre- and post-intervention. Inspection of the data

TABLE IV

Physical environment questionnaire pre- and post-intervention scores

presented in Table IV will reveal that there were very few changes of any kind in the wards' physical environments.

Discussion

Given the limited number of wards available for study, the controlled design provided the most stringent test of whether feedback affected ward practice. The results provided some statistical evidence that feedback about treatment and care practices (Individual Programmes of Treatment and Care Questionnaire) led to improvements in those practices. However, although there was a similar tendency to improve in wards receiving feedback about ward management and community contact practices this was not significant. The hypothesis that feedback about these latter two categories of practice led to wards changing those specific practices was not supported.

The study's quasi-experimental design was used to investigate whether the feedback had led to a generalised improvement in practices. The first part of this analysis revealed that there had been a significant improvement in practices on all four Questionnaires (Table II). The second part of the analysis attempted to establish whether this improvement had coincided with changes in other important ward variables which equally could have led to change in practice. A number of ward variables including nurse patient ratios, level of other professional staff involvement, number of patients on the wards, percentage of patients over 60 and the physical environment, all proved not to have changed significantly between pre- and post-feedback assessments (Table III). Clearly these variables could not account for the observed improvements in practice.

There is, however, a possibility that the changes were due to maturation (Cook & Campbell, 1979). Maturation refers to the fact that the practices could have been developing/maturing for some time and the results merely reflected these ongoing developments. Whilst this explanation is possible it is clearly unlikely for two main reasons. Firstly, large psychiatric institutions are not noted for their changes in practice and indeed many organisational writers have described with considerable emotion the difficulties and resistance to change in such establishments (Fairweather *et al*, 1974; Georgiades & Phillimore, 1975; Mealiea, 1978; Broome, 1979). Secondly, as with the last point, large psychiatric institutions are not noted for their speed of change and the recorded changes occurred within a relatively short period. Given these two points it is considered unlikely that a straightforward maturation explanation is sufficient to account for the changes.

Clearly a number of variables that might have caused the changes in practice were not recorded. It is indeed possible that the reasons for change varied between wards, so that in some cases it was due to increases in nurse/patient ratios and in others an increase in the percentage of patients over 60. Included in the unrecorded variables would be changes in the quality of staff (although there were very few new staff acquired by the wards during the 9 months of the study) and changes brought in by old staff, unrelated to feedback (for example, if staff introduce a change in practice as a result of a nurse teaching lecture).

Obviously, the simple pre- and post-intervention design makes it impossible to come to firm conclusions because of the important unrecorded and unconsidered variables. However, from the attempts made to record important variables and to estimate their significance it would seem unlikely that they would have led to such generalised changes in practice as were recorded between pre- and post-assessments.

One major issue raised by the study concerns the general applicability of the Model Standards Questionnaires and feedback as a means of improving the quality of care. Within psychiatric hospitals there has been a tendency when attempting to develop rehabilitation services to set up a special unit or develop a particular part of the rehabilitation service (Fairweather *et al* 1974; Paul & Lentz, 1977; Cope & Cox, 1980). This has resulted in the setting up of particular units such as the 'token economy' (Hall *et al*, 1977), the Lodge group (Fairweather *et al*, 1974), and even "the therapeutic community", (Jones, 1952). The problem with setting up such units in terms of the rest of the hospital (i.e. the whole system) is that many wards become neglected and receive little input. A secondary effect is that staff in the remaining wards become resentful about the 'new units' that receive all the 'good things' and the resentments result in the isolation of these 'new units'. Such special rehabilitation units seldom seem to lead to a generalised improvement in the hospital's rehabilitation service as a whole.

The type of intervention described in this study attempted to avoid these difficulties by designing an intervention likely to improve the practices on the 'back wards' in addition to the units already functioning well. When looking at the hospital's ward-based rehabilitation service as a whole the failure to attempt to change the wards receiving little input (back wards) simply represents an avoidance of the most difficult areas rather than attempting to overcome the difficulties. It should be pointed out that this runs counter to the suggestions of Georgiades

& Phillimore (1975) that the line of least resistance should be followed when attempting organisational change. They argue that only the parts of the system that are keen and ready for change should be worked with. In a hospital this suggestion can lead to unfortunate misunderstandings such that certain wards become designated 'bad' without attempting to investigate why this is so and without identifying and encouraging the development of the healthy parts of that ward system. For example, within the present study a particular ward was noted hospital-wide for providing a custodial form of care and yet in response to the recommendations to improve its level of community contact, it made quite marked changes in this area.

It is not being argued here either that the development of special units within large hospitals is better than attempting to improve a whole section of the hospital service or vice versa. The point is that these different types of intervention will have differential effects. The present work is one of the few systematic research projects to have attempted to evaluate an intervention designed to have a generalised effect on a hospital's service.

Acknowledgements

The author is grateful to the members of the rehabilitation committee and hospital staff who took part in the study and to Dr Fraser Watts and Dr David Sperlinger for comments on earlier versions of this paper.

Depression, Dementia and Disability in the Elderly

R. A. GRIFFITHS, W. R. GOOD, N. P. WATSON, H. F. O'DONNELL, P. J. FELL and J. M. SHAKESPEARE

A structured sample of mobile elderly patients in a rural community practice was assessed on validated rating scales for depression, dementia and disability. A total of 62% of the sample was abnormal on at least one variable. The overall prevalence of depression was 13%; the overall prevalence of dementia was either 10 or 18% depending on the criterion of Mental Test Score (MTS). Depression and dementia were related, depression being more common in females. In depressed and demented patients, MTS was age-related in those over 60 years; in depression alone, MTS was not age-related. Dementia was age-related, particularly over the age of 75. Disability increased with age and was more common in females. Disability was associated with both depression and dementia.

Depression and dementia affect approximately 10–15% and 5–10% of the elderly population respectively, and both increase with age. Differences in diagnostic criteria for dementia and depression produce the greatest variation in reported prevalence rates (Mortimer *et al*, 1981; Blazer, 1982). Depression is more common in elderly females (Freedman *et al*, 1982); dementia is more common in elderly females than in elderly males, particularly in those aged 75 and over (Gurland *et al*, 1980; Kay & Bergmann, 1980). Chronic physical illness, and impaired vision and hearing loss, have been implicated in the aetiology of affective disorders in elderly patients (Roth & Kay, 1956; Herbst & Humphrey, 1980). Patients with senile psychosis (senile dementia) have less physical illness than have patients with affective disorders, but patients with arteriosclerotic psychosis (arteriosclerotic dementia) have more (Kay & Roth, 1955). Disability and dependence increase with age, major factors being dementia and functional psychiatric disorders, particularly depression (Akhtar *et al*, 1973).

There is considerable difficulty in obtaining a random sample of elderly patients in the community, non-response to letters being a particular problem. Up to one-third of initial contacts may not respond or may be excluded (Williamson *et al*, 1964; Milne *et al*, 1971; Herbst & Humphrey, 1980; Gurland *et al*, 1983).

Rating scales for depression and dementia have limitations in diagnosis; abbreviated scales may have more validity for measuring severity and extended scales for measuring response to treatment (Hodkinson, 1972; Bech *et al*, 1975).

We assessed depression, dementia and disability by validated rating scales to determine their association and to identify patients at risk in the community.

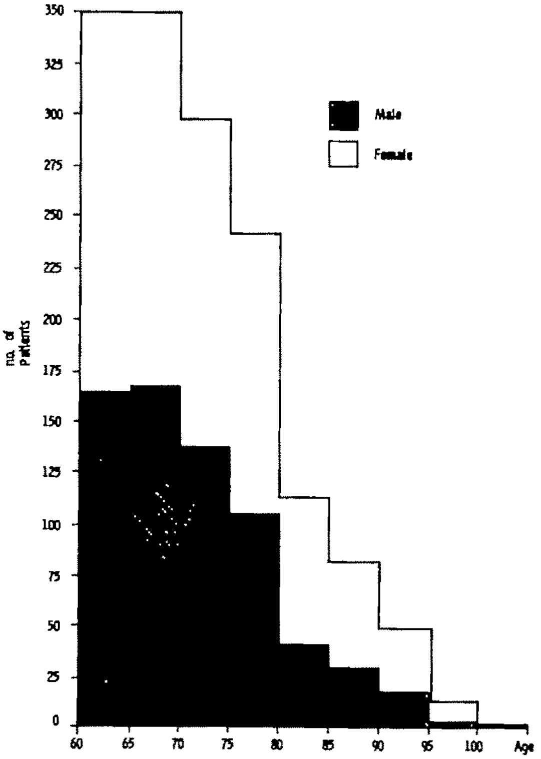

FIG. 1 Age distribution in quinquennia of 1498 patients aged 60 years and over enrolled at Deddington Health Centre on 1 October 1980.

Subjects

The study was undertaken in 1979, in a rural group practice in Oxfordshire, which had 1500 patients aged 60 years and over. The age distribution of these patients, in quinquennia, is shown (Fig. 1). The practice population was fairly stable, with a turnover of 8% per annum. The study was made on 200 patients to provide 20 men and 20 women in each 5-year group from 60 to 79 years and a similar group aged 80 and over. All patients aged 60 and over attending the health centre for any reason were referred by the principals or research nurse; elderly relatives and friends accompanying these patients were also asked to participate. To complete the quinquennia, patients were identified randomly from the practice list and contacted by letter or telephone. The patients included were those who were willing and able to attend the health centre; apart from minor current medical problems, they were not ill. These patients were a 'good' group, in that they were able to travel by car or practice bus or walk from the village. All surviving patients were called for review in 1980, by telephone or letter.

Assessment

Subjects willing to participate received an appointment for assessment at the health centre. All subjects were assessed at single interview by one observer on three standard rating instruments, for depression, dementia and disability. No subject failed to attend, and all were rated on all three instruments.

Depression score

Hamilton (1960) designed a Depression Rating Scale (HDRS) for the assessment of patients clinically diagnosed as depressed, and considered its greatest value to be in assessing the response to treatment. But scoring helps to differentiate endogenous and neurotic depression (Carney *et al*, 1965). Rating scales for depression are widely used (Hamilton, 1960, 1976; Beck *et al*, 1961; Zung, 1965; Beck, 1967; Weissman *et al*, 1977; Blazer, 1980, 1982). The prevalence of reported depression differs from study to study, which may be attributable to the different criteria of various rating scales (Blazer, 1982).

Comparisons of scales indicate that the long-established HDRS is most appropriate in community studies in the elderly (Kearns *et al*, 1982). Interview length may be a determinant of maintained interest (Hamilton, 1976). Some scales are too long (Wing *et al*, 1974; Copeland *et al*, 1976; Åsberg *et al*, 1978). The HDRS is a more precise discriminator of diagnostic groups than self-rating scales (Miller, 1980) and, as might be expected, fulfils the scale criteria of validity, reliability and sensitivity (Hamilton, 1976). Therefore we considered the HDRS most appropriate for use in the elderly.

The HDRS presupposes that all scores are the consequence of depression. We adapted the Hamilton Scale to form a semi-structured, interviewer-assisted questionnaire (Fig. 2), considering that the more formalised, structured approach would provide a more uniform data set. Taking into account the multiple disabilities of the elderly, it was considered that a score of 0–13 would include all normals but would not exclude all depressed patients.

Mental Test Score

The Information–Memory–Concentration Test of Blessed *et al* (1968) as modified by Hodkinson (1973) – the Mental Test Score (MTS) – has been used to evaluate medical factors in dementia and confusional states in the elderly. The maximum score on this test is 34; Lloyd (1970) and Hodkinson (1972) assumed a normal range of 25–34. It has been shown that the maximal improvement of scores on serial testing of 'normals' was 4.75, and that only 10% of all patients had a variation of 5 or more on serial testing (Stonier, 1973). Normality for this test can therefore be taken as 29–34, which would include all normals but would not exclude all demented patients.

To rationalise the direction of impairment in the three instruments used, the values for dementia are expressed as decrement of MTS (dMTS) – the score deficit below maximum (34). Our normal range is 0–5.

Usual activities (disability rating)

Garrad & Bennett (1971) discussed the measurement of disability by clinical assessment, by standard test of performance, and by questioning the patient on his current level of performance. They considered the third method to be most suitable for large-scale surveys conducted in patients' homes. They developed a 'Usual Activities' rating scale (UA), and a modification was used.

Statistical and computing techniques

The distributions of HDRS, dMTS and UA were highly skewed, and it would have been inappropriate to have used statistical techniques dependent on normal distribution. The skewness and kurtosis of the distributions of HDRS, dMTS and UA were calculated, using untransformed, square-root and logarithmically transformed data. Normality was assessed with the Y_S^2 test of Bowman & Shenton (1975). Both the untransformed and the logarithmically transformed distribution of data were not acceptably normal, but the distributions of the square-root transformed data were acceptably normal at 90, 95 and 99% levels. Therefore subsequent statistical analyses were performed using the square-root transformed data.

The associations of HDRS with dMTS, UA and dMTS and UA with HDRS were examined by linear and polynomial regression analyses. The residual sums of squares (RSS) and associated *F*-statistic of the linear and polynomial regression lines were calculated for comparison of goodness of fit. The regression lines, calculated from the transformed data, were plotted on axes labelled with untransformed values.

The relationships between HDRS and dMTS, UA and dMTS, and UA and HDRS were assessed using one-way analysis of variance (ANOVA) between each variable and sex, with age and the two remaining variables as covariates; the technique was constrained to include factors and then covariates serially, and all but two-way interaction terms were ignored. The classical experimental approach was adopted; each factor or covariate effect was adjusted for all preceding effects entering the analysis.

The relations of HDRS, dMTS and UA with age and sex were tested, using multiple linear regression analysis. These tests were repeated for the upper quartile of each data set – the 'best' 25%. The relation of dMTS with age in the subgroups 'depressed' and 'depressed and demented' was

FIG. 2 continued

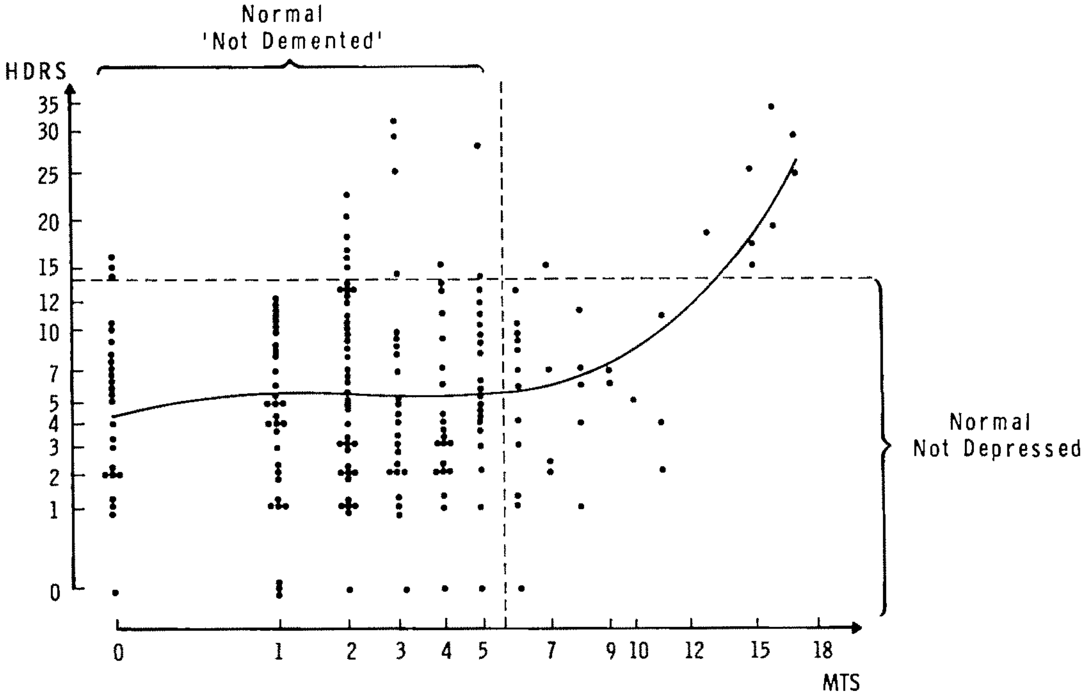

FIG. 3 Relationship between Hamilton Depression Rating Scale (HDRS) score and Mental Test Score (MTS) in 200 elderly people. Square-root transforms of the data are plotted; the axes are labelled with the untransformed values.

tested using linear regression analysis, and one-way ANOVA of dMTS by sex, with UA, HDRS and age as covariates.

In the analysis of variables with age, each of these variables is expressed graphically as the square of the mean of the square roots of the raw data - the square mean root (SMR). The analyses were performed on the individual square roots. Differences in each variable, associated with response patterns at annual review, were tested using χ^2, and two-way ANOVA by sex and response patterns, with the remaining variables and age as covariates. The technique was constrained to include covariates, then the factor 'sex', then the factor 'response', serially; all but two-way interactions were ignored, and the classical experimental approach was adopted.

These tests were performed on the University of Oxford's ICL 2988 computer, using the Statistical Package for the Social Sciences (SPSS [Nie *et al*, 1975]) and the SPSS Update 7-9 (Nie & Hull, 1981). Skewness and kurtosis were calculated using SPSS program 'Condescriptive'; simple linear regression was performed using 'Scattergram'; multiple linear regression and polynomial regression were performed using 'Regression'; paired t-tests were done by SPSS program 't-test'; and analysis of variance was undertaken using 'ANOVA'. The Y_S^2 *test and* χ^2 analysis of trend were performed manually.

Results

Psychometric tests (Fig. 3)

The scattergram of HDRS and dMTS showed that 13% of subjects were 'demented only', 8% were 'depressed only',

TABLE I
Prevalence of depression and dementia in 100 male and 100 female elderly people

	Depressed only	*Demented only*	*Depressed and demented*	*Normal*	*Total*	*All depressed*[1]	*All Demented*[2]
Male	1	16	2	81	100	3 (3%)	18 (18%)

Total	16	26	9	149	200	25 (12.5%)	35 (17.5%)

1. Sum of 'depressed only' and 'depressed and demented'.
2. Sum of 'demented only' and 'depressed and demented'.

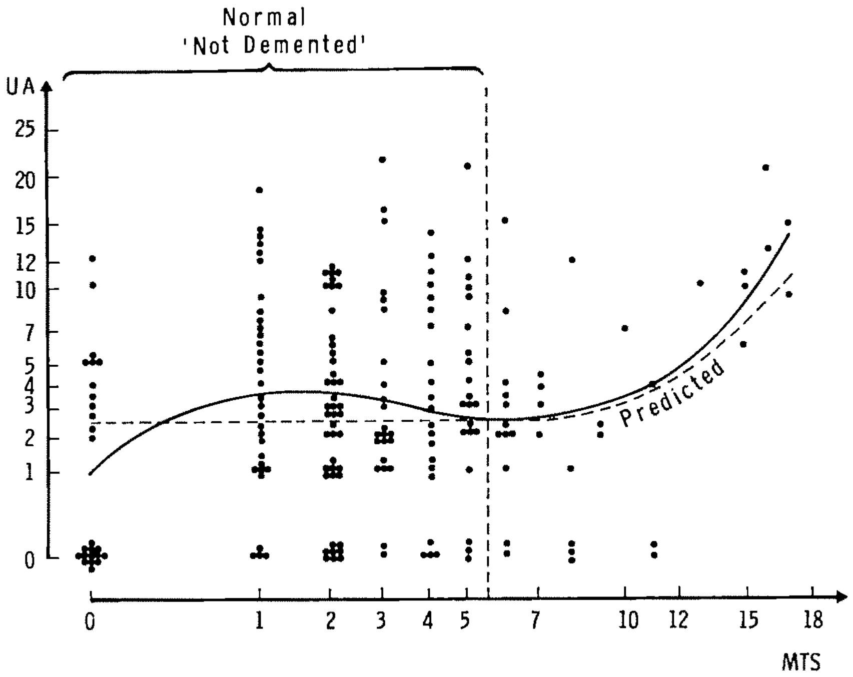

FIG. 4 Relationship between usual activities (UA) score and Mental Test Score (MTS) in 200 elderly people. Square-root transforms of the data are plotted; the axes are labelled with the untransformed values.

and 4.5% were 'demented and depressed'. The overall prevalence was 17.5% with dementia and 12.5% with depression; the prevalence of dementia in males and females was similar (M = 18%; F = 17%), but the prevalence of depression in males and females was disparate (M = 3%; F = 22%). The apparently lower prevalence of dementia alone in females was an artefact of the higher prevalence of depression with dementia (Table I). Small changes in criteria would produce disproportionately greater changes in prevalence. If the criterion of abnormality of the dMTS was altered from 6 (our criterion) to 9 (Hodkinson's criterion, *vide supra*), the overall prevalence of dementia fell from 17.5 to 10%.

A cubic polynomial provided a better model of the relationship between depression and dementia than did a quadratic ($F = 8.10$; d.f. = 3, 196; $P < 0.001$); introduction of a quartic term did not produce significant improvement. Raised HDRS was associated with raised dMTS (cubic regression, $R = 0.39$; F = 35.90; d.f. = 3, 196; $P < 0.001$). After extraction of the effects of sex, age and UA, HDRS was significantly related to dMTS (one-way ANOVA, $P < 0.002$).

Usual activities (disability rating)

Scores ranged between 0 and 24; 50% of subjects had significant disability in more than two items of the schedule. Forty-one (20.5%) of subjects had no disability. The median was 2.5, which reflected the competence of our sample; it would be expected that, in certain groups such as the housebound, the distribution would shift towards greater disability.

Relationship of dMTS to usual activities score (Fig. 4)

A cubic polynomial provided a significantly better model of the relationship between dementia and disability than did a quadratic ($F = 14.33$; d.f. = 3, 196; $P < 0.001$). Introduction of a quartic term did not provide significant improvement. Disability appeared to be related significantly to dementia (cubic regression, $R = 0.33$; $F = 24.94$; d.f. = 3, 196; $P < 0.001$).

However, after extracting the effects of sex, age and HDRS, there was no association between UA and dMTS (one-way ANOVA).

The regression equation produced by solving the separate equations for HDRS on dMTS, and UA on HDRS (*vide infra*) produced a predicted description of the relationship of UA to dMTS, which is also shown in Fig. 4. This predicted relationship was constructed by substituting the equation:

$$\sqrt{\mathrm{HDRS}} = a + b\,\sqrt{\mathrm{dMTS}} + c\,\mathrm{dMTS} + d(\sqrt{\mathrm{dMTS}})^3$$

into the equation:

$$\sqrt{\mathrm{UA}} = e + f\,\sqrt{\mathrm{HDRS}} + g\mathrm{HDRS}$$

This was remarkably consistent with the observed data.

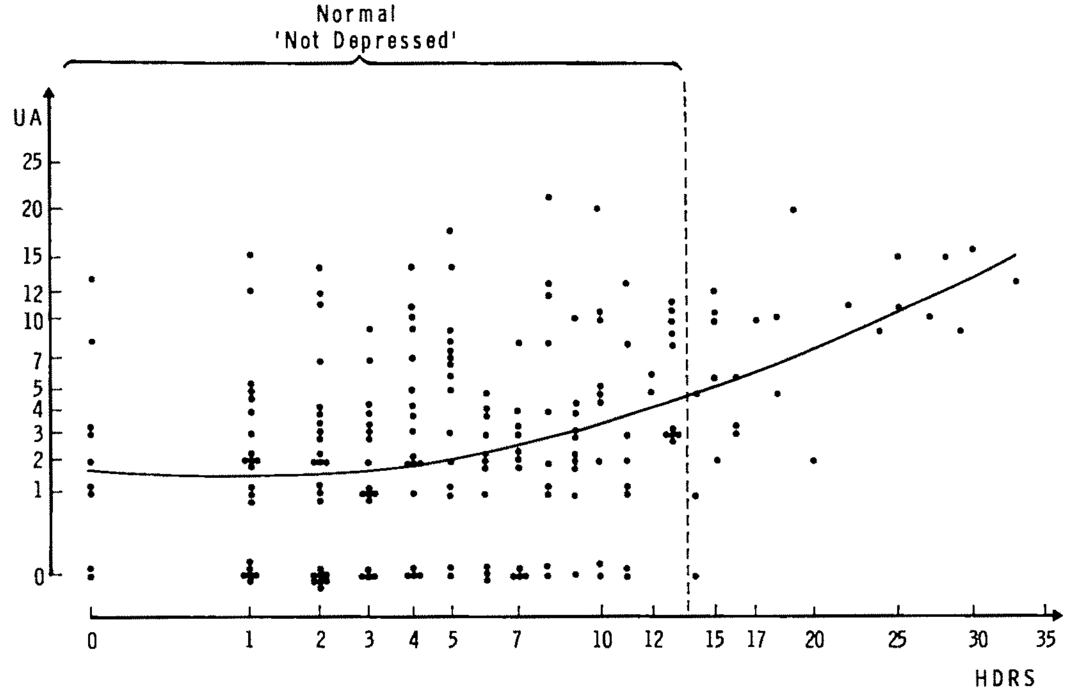

FIG. 5 Relationship between usual activities (UA) score and Hamilton Depression Rating Scale (HDRS) score in 200 elderly people. Square-root transforms of the data are plotted; the axes are labelled with the untransformed values.

Since UA and dMTS were not correlated (one-way ANOVA, *vide supra*), then a secondary relationship, of each with HDRS, was implied.

Relationship of usual activities score to HDRS (Fig. 5)

A quadratic polynomial provided a better model of the relationship between disability and depression than did a linear polynomial ($F=6.73$; d.f.$=3$, 197; $P<0.005$); introduction of a cubic term did not provide a significant improvement. Raised UA was associated with raised HDRS (quadratic regression, $R=0.41$; $F=40.28$; d.f.$=3$, 197; $P<0.001$).

After extracting the effects of sex, age and dMTS, UA was significantly associated with HDRS (one-way ANOVA, $P<0.001$).

Age and sex differences

In this structured sample, the age distribution of males and females was not different, either in the individual quinquennia or in the whole sample (paired *t*-test).

Hamilton depression rating scale (Figs 6 and 7)

Depression increased with age (two-way ANOVA, $P<0.01$): in females, depression increased from 60 to 69 years. At age 60–64 years, males and females did not differ but, at 65 years and over, females scored higher than males (paired *t*-test, $P<0.01$).

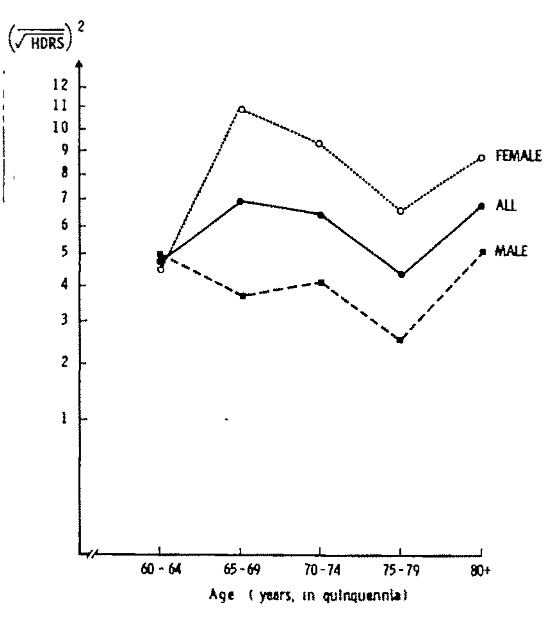

FIG. 6 Relationship between depression and age in 200 elderly people (100 male, 100 female). Square-root transforms of the data are plotted on the ordinate: the abscissa is linear.

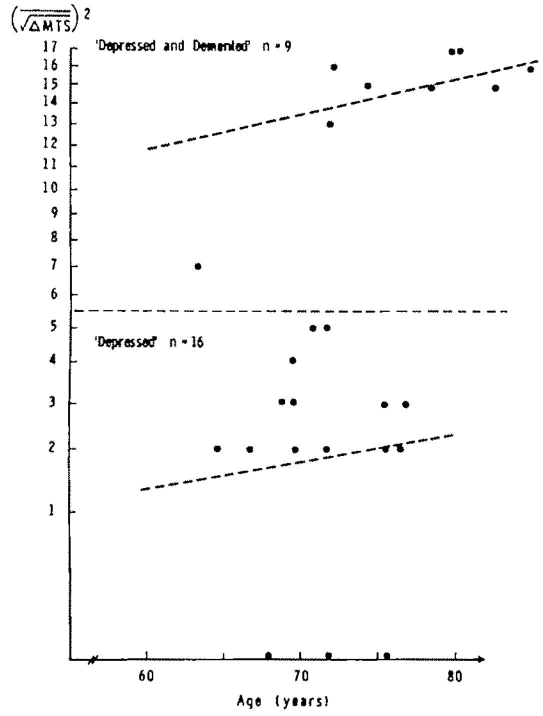

FIG. 7 Relationship between Mental Test Score (MTS) and age in depressed and demented elderly people. Square-root transforms of the data are plotted on the ordinate: the abscissa is linear.

Two groups of depressed patients are seen in Fig. 3. One group, the 'depressed only', had normal dMTS; the other, the 'depressed and demented', showed a relationship of HDRS to dMTS. The 'depressed and demented' group showed a trend of association between dMTS and increasing age (Fig. 7) (χ^2 analysis of trend, $P<0.01$).

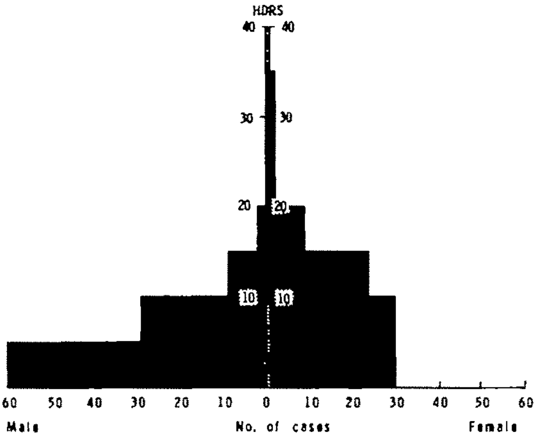

FIG. 8 Distribution of the Hamilton Depression Rating Scale (HDRS) score by sex in 200 elderly patients.

Insufficient cases of 'depressed' and 'depressed and demented' subjects were available to perform satisfactory ANOVA on these subjects separately from the whole group.

The distribution of HDRS score by sex is shown in Fig. 8 and SMR scores for both HDRS and dMTS in Table II. Females scored higher than males on every item of the HDRS. Females scored 14.5% of the maximum score and males 7.8%. In particular, 71% of those reporting sensations of depression were female. There was no significant difference between males and females in the MTS score total, nor in pattern of response (two-way ANOVA). On the HDRS, females scored more highly than males did ($P<0.001$); increased HDRS score was related to increased decrement of MTS ($P<0.02$; two-way ANOVA).

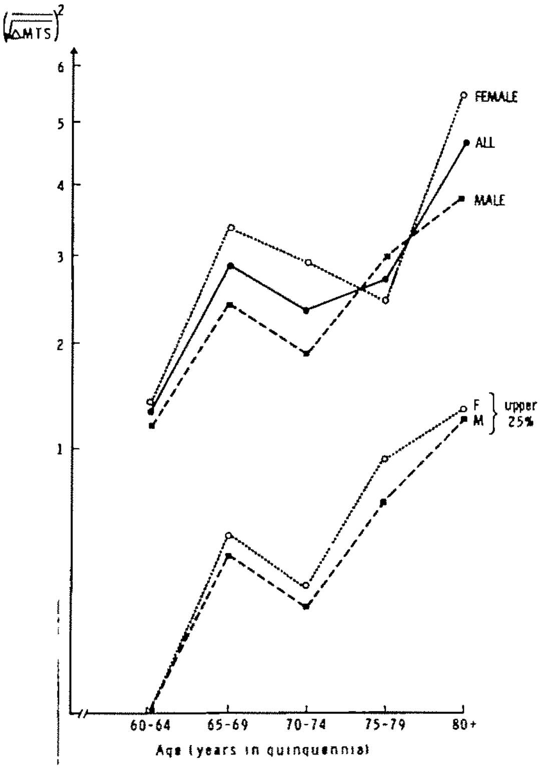

FIG. 9 Relationship between Mental Test Score (MTS) and age in 200 elderly people (100 male, 100 female). The square-root transform of the data is plotted on the ordinate: the abscissa is linear.

Mental test score (Fig. 9)

Dementia increased with age ($P<0.001$), but not significantly in those aged less than 75 years. Although females were more impaired, this was not significant (two-way ANOVA). The upper quartile of these patients showed a significant age-related increase in dMTS (linear regression, $P<0.01$).

TABLE II
Psychometric test scores in males and females

	Hamilton Depression Rating Scale score (HDRS)			*Decrement of Mental Test Score (dMTS)*		
	$(\overline{\sqrt{HDRS}})^2$	*Back-transformed 95% confidence limits*	*Range*	$(\overline{\sqrt{dMTS}})^2$	*Back-transformed 95% confidence limits*	*Range*
Male	3.98	3.24–4.80	0–20	2.36	1.84–2.94	0–15
Female	7.83	6.55–9.22	0–34	2.98	2.38–3.64	0–16

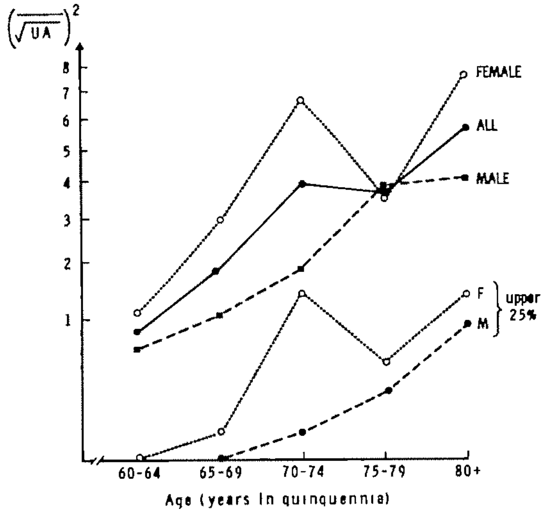

FIG. 10 Relationship between usual activities (UA) score and age in 200 elderly people (100 male, 100 female). Square-root transforms of the data are plotted on the ordinate: the abscissa is linear.

Usual activities (disability rating; Fig. 10)

Disability increased with age ($P<0.001$) and females were more impaired than males ($P<0.001$; two-way ANOVA). The upper quartile showed a significant trend with age (χ^2 analysis of trend, $P<0.02$); the difference between males and females was not significant (paired t-test).

Annual review

All patients were called for review in 1980. The scores discussed are those measured in 1979.

Response

Ten (5%) patients had died and two (1%) had moved from the practice. Non-repliers were those who did not reply to the follow-up request; refusers were those who replied but declined to participate.

Hamilton depression rating scale (Fig. 11)

Non-repliers had a higher HDRS than responders (χ^2, $P<0.01$), and patients who died also had a raised HDRS (χ^2, $P<0.01$). The refusers had a lower HDRS than the responders, but this was not significant. However, after extraction of the effects of age, sex, UA and dMTS, response type ('responded', 'did not reply', 'refused' or 'died') was not correlated with HDRS (two-way ANOVA).

Mental test score (Fig. 11)

Refusers did not differ from responders. Non-repliers and the patients who died had a greater dMTS in 1979 (χ^2, $P<0.01$; two-way ANOVA, $P<0.002$). After extraction of the effects of other factors and covariates, response type was significantly correlated with dMTS (two-way ANOVA, $P<0.002$).

Usual activities (disability rating; Fig. 11)

There was no significant difference between responders and non-repliers; refusers and those who died had shown a significantly higher degree of disability in 1979 (χ^2, $P<0.02$ and $P<0.005$ respectively). After extraction of the effects of other factors and covariates, response type was correlated significantly with UA (two-way ANOVA, $P<0.05$). The adjusted deviations for each response type show that refusal was not significantly correlated with increased UA, but death was.

Discussion

In the elderly, rating scale measures of depression, dementia and disability are inter-related and age-dependent. The criterion adopted for depression, HDRS > 13, showed a prevalence of depression of 12.5% in the sample, which is in agreement with previous community studies. The criterion we adopted for dementia, MTS < 29, showed a prevalence of dementia of 17.5% in the sample. If the criterion suggested by Lloyd (1970) and Hodkinson (1973), MTS < 26, was substituted, the prevalence of dementia was 10%. The latter figure was more in keeping with previous studies.

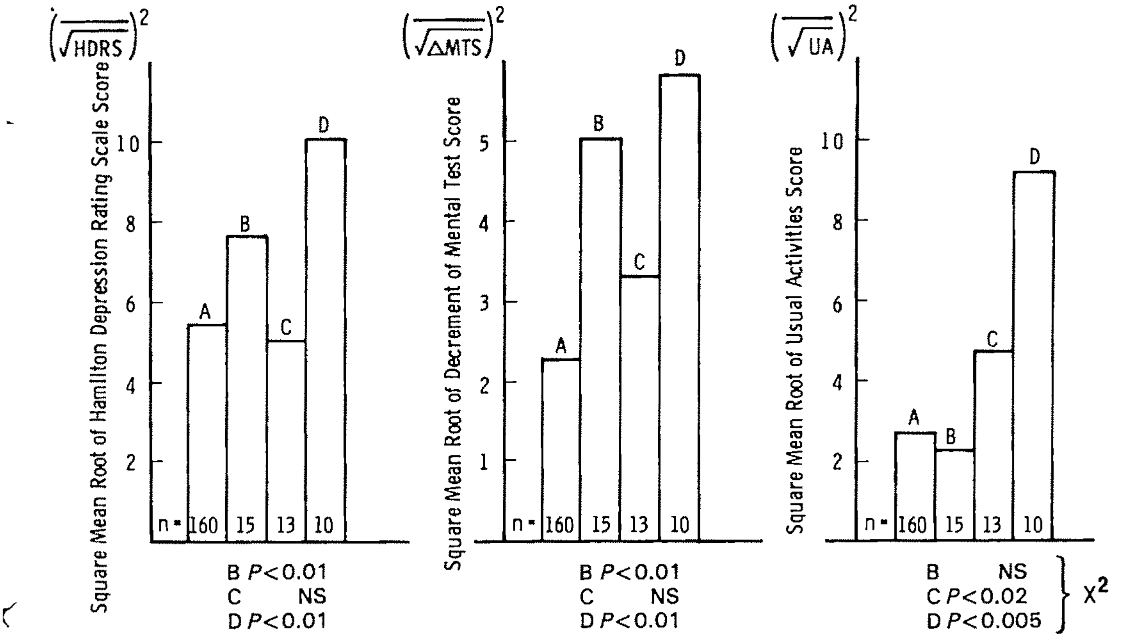

FIG. 11 Depression, dementia and disability at annual review. A, responders; B, did not reply; C, refused; D, died.

The prevalence of dementia did not differ between males and females throughout the age range, but the prevalence of depression did differ, with females scoring significantly higher on the HDRS than did males over the age of 65 years. In the 25% of 'best' patients, only 0.33% of all total scores showed values outside our normal range. Therefore, the 'best' 25% of patients may be regarded as unimpaired.

Figure 3 shows that increasing dementia is associated with increasing depression. There was insufficient inter-correlation between the items of the MTS and HDRS scales to explain this association, which suggests that these patients might have a particular type of depression associated with dementia. It also indicates that, taken in isolation, surveys of depression or dementia will produce overlap, which may account for some of the differences in community studies. A comparable study from New York (Gurland *et al*, 1980) showed a similar prevalence of depression and dementia and a similar age-related change to our study; a synthesis of the data from the New York and London studies confirms the necessity of combined assessment of depression and dementia (Gurland *et al*, 1983), as does a Washington study (Reifler *et al*, 1982). Considerably improved differential diagnosis between depression and dementia is obtained by multidimensional discriminant analysis (Gurland *et al*, 1982). However, it is assumed that depression and dementia are mutually exclusive diagnoses – a necessary concomitant of taking only one discriminant function. Analysis on the first two discriminant functions would permit classification as depressed, demented, or depressed and demented.

In this sample, the prevalence of depression was increased in females over the age of 65, being significantly higher than in males thereafter. There was no age-related trend in the least depressed quartile.

In this sample, females were not more demented than males; there was a significant overall increase in dementia over the age of 75 years. There was a slow increase in dMTS in the upper quartile of both males and females, which underlaid a change of greater magnitude in the more impaired. We consider this to be age-related benign senescent memory loss (Kral, 1978); the prevalence of maximum MTS (34/34) at age 80 was only 9% of that at age 60. Disability increased with age, and females were more impaired than males; the 'best' quartile showed a gradual increase in disability with age.

Depression and dementia are related. Depressed patients fall into two groups – those with normal dMTS in which dMTS is not age-related, and those with higher dMTS in which the dMTS is age-related. Depression and disability are also related; there was a correlation between increasing depression and increasing disability. By therapeutic modification of the HDRS, it might be possible to determine the degree of causality attributable to depression in this relationship.

While there is an association between disability and dementia, analysis of variance shows that this is secondary to the relationship of both these variables to depression. The predicted relationship between UA and dMTS, calculated from the regression equations of these with HDRS, corresponds closely to the directly calculated relationship.

Differences in disability do not influence response or refusal, but differences in MTS do; non-repliers and patients who died were more demented than were responders or refusers. Differences in HDRS do not influence response or refusal. As would have been expected, deaths occurred among the more disabled; physical disability is one determinant of poor outcome of depressive illness (Murphy, 1983).

Refusal is different from non-response; Akhtar (1972) found in a random sample that depression was more common among acceptors; dementia and anxiety were more common among refusers, but the differences were not statistically significant. It was concluded that refusers do not introduce significant bias into random sample estimates of mental health of the elderly patient.

Our figures of annual review show that non-response is probably allied to dementia and that refusal came from the least depressed. Disability played no part in either non-response or refusal.

Communicability and Thought Disorder in Schizophrenics and Other Diagnostic Groups

A Follow-up Study

A. BARNETT RAGIN and T. F. OLTMANNS

To evaluate qualitative differences in the nature of thought disorder, the 'cloze' procedure and the Scale for the Assessment of Thought, Language and Communication were used to compare speech samples from schizophrenic, depressive, manic, schizo-affective and normal subjects at two different times. At the acute phase, thought-disordered subjects (schizophrenics, manics and schizo-affectives) were less communicable than non-thought-disordered subjects (depressives and normals). Communicability increased with remission of the more flagrant features of disturbance. Comparison of the thought-disordered diagnostic groups in the rate and pattern of remission of specific features of thought disorder indicated that factors reflecting goal-disrupted cognition distinguished the groups.

The concept of formal thought disorder has figured prominently in psychiatric classification systems and in formulations of schizophrenia, including those of Bleuler and Kraepelin, but recent findings challenge the view that it is specific to schizophrenia. Comparable levels of thought disorder have been reported in manic and other psychotic patients (Andreasen, 1979*b*; Harrow & Quinlan 1977; Marengo & Harrow, 1984).

Efforts to assess diagnostic differences in the nature of thought disorder have suggested that traditional clinical descriptions of thought disorder vary in their diagnostic utility and specificity. Andreasen (1979*a*,*b*) found that certain phenomena traditionally regarded as indicators of thought disorder in schizophrenia, such as tangentiality, derailment, incoherence, illogicality and loss of goal, occurred with equal frequency in manic subjects. Of the 18 subtypes examined, only two – poverty of speech and poverty of content of speech – distinguished schizophrenics from depressives and manics. Other investigators have also found it difficult to identify diagnostic differences in the nature of thought disorder (Harrow *et al*, 1982; 1986; Harvey, 1983). As a consequence, investigators have argued that differences may emerge only through follow-up evaluation (Andreasen, 1979*b*; Harvey, 1983).

In a recent study, Harvey *et al* (1984) demonstrated that thought disorder is relatively stable in both manic and schizophrenic subjects during the first 10 days of hospital admission. Other studies have found indications of thought disorder in schizophrenic and in manic subjects 7 weeks following admission, during partial recovery (Harrow & Quinlan, 1977; Harrow *et al*, 1982; Grossman & Harrow, in press). However, it is not yet clear whether the course of thought disorder differs for schizophrenic and other thought-disordered groups over longer periods of time.

Reduced communicability, as measured by the 'cloze' procedure, has been found to distinguish thought-disordered from non-thought-disordered schizophrenics (Manschreck *et al*, 1979). In this procedure, raters attempt to supply words that have been deleted from a speech segment; the success of the raters in supplying the missing words provides an index of the predictability or communicability of the speech sample. This provides a method for quantifying the degree of listener confusion which is generated by a specific speech segment. In a previous study (Ragin & Oltmanns, 1983), we found that reduced communicability was associated with traditional clinical indicators of thought disorder, such as derailment, as assessed by the Scale for the Assessment of Thought, Language and Communication (TLC). The TLC is an instrument that can be used to evaluate 18 features of thought disorder in spontaneous speech samples (Andreasen, 1979*a*).

This paper extends our previous report with a follow-up examination of communicability and its relationship to specific features of thought-disordered speech in five diagnostic groups: schizophrenics, depressives, manics, schizo-affectives and non-psychiatric subjects. Further subjects were added to those represented in the previous report. All subjects were assessed at two instances: at admission and following hospital discharge. Post-hospital evaluation was necessary to determine whether thought disorder is only associated with acute disturbance in some psychotic groups, but is more persistent in schizophrenics, and to provide important evidence concerning the relative persistence of specific features of thought disorder among different diagnostic groups. Failure to demonstrate differences among groups might suggest that thought disorder is a general feature of psychosis. Alternatively, specification of diagnostic differences in the rate and pattern of remission of clinical features of thought disorder could further understanding of schizophrenia and other psychotic disorders.

Method

Speech samples

Subjects in the study included 12 schizophrenic, 12 depressive, 12 manic and 12 schizo-affective patients, interviewed shortly after admission to a psychiatric hospital. The composition of the current sample was as follows: eight schizophrenics, five depressives, ten manics and eight schizo-affectives participated in a previous study (Ragin & Oltmanns, 1983), while others were added in order to ensure adequate sample sizes. The non-psychiatric subjects were sampled specifically for the purposes of this study; therefore, none of these subjects were represented in the prior investigation. In addition, a non-psychiatric control sample of 12 subjects (municipal employees and clerical workers) was also interviewed at two instances. The non-psychiatric subjects were screened for prior personal or family psychiatric history before being included. At the beginning of each audiotaped interview, each subject was asked to describe how he or she had been feeling lately. The psychiatric patients were asked to provide an account of the events surrounding admission to the hospital, and the non-psychiatric ones to describe how they had come to their present employment. The interviewer tried to avoid interrupting the subject, and provided only minimal prompts necessary to facilitate discourse. For the psychiatric patients, the remainder of the interview followed the Schedule for Affective Disorders and Schizophrenia (SADS) (Spitzer & Endicott, 1978). Diagnoses were determined by two independent judges (a psychologist and a psychiatrist) using the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1978). Disagreements were resolved through further discussion. The groups did not differ significantly on any of the demographic features. Demographic information and information on length of hospital stay is presented in Table I.

TABLE I
Summary of subjects' demographic characteristics

	Schizophrenics	*Manic*	*Schizo-affectives*	*Depressives*	*Normals*
Sex: male/female	8/4	10/2	9/3	7/5	9/3
Age: years					
mean	28.4	30.1	26.3	30.2	37.0
s.d.	7.7	9.4	5.5	4.9	11.8
Education: years					
mean	12.6	13.1	13.0	11.7	13.0
s.d.	2.5	1.7	1.4	2.4	1.2
Number of past admissions					
mean	2.6	2.8	1.7	0.5	NA
s.d.	1.5	0.7	2.2	1.4	NA
Months between initial and follow-up testing					
mean	8.2	7.1	5.6	6.6	7.6
s.d.	2.9	2.2	2.8	3.8	0.9
Medication: % initial follow-up					
Neuroleptic	83/58	08/0	58/25	0/08	NA
Antidepressant	0/0	0/08	08/0	75/50	NA
Lithium Carbonate	0/08	33/50	25/08	0/0	NA
Neuroleptic & lithium	17/0	58/33	08/33	0/0	NA
Antidepressant & neuroleptic	0/0	0/0	0/0	08/08	NA
None	0/33	0/08	0/33	17/33	NA

TABLE II
Definitions of clinical thought-disorder categories (Harvey & Neale, 1983)

Category	*Definition*
Poverty of speech	Restriction in the amount of spontaneous speech
Poverty of content	Speech adequate in amount but low in information of speech
Pressure of speech	Increase in amount of spontaneous speech
Distractibility	Interruption of a train of discourse, with focus shifted to an external object
Tangentiality	Replying to a question in a manner not related to the question
Derailment	Ideas expressed in spontaneous speech are obliquely related to previous speech
Illogicality	Overtly expressed reasoning that breaks logical rules
Circumstantiality	Indirect and lengthy speech gets to a goal slowly if at all
Loss of goal	Speech that never reaches logical end points
Blocking	Interruption of a train of speech, with comment from patient that thought is blocked

Thought disorder was assessed at both the initial and follow-up time periods, using Andreasen's (1979*a*,*b*) Scale for the Assessment of Thought, Language and Communication. The ratings include 18 separate subcategory scores and a global measure of thought disorder. Subcategories include among others: derailment, tangentiality, distractibility and loss of goal. A summary of the rating system, including definitions of the most frequent subcategories, is presented in Table II. Ratings were based on the independent judgements of two research assistants, who listened to each audiotaped interview and assessed either the actual number of instances in the 200-word sample, or, where appropriate, provided an ordinal rating of 0–4 for each of the thought disorder categories. At the initial time period, all of the schizophrenic, manic and schizo-affective subjects and none of the depressive and non-psychiatric subjects in the study would be considered thought disordered, based on one common criterion employed in previous reports – a score of two or higher on the Andreasen global rating (Andreasen, 1979*a*,*b*; Harvey 1983). Reliabilities for the more frequently occurring ratings ranged from 0.46 to 0.96, with a weighted kappa value for the global rating of 0.91. These reliability ratings were based on a fairly large sample, including a subsample of the subjects represented in the present study, in addition to subjects not included in this group, for a total n of 51.

The 48 psychiatric subjects were all contacted following discharge from the hospital to arrange follow-up testing. There were other subjects who were tested initially, but were unwilling to participate in follow-up testing due to relocation or lack of interest; these included two schizophrenic, two depressive, one manic and three schizo-affective subjects. The interviews were conducted in the subject's home, between 3 and 13 months following the initial testing: at the beginning, each subject was asked to describe how he had been feeling and what he had been doing since the last interview. The remainder of the psychiatric interviews followed the SADS; the follow-up interviews were also rated for thought disorder, using Andreasen's system.

The first uninterrupted 200-word segment from each interview was transcribed; to ensure confidentiality, it was necessary to change proper names or personal information that appeared in the original speech segment (e.g. birthdate, place of birth, employer). These changes were made consistently throughout the cloze transcript, so that they did not alter the communicability of the passage. The transcripts were prepared for cloze analysis by omitting all punctuation and replacing every fourth word with a blank.

Cloze procedure

Four introductory psychology students served as judges; each was asked to cloze all 120 passages — two from each of the 60 subjects, passages being presented in random order. All raters received the same instructions: they were asked to fill in the missing words, were urged to complete every blank and were given as much time as they needed to rate all 120 samples (averaging about 20 h over the course of 1 month).

The proportion of correctly filled blanks was computed to produce a cloze score, which was determined without knowledge of diagnosis or time period. For the most part, the criterion for scoring was a perfect match with the word in the original segment, but some allowances were made in scoring. If the rater supplied a synonym, it was scored as a correct response, since the speaker's meaning was communicated. In some instances, the word to be supplied was a proper name or a number that the rater could not guess, because the exact name or number could not be inferred from the context. In these instances, the blank was considered correctly rated if any proper name was supplied, where a proper name had occurred in the original passage, or if any number was supplied where a number had occurred. However, this practice was only necessary when it was impossible for the rater to infer the correct proper name or number from the context. In the few cases where a rater failed to fill in a blank, the omission was treated as an incorrect response.

Results

The means and standard deviations for the communicability measures (the cloze scores) at each of the two time periods are presented in Table III. Initially, the cloze scores at each time period were examined independently. One-way analysis of variance at the initial time period indicated a significant main effect for diagnosis ($F(4, 55) = 3.5$, $P < 0.05$). Table III indicates that when interviewed at the

TABLE III
Means and standard deviations for the cloze measure of communicability[1]

	Mean	*s.d.*	*Mean*	*s.d.*
Schizophrenics	0.549	0.061	0.649	0.092
Manics	0.500	0.071	0.578	0.083
Schizo-affectives	0.553	0.121	0.657	0.093
Depressives	0.590	0.113	0.598	0.138
Normals	0.633	0.076	0.655	0.083

1. Based on proportion correct.

initial time period, the normal subjects had the highest communicability scores, followed by depressives, schizo-affectives, schizophrenics and then manics. Planned comparison of the means for the schizophrenics and normals resulted in a significant difference ($P<0.01$). At the initial time period, schizophrenics were less communicable than were non-psychiatric subjects, which is in accord with earlier studies demonstrating reduced communicability among schizophrenics (Salzinger *et al*, 1964, Ragin & Oltmanns, 1983). Because the remaining comparisons were *post hoc*, they were assessed using the Newman–Keuls procedure, which resulted in a significant difference between the extreme groups: normals and manics. Table III indicates that the depressive subjects had generally higher communicability scores than the thought-disordered subjects had; in this, they resembled the normal subjects. Planned comparison of the thought-disordered (schizophrenics, manics and schizo-affectives) *vs* the non-thought-disordered groups (depressives and normals) resulted in a significant main effect for the grouping factor ($F(1, 58)=10.10$, $P<0.01$). Schizophrenics, manics and schizo-affectives (mean = 0.534, s.d. = 0.089) were less communicable than were depressives and normals (mean = 0.611, s.d. = 0.096).

One-way analysis of variance at the follow-up time period indicated no main effect for diagnosis. The groups did not differ significantly with respect to communicability following remission of psychiatric symptoms.

To assess the stability of communicability between the acute phase of disturbance and following hospital discharge, cloze scores from each of the two time periods for the 60 subjects were submitted to a repeated measures analysis of variance, with diagnosis and time as factors; this indicated a significant main effect for time period ($F(1, 58)=18.36$, $P<0.001$). Communicability increased for all groups between the initial and follow-up testing. As might be expected, correlations of the initial cloze scores with change scores for the individual psychotic groups were significantly negative. Thus, the subjects who were the least communicable at the initial time period (i.e. those who had the most potential for change) did in fact change the most. The interaction of time and diagnosis failed to reach significance at the 0.05 level ($P=0.13$). The means in Table III suggest that, on the measure of communicability, the groups tended to converge with the passage of time and remission of psychiatric symptoms.

Table IV presents the results of the correlational analysis of cloze scores and the Andreasen ratings. Of the 18 Andreasen subcategory scores, eight occurred infrequently; correlations with cloze measures were not computed for these ratings. Examination of the remaining ratings for the initial time period indicated that four subcategory scores were significantly correlated with communicability: derailment ($r=-0.29$, $P<0.05$), loss of goal ($r=-0.35$, $P<0.001$), pressure of speech ($r=-0.30$, $P<0.05$), and poverty of speech ($r=0.37$, $P<0.001$).

TABLE IV
Correlations of cloze scores with Andreasen thought-disorder ratings

Time period:	*Initial*	*Follow-up*
Poverty of speech	0.37***	0.37**
Pressure of speech	−0.30*	0.15
Distractibility	−0.13	0.11
Tangentiality	−0.03	0.13
Derailment	−0.29*	−0.18
Circumstantiality	−0.18	−0.23*
Loss of goal	−0.35***	−0.18
Blocking	0.06	—[1]

Illogicality	0.04	−0.07

1. A correlation could not be computed for this measure.
*$P<0.05$; **$P<0.01$; ***$P<0.0001$.

To assess potential diagnostic differences in the nature of thought disorder, the groups were compared on the four indices of thought disorder which were linked significantly to communicability. This included a cross-sectional analysis at the initial time period, as well as a longitudinal examination across the time periods. One-way analyses of variance at the initial time period resulted in one significant main effect: at the initial testing, the manic subjects received significantly higher scores on pressure of speech than did the other subjects ($F(3, 42)=4.4$, $P<0.01$).

Next, the subcategory ratings were submitted to a repeated measures analysis of variance, in order to evaluate diagnostic differences in the course of particular indices of thought disorder over time. Thus, the effect of interest was the interaction of time with diagnosis: significant interactions were obtained for two of the four subcategories: derailment and loss of goal ($F(4, 55)=2.90$, $P<0.05$; $F(4, 55)=3.78$, $P<0.01$, respectively). Means and standard deviations for these measures at each of the two time periods are presented in Table V: the significant interactions for derailment and loss of goal were due to the convergence of the scores between the two time periods. Among the thought-disordered diagnostic groups, the schizo-affective and schizophrenic subjects demonstrated a relatively greater degree of change than did the manic subjects on these measures. At the initial testing, during the acute phase of disorder, the schizo-affective and schizophrenic subjects received high scores on derailment and loss of goal, but by the time of follow-up, the scores for these subjects were very similar to those of the non-thought-disordered

TABLE V
Means and standard deviations for derailment and loss of goal

diagnostic groups (depressives and normals). The manic subjects displayed moderate levels of these features at the initial testing, but in contrast to the other thought-disordered subjects, did not demonstrate significant declines in derailment or in loss of goal between initial testing and follow-up. Paired *t*-tests of these differences supported these impressions. Schizophrenic and schizo-affective subjects demonstrated significant declines on the measures of derailment and loss of goal ($P<0.05$), while the manic subjects did not.

Discussion

Are there diagnostic differences during the acute inhospital phase of the psychiatric episode?

The interview transcripts of recently admitted schizophrenics were less communicable than those of either depressives or non-psychiatric subjects. Normal raters experienced greater difficulty producing correct inferences concerning the speaker's intended message, on the basis of the provided context; this is consistent with previous reports of reduced communicability among schizophrenics (Salzinger *et al*, 1964; Ragin & Oltmanns, 1983).

Schizophrenics were not unique in this regard. The transcripts of manic and schizo-affective subjects also posed difficulties for normal raters. The results of the 'cloze' analysis were consistent with findings of thought disorder among non-schizophrenics, particularly manic and schizo-affective subjects, who were distinguished from the depressive and normal subjects, in whom thought disorder has generally been reported to be minimal (Harrow & Quinlan, 1977; Andreasen, 1979*a*). Based on definitions employed in previous reports (e.g. Harvey, 1983), all the schizophrenic, manic and schizo-affective subjects in the present study would have been considered thought-disordered at the initial time period. At that time, the thought-disordered subjects were less communicable than were the non-thought-disordered subjects (depressives and normals). However, there were no diagnostic differences among thought-disordered groups (schizophrenics, manics and schizo-effectives) on this measure.

The manic subjects did not achieve higher communicability scores than the schizophrenics did; this is inconsistent with clinical descriptions of manic speakers as easier to understand than schizophrenics (Redlich & Freedman, 1966; Janowsky *et al*, 1970; Lipkin *et al*, 1970). In fact, the means in Table III indicate that manic speakers were generally the least communicable at both time periods. This finding also fails to support the conclusions of several studies in which manic and schizophrenic speech was compared in the incidence of various structural linguistic features. On the basis of differences between schizophrenics and manics in the incidence of analytically derived linguistic measures (e.g. cohesive ties), investigators have argued that manic speech is more fluent (Morice & Ingram, 1982) and more cohesive (Wykes & Leff, 1982).

Are there diagnostic differences in the course of thought disorder?

When interviewed 5–8 months after the acute phase, following remission of the more flagrant features of disturbance, psychiatric subjects could not be distinguished from non-psychiatric subjects in communicability. The following pattern emerged: depressive and normal subjects remained relatively stable, while schizophrenic, manic and schizo-affective subjects demonstrated significant increases in communicability between the initial and follow-up testing.

Thought disorder, as measured by the cloze procedure, appears to be associated with the acute phase of the psychiatric episode; it does not appear to be a stable deficit among all schizophrenics or other thought-disordered populations. The Kraepelinian view of progressive deterioration among schizophrenics and the related view of better outcome among affective disorders has been challenged by a growing body of literature. It has been found that not all schizophrenics continue to display thought disorder when examined over extended post-hospital periods (Marengo & Harrow, 1984).

Longitudinal evaluation of communicability in the three thought-disordered diagnostic groups examined in this study did not reveal diagnostic differences in the course of thought disorder over time. The schizophrenic, manic and schizo-affective groups all demonstrated significant increases in communicability at follow-up testing. The hypothesis of a differential course for thought disorder among manic and schizophrenic subjects, suggested by Andreasen (1979*a*,*b*), which would be consistent with traditional views of schizophrenia and the affective disorders (Bleuler, 1911; Kraepelin, 1919), was not supported.

What specific clinical indices of thought disorder were associated with reduced communicability at the acute phase?

The association between communicability and specific clinical indices of thought disorder at the initial time period suggests an important role for pressure of speech, poverty of speech, derailment and loss of goal. Pressure of speech and poverty of speech reflect phenomena that are opposite in nature: the latter characterises speech that is inappropriately restricted and laconic, whereas the former is characterised by an inappropriate excess of verbal production. Pressured speech can be described as a rapid, incessant monologue which is difficult for the listener to interrupt. The association between these measures and the cloze scores were in opposite directions: high scores on poverty of speech were associated with increased communicability, while high scores on pressure of speech were associated with reduced communicability. Although both reflect inappropriate verbal behaviour, pressured speech appears to be more closely associated with confusion on the part of the listener. The association between poverty of speech and communicability is consistent with the view that reduced or slowed verbal production may be an attempt to compensate for disorganised thinking.

To assess potential differences in the nature of thought disorder, the schizophrenic, manic and schizo-affective subjects were compared on the features which were associated with communicability at the acute phase: pressure of speech, poverty of speech, derailment and loss of goal. Examination of the specific indices of thought disorder at the initial time period failed to uncover any features of thought disorder that were specific to the diagnosis of schizophrenia. Of the four features examined, only pressure of speech distinguished among the thought-disordered diagnostic groups at the initial time period: the manic subjects received the highest scores on this measure. Associative errors have been demonstrated to increase under time pressure among thought-disordered subjects (Hemsley & Hawks, 1974). Descriptions of mania have emphasised the increase in verbal production (Redlich & Freedman, 1966) and the push of speech (Kraepelin, 1919). The negative association between communicability and pressure of speech may indicate that the incomprehensibility of manic speech, or manic thought disorder, is tied to this feature and supports views of a manic rate disorder (Harrow *et al*, 1986).

Do differences between thought-disordered diagnostic groups emerge when the significant clinical indices are examined over time?

The three thought-disordered diagnostic groups demonstrated a similar course for the features that were linked to quantity of speech: poverty and pressure. However, the groups differed in the features that were associated with goal-disrupted discourse: derailment and loss of goal. When initially tested during the acute psychiatric episode, the schizophrenic and schizo-affective subjects received high ratings on these features, while the manic subjects received more moderate scores. Between the initial and follow-up testing, 5–8 months following the acute phase of disturbance, the manic subjects remained fairly stable on the measures. However, the incidence of derailment and loss of goal declined significantly for the schizophrenic and schizo-affective subjects, dropping below the scores of the manic subjects.

In contrast to many features such as neologisms and clanging, described by Andreasen, derailment and loss of goal reflect communication deviance at the level of discourse planning and organisation. Discourse planning has been described by Deese (1978) as a process by which the speaker maps out his intended message. This form of communicative difficulty is in contrast to linguistic anomalies that occur at more immediate levels of discourse, such as the level of the individual word (e.g. neologisms), or at the level of the individual proposition (e.g. word salad). In the current study, features based on word-to-word difficulties occurred only rarely, if at all. Findings that syntactic organisation is maintained in thought-disordered subjects also suggest that thought disorder is not adequately explained by deviance at the more immediate levels of discourse (Gerver, 1967; Rochester, 1973).

Previous research comparing thought-disordered groups has generally found similarities rather than differences between the diagnostic groups (Andreasen & Powers, 1974; Harrow *et al*, 1982). Diagnostic-specific impairments have proved difficult to identify. The strong relationship that was found between thought disorder and clinical indices reflecting goal-disrupted cognition suggests that further research should be directed at these features specifically. More detailed evaluation of these phenomena and their relationship to other features of schizophrenia, schizo-affective disorder and mania may help to clarify important diagnostic and aetiological issues.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information

Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. THE DEPIXOL

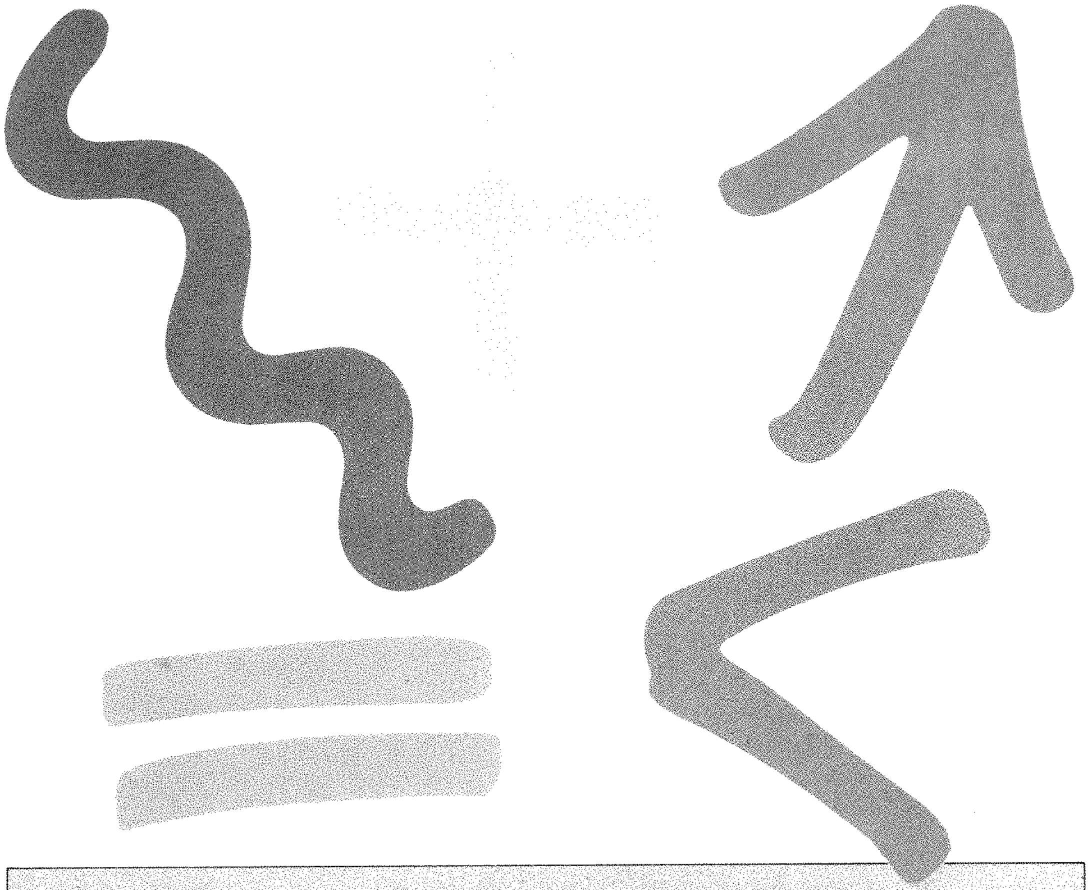
cis(Z)-flupenthixol decanoate



DIFFERENCE

= *Proven antipsychotic effect* (1-7)

↑ *Restores mood* (1-3) ∿ *Dosage flexibility* < *Cost-effective therapy* (8)

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.
Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.
Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children. Not recommended for children.
Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.
Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.

Further Information Overdosage should be treated, (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

A Comparative Hospital Survey of Psychotropic Drug Prescribing

M. MUIJEN and T. SILVERSTONE

In a survey of psychotropic drug prescribing for in-patients in three different types of psychiatric hospitals, the prevalence of combinations of more than one psychotropic drug varied from 45% in one hospital to 94% in another, with significant consistent differences between the use of drug combinations in the various hospitals. Combinations of two antipsychotic drugs were particularly frequent; the hospital with the lowest prevalence of polypharmacy was the only one with an associated psychopharmacology unit. Access to clinical pharmacology teaching may be an important factor in determining appropriate drug-prescribing habits.

A generally accepted principle of good therapeutic practice is not to prescribe more drugs to an individual patient than are strictly necessary. In psychiatry, the prescription of more than one or two psychotropic drugs to a given patient is unlikely to be beneficial and may be harmful (Merlis *et al*, 1970, 1972*a*; Hollister, 1974; Fann & Wheless, 1978), yet previous surveys (Sheppard *et al*, 1969; Merlis *et al*, 1970; Hemminski, 1977; Prien *et al*, 1973; Yosselson-Superstine *et al*, 1979; Michel & Kolakowska 1981; Morgan & Gopalaswamy, 1984; Edwards & Kumar, 1984) have shown that the habit of multiple drug prescribing is widespread.

Different studies have revealed wide variation in prescribing patterns: in a State Hospital in the USA 28% of chronic patients received multiple drug prescription (Sheppard *et al*, 1969), while in a Finnish mixed psychiatric population, 69% did so (Hemminski, 1977). There is a similar variation for specific drug combinations: approximately 10% of patients were given two antipsychotics in three studies (Sheppard *et al*, 1969; Hemminski, 1977; Michel & Kolakowska, 1981) but, in the fourth, Yosselson-Superstine *et al* (1979) found an incidence as high as 67% in an Israeli hospital. Despite such variations, there appear to be some general trends in multiple drug prescribing. For example, Hemminski (1977) noted a relationship with age: the incidence of polypharmacy among younger and older patients was lower than that in the age-group 51–60 years. Sheppard *et al* (1969) found that multiple drug prescribing occurred in 39% of female patients, compared to 19% of males.

There are difficulties in comparing one study with another, due to differences in sample selection and methodology: the American survey (Sheppard *et al*, 1969) was confined to chronic patients, the three English studies (Michel & Kolakowska, 1981; Edward & Kumar, 1984; Morgan & Gopalaswamy, 1984); involved acute, chronic and day patients, and the Finnish survey (Hemminski, 1977) included out-patients. The Israeli survey (Yosselson-Superstine *et al*, 1979) gave little precise information about the patients' characteristics.

The present study compared similar populations of patients in three different types of hospital in south-east England, to determine whether the pattern of psychotropic drug prescribing within the UK varies much from one hospital to another, or whether there are general overall similarities. Where appropriate, we have compared our findings with those of other recent UK surveys, one undertaken in an academic department of psychiatry (Michel & Kolakowska, 1981) and the two others in mental hospitals (Edwards & Kumar, 1984; Morgan & Gopalaswamy, 1984).

Method

The three hospitals which participated in our study were a London teaching hospital department with an inner city catchment area (hospital A), a provincial mental hospital with a university town and rural catchment-area, which provides a teaching facility for the local medical school (hospital B), and a large mental hospital in the Greater London Area with both an inner city and suburban catchment area (hospital C).

Only patients on acute admission wards were included. There were six such wards in hospital A (89 patients), three in hospital B (57 patients), and five in hospital C (104 patients), all serving a designated sector within the overall catchment area. Wards with specialist functions (alcohol, geriatric, adolescence, rehabilitation or long-stay) were excluded. Also excluded were patients on long-leave (i.e. longer than 1 week), as were patients who had been admitted less than 3 days before the survey.

Each ward was visited on a particular day, and the following information for each patient was recorded from the case notes and treatment sheets: diagnosis, sex, age and length of stay in hospital. All psychotropic drugs given the day before the survey were recorded (name of drug, dosage, number of administrations). As required (p.r.n.) medication was only included if given, it was otherwise recorded separately. The medication which had been given on the third day after admission was also recorded. Comparing this to the survey day medication allowed an observation of the change in medication which had taken place during the admission.

Results

Characteristics of patients

The characteristics of the patients in the three hospitals in terms of numbers, sex ratio, age distribution and diagnosis are given in Table I. The lower proportion of elderly (over 65) in hospital C is due to the fact that it has an active psychogeriatric department, to which most such patients are admitted. There was some variation in sex ratios between the hospitals, with a higher percentage of female patients in hospital B. Depressive illness was more predominant in women; the other diagnoses were equally represented in the two sexes.

General patterns of prescribing

The number of drugs given per patient in each of the three hospitals is shown in Table II, which includes the corresponding figures from two of the previous single-centre UK studies (Michel & Kolakowska, 1981; Morgan & Gopalaswamy, 1984) for comparison. More than one psychotropic drug was being given to less than half of the patients in hospital A (48%), compared to 82% in hospital B, and 74% in hospital C ($\chi^2 = 25.9$, $P < 0.001$). Similarly, more than two drugs were prescribed to 13% in hospital A, compared to over 40% in hospitals B and C. Within each hospital, there was consistency in the degree of multiple drug use between the different wards. Neither the age nor sex of the patients significantly affected the pattern of prescribing.

If the number and types of drugs given per diagnosis are examined (Table III), the same overall variation in prescribing pattern is seen, with a higher number of patients in hopsitals B and C receiving more than one drug than in hospital A. Many of these differences reach statistical significance. However, there were two exceptions to this general trend: the medication given to patients diagnosed as having personality disorders and to those diagnosed as having organic disorders was similar in all three hospitals, with more than one drug being given to only four of the 12 patients with the former diagnosis and four of the 24 with the latter.

Table I
Patient characteristics

Characteristics	*A (n = 89)*	*B (n = 57)*	*C (n = 104)*
Sex ratio (F:M)	1.5	3.7	0.9
Proportion aged			
18–39	39	37	40
40–64	36	45	52
65 and over	25	18	8
Percentage diagnosed as:			
schizophrenic	33	23	35
manic	12	14	21
depressed	24	45	21
organic	14	6	7
other	17	12	16

Table II
Number of drugs prescribed in each hospital

Percentage of patients receiving	*Hospital A*	*B*	*C*	*Michel & Kolakowska (1981)*	*Morgan & Gopalaswamy (1984)*
No drugs	25	5	4	19	8

3 drugs	11	26	29	18	24
>3 drugs	2	16	15	5	12

The most frequent combination of drugs was that of an antipsychotic and an anticholinergic drug, while the next most frequent was the prescription of more than one antipsychotic drug, which occurred in 69% of the patients in hospital B (Table III).

For mania, most patients were prescribed a combination of lithium carbonate and an antipsychotic drug, with some patients receiving more than one antipsychotic.

Table III
Type of drugs used per diagnosis for number of patients

	A		*B*		*C*	
	n	*%*	*n*	*%*	*n*	*%*

antidepressant and antipsychotic	3	15	15	58	8	36
antidepressant and benzodiazepine	2	10	11	42	15	68

Seventy-five per cent of the patients diagnosed as suffering from depression were on at least one antidepressant. Antidepressants were given to five manic-depressive patients in a depressed phase of their illness, after having been admitted earlier in a manic state. Four patients, all on the same ward, were prescribed more than one antidepressant.

Twenty-two patients (14%) were on a depot antipsychotic as the only antipsychotic, while 41 patients (26%) were on a combination of oral and depot antipsychotics.

Some interesting patterns emerged when the specific use of the different antipsychotics was analysed. Depot neuroleptics were mainly used for schizophrenic patients; only four manic and five depressed patients were on this type of preparation, with all but one of these depressed patients being on flupenthixol decanoate.

For the treatment of schizophrenia and mania, chlorpromazine and haloperidol were the most popular drugs. The expectation that haloperidol would be the drug of choice for treating mania was not fulfilled – chlorpromazine was used as often. For depression both thioridazine and chlorpromazine were often prescribed, with chlorpromazine predominating in the younger patients. The use of thioridazine was largely restricted to a group of patients who were female and elderly, with a diagnosis of depression or dementia; within the brain-damaged group, this drug had a monopoly amongst the anti-psychotics.

Benzodiazepines were prescribed to 18 patients in hospital A (20%), 25 in hospital B (44%) and 54 in hospital C (52%), usually as hypnotics. Only seven patients were on benzodiazepines as the only form of medication, all given as hypnotics. Three different hypnotics (flurazepam, nitrazepam and temazepam) were prescribed in approximately equal numbers. Day-time benzodiazepines were given to five patients in hospital A (5.5%), nine in hospital B (16%), and eight in hospital C (6%). All but three of these were given diazepam. Eleven patients in the three hospitals were receiving two different benzodiazepines, one being used as a day-time anxiolytic and the other as a hypnotic.

Antiparkinsonian drugs were given to 84 of the 150 patients on antipsychotics (53%); 52 of these had been on such drugs from the time of admission. When only the 52 patients who had been in hospital for longer than 3 months at the time of this survey were considered, it was found that 34 had been on antiparkinsonian drugs continuously. Duration of treatment with antipsychotics did not appear to be an important factor in the decision whether or not to discontinue treatment – only seven patients had had the anticholinergic drugs stopped, all were in hospital C and, in all of these, it followed reduction in the dose of neuroleptics.

A total of 99 patients had a prescription for one or more p.r.n. drugs. In 52, this involved a drug which was not being given as regular medication: an antipsychotic in 16 cases, of which seven constituted a potential second antipsychotic, in 16 an anticholinergic, and in 23 an hypnotic. Six patients could have had two new drugs added, and one patient even three. The incidence was similar in all the hospitals, although there was a marked variation between wards, especially in hospital A.

Discussion

In this, the first comparative survey of psychotropic drug prescribing undertaken in the UK, we found a wide variation from one hospital to another. The overall percentage of patients on a combination of more than one psychotropic drug in the three hospitals surveyed, although high (68%), was comparable with other studies in which figures varying from 28% (Sheppard *et al*, 1969) to 69% (Hemminski, 1977) were quoted. However, there was a marked difference in this respect between the three hospitals – half as many of the patients in hospital A as in hospitals B and C were prescribed more than one drug, which was true for almost every type of drug combination. The difference was even more marked for combinations of more than two drugs. Within each hospital, there was little difference in the prescribing of drug combinations from one ward to another.

Among combinations of psychotropic drugs, one that was especially common was that of two antipsychotic drugs. There is little evidence of any benefit being derived from the use of two antipsychotics rather than one (Freeman, 1967; Hemminski, 1977) and those studies which have shown a favourable result with combinations (Casey *et al*, 1962; Bennett & Hamilton, 1963; Talbot, 1967) suffer from serious methodological weakness. Furthermore, such combinations increase the risk of unpredictable interactions and side-effects (Hollister, 1974). An exception may be made for patients on depot drugs, for whom an oral antipsychotic may be added temporarily, although it should generally be possible to add the same drug orally as is being given in depot form.

Anticholinergic drugs were prescribed to a high proportion of patients on antipsychotics, many of them continuing to take anticholinergics for longer than 3 months.

Another popular combination was that of antipsychotic and an antidepressant in depressive illness. In the comprehensive review by Boulanger & Zarifian (1981) of the pharmacological and clinical aspects of the antipsychotic/antidepressant combinations, two indications are given for this: psychotic or agitated depression and clinical depression in schizophrenia. One of the few common findings in our three hospitals was the low number of antidepressants prescribed for schizophrenics; on the other hand, the combination of an antipsychotic and an antidepressant in depressed patients varied between 10 and 54%.

The finding of considerable differences in prescribing between, but not within the three hospitals surveyed suggests a consistent policy for prescribing within each hospital. There are a number of possible explanations for such a variation. First, there is a difference in the population served by the hospitals. Hospital A serves a deprived inner-city area with a working-class population, while hospital B serves a country, city and rural area, with a predominantly middle-class population. Hospital C serves two distinct areas, a deprived one comparable with that of hospital A and a suburban one more comparable with that of hospital B. As there was no difference in prescribing habits between the wards of hospital C, in spite of marked variations in socioeconomic status of patients from one ward to another, it is unlikely that variation in population accounts for the findings. Secondly, there were differences in the proportions of diagnostic categories: hospitals A and C had similar proportions of schizophrenic, depressed and manic patients, whereas hospital B had a relative excess of depressed patients. Nevertheless, more drugs were prescribed per patient over all the diagnostic categories in hospitals B and C, compared to A. This would suggest that the variation in terms of drug prescribing could not be explained simply on the basis of a difference in distribution of diagnostic categories.

Finally, the three hospitals have a different academic input. Hospital A is the only one in this survey with an academic department specialising in psychopharmacology, and this may have resulted in a greater emphasis being placed on more rational drug prescribing. In keeping with this possibility is the similar lower rate of polypharmacy seen in the Oxford University Department, which also has an active psychopharmacology unit (Michel & Kolakowska, 1981). Thus, the further development of clinical psychopharmacology teaching could have a real impact in reducing the frequency of multiple psychotropic drug prescribing, to the benefit of both patients and staff, as well as to the finances of the National Health Service. There is good evidence to suggest that drug prescribing is more influenced by training and exchange of ideas between doctors than by the presenting symptoms of patients (Merlis *et al*, 1972*b*; Edwards, 1982).

Acknowledgement

We wish to thank all the consultants in the three hospitals who allowed us to survey their prescribing patterns in their wards.

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.
Children Not recommended.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.
CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia.
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Children Not recommended.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.
Package quantities & NHS price (correct at of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7.

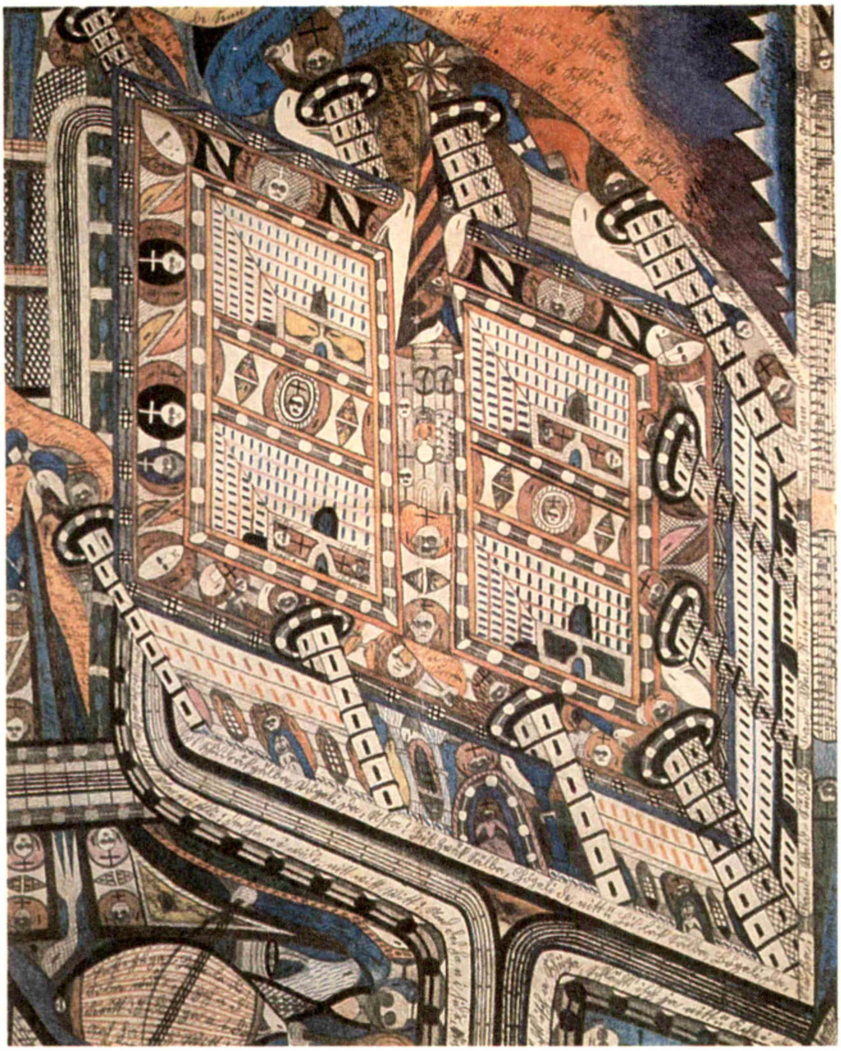
A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.



A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*

haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼**Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side Effects: In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

The Compulsory Detention of Males of Different Ethnic Groups, with Special Reference to Offender Patients

D. McGOVERN and R. COPE

Compulsory detention rates of white, West Indian and Asian males under Part IV and Part V (offenders) of the 1959 Mental Health Act were compared: British-born West Indians and Asians were differentiated from migrants. Rates for Asians were similar to those for whites, but West Indians were significantly over-represented amongst compulsory detentions, especially as offender patients. A high total number of admissions and diagnostic differences accounted for the excess of West Indians admitted under Part IV, but not Part V.

The present study arose from the authors' impression that males of West Indian origin were over-represented, especially as offender patients, amongst compulsory admissions to psychiatric hospitals, compared with whites and Asians. This excess included both British-born and migrant West Indians.

The literature on immigrant groups and offender patient status is scarce: the only detailed study is that of Walker & McCabe (1973), who found nearly three times the expected number of West Indian immigrants, but fewer than expected Asians, in a sample of male offender patients. Norris (1984) found that 12% of male patients who left Broadmoor Hospital between 1974 and 1981 were 'non-white' (mostly West Indians). Other studies of detained patients have not separated offender patients for special analysis: Rwegellera (1970), Littlewood & Lipsedge (1977, 1981*a*) and Ineichen *et al* (1984) reported an excess of West Indians among compulsory admissions, and Pinto (1970) described the same for Asians. However, Szmukler *et al* (1981) found that ethnicity was not significantly associated with compulsory admissions, and Hitch & Clegg (1980) found no excess of formal admissions in a sample of New Commonwealth patients. Most of the studies considered migrants only, though Ineichen *et al* (1984) grouped together migrant and British-born West Indians. Significant numbers of the British-born children of immigrants are now adult, and warrant separate study to distinguish the effects of migration from other factors.

The present study examines three hypotheses:

1. That males of West Indian ethnic origin (both migrant and British-born) have significantly higher compulsory admission rates than have whites. This occurs for both non-offender patients who were detained under Part IV of the 1959 Mental Health Act (Sections 29, 25, 26) and offender patients detained under Part V (Sections 60, 65, 72 and 73), and the excess is independent of age, the total number of admissions and diagnosis. However, Asians have similar detention rates to those for whites.
2. That if West Indians do have excessive compulsory admission rates, this excess is greater under Part V (offender patients) than under Part IV (non-offender).
3. That there are no differences in detention rates between British-born West Indians and migrant West Indians.

There is no satisfactory classification of ethnic groups, but in this paper we refer to the following:

(a) Those born in the United Kingdom of British or Irish ancestry – *white*.
(b) Those of West Indian ancestry, which includes *West Indian immigrants* born in the Caribbean, and *British West Indians* born in the United Kingdom.
(c) Those of Asian ancestry which includes *Asian immigrants* born in the Indian subcontinent or East Africa and *British Asians* born in the United Kingdom.
(d) Others.

Throughout the study, we refer to the 1959 Act, which was in operation during the research period. The equivalents in the 1983 Mental Health Act are Part II (non-offender patients detained under Sections 2, 3 and 4) and Part III (offender patients detained under Sections 37, 41, 47 and 48).

Method

The psychiatric hospital selected for the study, All Saints', Birmingham, was chosen because its catchment area includes a large proportion of West Indian and Asian immigrants and their children. There are no other psychiatric units in the catchment area.

Sample

Three samples were obtained from the case notes of male patients between the ages of 16 and 65 years. Patients residing outside the catchment area were excluded, as were admissions to the Alcohol and Addiction Unit, because this offers a Regional service and does not admit compulsory patients. The samples were:

(i) All male patients admitted under Part V of the Mental Health Act 1959 for the 8-year period 1 January 1975 to 31 December 1982. There were 67 individuals.
(ii) All male patients admitted under Part IV of the Act in the 4-year period 1 January 1979 to 31 December 1982, comprising 217 individuals.
(iii) A list was obtained of all male admissions during the 4-year period 1 January 1979 to 31 December 1982, and alternate cases chosen, giving a 50% sample of individuals (574 cases). For each individual, the first admission only during the period was studied. This sample will be called the 'general admission sample'.

Information obtained from case notes

The following were recorded:

(i) age on admission;
(ii) ethnic group: (white, West Indian, Asian or other), identified from nursing records, which included colour, place of birth and clinical histories;
(iii) country of birth;
(iv) legal status: informal and formal: Part IV (29, 25, 26) and Part V (60, 65, 72 or 73) of 1959 Mental Health Act. There were no admissions under Section 136;
(v) final case note diagnosis: under one of the following: schizophrenia, paranoid psychosis, affective disorder, neurosis and personality disorder, drug or alcohol abuse, organic psychosis, drug-induced psychosis, other.

Catchment area population

The catchment area includes Sandwell Metropolitan Borough and the whole or part of seven wards in north-west Birmingham. The main ethnic groups are whites, West Indians and Asians.

Estimation of whites and West Indian and Asian migrant males

Total numbers were calculated for the precise catchment area, using tables for country of birth, by sex in the 1981 Census (Office for Population Censuses and Surveys [OPCS], 1982*a*); small area statistics and figures for enumeration districts were used where necessary. Unfortunately, there is no direct published estimate of the breakdown into age groups for country of birth below West Midlands County level. After consultation with Birmingham Central Statistical Office and in order to avoid possible variation within the county, table 11 in the Census (OPCS, 1982*a*) was used to obtain a breakdown into age groups. This gives "persons usually resident in private households, whether born inside or outside the United Kingdom by age of residents by birth place of head of household". Those born outside the UK are assumed to be immigrants from the country of birth of the head of the household. In fact, the percentages for each age group for Sandwell and Birmingham differed very little from the equivalent in the West Midlands County table mentioned above; these percentages were applied to our previous estimate of total numbers in each group. The eventual estimate for British West Indians and Asians was subtracted from that for all residents in the equivalent age groups (apart from numbers of the appropriate foreign-born groups) to leave an estimate for the white group.

British West Indians and Asians

No question on ethnic origin was asked in the 1981 census. However, there is support for the use of the birth-place of the head of the household (OPCS, 1982*a*, table 11) as an indicator of the ethnic group of those living in the house from both the Labour Force Survey (OPCS, 1982*b*) and the Birmingham Central Statistical Office (1984). The Labour Force Survey asked a direct question on ethnicity, but results were published for large areas only. In the West Midlands Metropolitan County, it was estimated that 89% of persons living in houses where the head was born in the New Commonwealth were of the same ethnic origin. It concluded that the birth-place of the head of the household was a good indicator of ethnic group, especially in large urban areas. The Birmingham Central Statistical Office (*op cit*) came to a similar conclusion, after checking census data with separate estimates of ethnic minority births and school children.

The figures for Sandwell were derived directly from the census. Those people born in the UK living in a house whose head was born in the Caribbean were assumed to be British West Indians. The census does not provide this information for individual wards, and the estimate for Birmingham wards was provided by the Birmingham Central Statistical Office (1984). Their data are derived from knowledge of the immigrant figures for wards, birth statistics and census data on the birth-place of the head of the household by individual country for Birmingham as a whole.

Reference to the head of the household table as an indicator of ethnic group neglects minority householders who were born in the UK. It was important not to underestimate the numbers of British West Indians, because this would introduce a bias in favour of the first hypothesis. Therefore we consulted the only other recent estimate of population by ethnic group – that in the 1978 National Housing & Dwelling Survey (Department of the Environment, 1979), which was based on a 1.6% sample in Birmingham. Having adjusted for population trends between 1978 and 1981, we found that this survey's estimate for the West Indian ethnic group exceeded the one described above by just over 10%. We therefore increased the estimate of British West Indians by this amount and applied the breakdown into age groups given in the head of household table, assuming equal numbers for each sex.

Analysis of data

Attention will be focused upon comparisons of the age-specific section rates (per 10 000 population) for immigrant groups with those for the white population. For Part IV rates, differences are tested for significance using the χ^2 test with the continuity correction. However, this test is inappropriate for testing differences between Part V age-specific rates, because the expected values for the immigrant groups are too small (near to unity or less). An overall weighted 'risk' ratio has therefore been computed for the West Indian migrants admitted under this section (excluding those born in Britain), after first testing for homogeneity.

Results

Table I shows the breakdown by ethnic group of the local male population between the ages of 16 and 65.

TABLE I

Age and ethnic group distribution of male residents (age 16–65) of catchment area

	Age group				
Ethnic group	*16–29*	*30–44*	*45–65*	*All Ages*	*%*
White	32 790	32 120	44 100	109 010	82.4
West Indian migrant	1210	1830	2550	5590	4.2
British West Indian	2440	140	—	2580	1.9
Asian migrant	5830	4330	3230	13 390	10.1
British Asian	1000	90	50	1140	0.9
Others				610	0.5
All groups				132 320	100

Detentions under Part IV

Numbers detained and detention rates per 10 000 of the population at risk are shown in Table II. The rates give the risk of being on a section at least once in the 4-year period, regardless of the number of admissions.

Highest rates are found in the West Indian migrants. The youngest group has a rate 17 times that for whites, and the middle group seven times; both these differences are highly significant ($P<0.001$). Unlike whites, the West Indians show sharply decreasing rates with increasing age.

The difference between the British West Indians and whites is also highly significant ($P<0.001$), but there is no significant difference between the British West Indians and the West Indian migrants.

No British Asians were detained. The 4-year rates for Asian migrants slightly exceed those for whites, but only for the 30–44-year group is this significant ($P<0.01$).

Detentions under Part V

Table III gives numbers detained and rates per 10 000 of the local population at risk. The rates give the risk of being detained under Part V at least once over the 8-year period.

The most striking differences are found once more between the West Indian migrants and whites. Rates for migrants all grossly exceed the comparable rates for whites, even in the oldest group. (Although it is likely that the ratio of the rate for immigrants to the rate for whites decreases with age, on these data the χ^2 test for heterogeneity gives a value of 4.37, which for two degrees of freedom gives $P>0.1$. The weighted mean ratio is 13.65 with 95% confidence limits of 9.02 and 23.23. using a method described by Armitage [1980].)

No British Asians were detained and only three Asian migrants; little can be made of such small numbers, but they would appear not to be over-represented. Only four British West Indians were detained; again, we were reluctant to make much of these numbers.

There is an additional problem with the British West Indian group. The population estimate is for 1981, but this particular sample of patients is derived from as far back

TABLE II

Male patients detained under Part IV and 4-year detention rates per 10 000 population at risk

	Age group							
	16–29		*30–44*		*45–65*		*All ages*	
Ethnic group	*n*	*Rate*	*n*	*Rate*	*n*	*Rate*	*n*	*Rate*
White	29	8.8	41	12.8	55	12.4	125	11.5
West Indian migrant	18	148.8**	16	87.4**	5	19.6	39	69.7
British West Indian	19	77.9**					19	73.6
Asian migrant	8	13.7	15	34.6*	6	18.6	29	21.7

*$P<0.01$; **$P<0.001$. The asterisked significance levels apply to ethnic minority group vs white, for similar age groups (N.B. differences for 'all age groups' not tested).

For 16–29 year old West Indian migrant versus British West Indian $\chi^2=3.38$ ($0.1>P>0.05$).

TABLE III

Males detained under Part V and 8-year detention rates per 10 000 population at risk

	Age group							
	16–29		*30–44*		*45–65*		*All ages*	
Ethnic group	*n*	*Rate*	*n*	*Rate*	*n*	*Rate*	*n*	*Rate*
White	12	3.7	18	5.6	7	1.6	37	3.4
West Indian migrant	11	90.9	7	38.3	5	19.6	23	41.1
British West Indian	4	16.4		—		—	4	15.2
Asian migrant	1	1.7		—	2	6.2	3	2.2

Weighted risk ratio of West Indian migrant : white = 13.65, with 95% confidence limits 9.0 to 23.2

as 1975 in order to obtain sufficient numbers of Part V detentions. The British West Indian group is a young one, with the 16–29 age group most probably growing each year from 1975. The population figures are therefore almost certainly an over-estimate as far as the early years of the 1975–1982 period. The true British-born rates will therefore be higher.

Comparison between Part V and Part IV detention rates

The West Indian migrants have increased rates for both Part V and Part IV compared to those for whites, but the increase is greater for Part V than for Part IV for all age groups, markedly so for the youngest and oldest groups. The former have a rate 25 times that of young whites for Part V, while the comparable rate for Part IV is 17 times that for whites; the latter have a rate 12 times that of whites for Part V, whereas the comparable Part IV rate is 1.5 times that for whites.

There were no British Asians detained under either Part, and insufficient numbers of migrant Asians and British West Indians detained under Part V to make meaningful comparisons.

TABLE IV

General admission sample (50% sample over 4 years)

Total	65	9	6.8	13.8	0	

1. Part IV section rate was based on a 50% sample, double to obtain the full section rate.

*$P = 0.05$; **$P < 0.001$. Significance levels apply to ethnic minority group *vs* white for similar age groups (differences for total age groups not tested apart from Part V section rate per 100 admissions).

Diagnosis under Part IV and Part V

Schizophrenia was the commonest case note diagnosis under both Parts; 110 Part IV patients (51%) and 52 Part V patients (78%) were diagnosed as schizophrenic.

General admission sample

This sample was obtained to determine whether differences in compulsory detention rates between groups are affected by taking into account the total numbers of admissions and diagnostic differences. Details were recorded from the first admission for each individual in the 4-year period. Table IV shows numbers of admissions, detentions on Part IV and Part IV rates. Part V detentions are given, but Part V rates are not shown because numbers are so small. In order to take account of total number of admissions, the section rates per 100 admissions are calculated for Parts IV and Part V.

Numbers in the British Asian, mixed Asian/white and other groups total 17 and are excluded from the table, being too small for analysis.

Part IV section rates

These rates were calculated from the 50% sample of admissions. The overall pattern of Part IV sections is, as expected, similar to that given in Table III, but, in this sample, the rate refers to the risk of being on a section on one particular admission only. Therefore the differences between the groups are not quite so large and, with the smaller numbers, only the youngest group of West Indian migrants, in addition to the British West Indians, have rates significantly higher than those for whites ($P<0.001$). The rates for Asians are no longer significantly different from those for whites.

Part IV section rate per 100 admissions

Once the total number of admissions in each group is taken into account, differences between the groups diminish. Although there is still a trend for West Indians of both groups to be detained more frequently on sections, the differences are not statistically significant.

Part V detention (offender patients)

These comprised 13% of all compulsory detentions. The fact that numbers are so small should be taken into account in interpreting the analysis.

Part V detentions per 100 admissions

Because of the small number in individual age groups, these are given only for the total group of whites and West Indian migrants. The rate for West Indian migrants was 6.4, compared with 1.4 for whites. Applying Fisher's exact test, the probability of getting a result for the West Indians which exceeds the white by this extent or more is 0.05, i.e. the difference is just significant at the 5% level on a one-tail test.

Diagnosis

The final case note diagnosis for each of the main ethnic groups is given in Table V. The percentage of Asian migrants diagnosed as schizophrenic is slightly higher than the corresponding percentage for whites; otherwise, the two groups have similar diagnostic patterns. There are large differences between the West Indians and the Asian and white groups.

Approximately two-thirds of the West Indian migrants (64.5%) and British West Indians (68%) were diagnosed as schizophrenic, compared with one-third of the whites (32%) and Asians (39%). Thus, the proportion of West Indians with a diagnosis of schizophrenia is twice that of the other two groups. In addition, eight West Indian patients (four from each group) have diagnoses of drug-induced psychosis – a diagnosis not given to either whites or Asians; in each case, the drug implicated was cannabis. A lower proportion of West Indians have diagnoses of affective disorder, alcoholism and neurosis/personality disorder. There is little difference in the diagnoses given to the two West Indian groups.

TABLE V
Distribution of diagnosis in general admission sample

	White		*West Indian migrant*		*British West Indian*		*Asian migrant*	
Diagnosis	*n*	%	*n*	%	*n*	%	*n*	%
Schizophrenia	134	32	30	64.5	17	68	25	39
Paranoid psychosis	9	2	—	—	—	—	—	—
Affective disorder	124	29.5	7	15	2	8	19	29
Neurosis/personality disorder	71	17	3	6	2	8	9	14
Alcohol/drug abuse	49	11.5	—	—	—	—	8	12
Organic brain syndrome	24	6	1	2	—	—	—	—
Drug-induced psychosis	—	—	4	8.5	4	16	—	—
Other	9	2	2	4	—	—	4	6
Total	420		47		25		65	

Two methods were used to assess the effect of diagnosis on compulsory detention. First, each individual from the minority group was matched by age (within 3 years) and diagnosis with a member of the white group. Cannabis psychosis was matched with schizophrenia (one in four cases of cannabis psychosis was detained under Part IV, compared with between one in five and one in six cases of schizophrenia). Apart from age and diagnosis, the matching was random. Part V patients were removed from each group before matching. Because of their small numbers, no corresponding matching was done for these offender patients. Of the 44 matched pairs of whites and West Indian migrants, nine whites and 11 West Indians were on Part IV orders. Of the 23 matched pairs of whites and British West Indians, four of the former and six of the latter were detained on Part IV orders. Although the West Indians were compulsorily detained slightly more often, the differences did not approach statistical significance.

Secondly, the main diagnostic difference between the groups was the excess of West Indian schizophrenics. All patients with this diagnosis were identified and the numbers on Part IV and Part V determined. Because of the small numbers, the groups were split into two age groups only (16–34 and 35–54). In the youngest age group (16–34), 13 out of 55 white schizophrenics (24%) were on Part IV, compared with five out of 22 West Indian migrants (23%) and five out of 16 British West Indians (31%). In the older age group (35–54), seven out of 59 white schizophrenics (12%) were on Part IV, compared with one out of ten West Indian migrants (10%). None of these differences approached statistical significance. The numbers of offender patients were so small that they could only be compared for the total age groups. Two out of 114 white schizophrenics (2%) were detained under Part V, compared with three out of 32 West Indian migrants (9%). Applying Fisher's exact test, the probability of getting such a result or higher is 0.07 on a *one-tail test*.

Because there were no white patients detained under Part V in the 16–34 age group, no comparison could be made with the British West Indians, all of whom were aged under 34 years.

Discussion

Our study differs from comparable studies in two ways. First, special efforts were made to gather a sample of offender (Part V) as well as non-offender (Part IV) patients and, secondly, British-born children of migrants were analysed separately. We limited the study to males because observations suggested that the hypotheses were less applicable to females. In this discussion, we shall consider first the results in relation to the main hypotheses.

The results broadly confirmed that West Indian males, both migrant and British, had high compulsory admission rates compared to those for whites. In accordance with the hypothesis, the excess under Part V was considerably higher than under Part IV for West Indian migrants. Contrary to the hypothesis, the Part IV differences were accounted for by differences in total number of admissions and diagnosis; the differences were greater in the younger age groups. It seems unlikely that the Part V differences can be explained in the same way. The third hypothesis predicted no differences in detention rates between migrant and British West Indians. Differences were found, but these did not reach statistical significance. Overall, results for Asians were similar to those for whites, as predicted.

Several aspects merit further discussion. The Part IV results suggest that the high rate of West Indian detentions can be explained by the excess of admissions with schizophrenia. This differs from previous work (Littlewood & Lipsedge, 1981a), which found excessive West Indian detentions to be independent of diagnosis. Ineichen *et al* (1984) suggested there was no excess of voluntary admissions among West Indians in their sample; however, the comparison group comprised white inner city residents, and no account was taken of differences in age structure between the two populations. No reference was made to diagnosis.

A pattern of high admission and first admission rates for West Indian migrants and a preponderance of schizophrenia has often been noted (Cochrane, 1977; Rwegellera, 1977; Carpenter & Brockington, 1980; Dean *et al*, 1981). There has been much debate about the nature of the illness – is it true schizophrenia (Rwegellera, 1977), paranoid psychosis (Carpenter & Brockington, 1980), an acute psychotic reaction (Littlewood & Lipsedge, 1981b) or a neurotic condition (*British Medical Journal*, 1980)? These different interpretations of the illness cast doubt on the validity of hospital diagnosis. Since our study relied on case note diagnosis, our data are subject to these uncertainties. The diagnosis of cannabis psychosis occurred uniquely in the West Indian groups; we included it as a separate entity only after noting its frequent occurrence. There has been debate about its validity (Carney & Lipsedge, 1984), but the fact that it is being made so often on West Indian males makes the phenomenon worthy of further study.

The results revealed large differences between whites and West Indians. However, no significant differences were found between British West Indians and migrants for Part IV detention rates. Both had a high number of admissions and a similar pattern of diagnoses. Further study of these groups may help clarify the problem of mental illness in immigrants. Only one of these groups has experienced a pre-migration culture as well as migration, albeit several years earlier than the period of study. However, both groups may share cultural interests and values, as well as the experience of social deprivation and racial antagonism. There may also be genetic similarities. Some of these factors may be important aetiologically, while others may be pathoplastic.

Although it is unclear how much they differ, there is every indication that both groups have a high morbidity for major psychiatric illness, particularly the youngest members. There would appear to be no support for Cochrane's (1983) hypothesis that "The deliberate creation of a counter culture among West Indian youths . . . may provide some protection from psychological problems".

The last part of the discussion will concentrate on the offender patients. The main difference between Part IV and V patients is that the latter are offenders: the West Indian excess under Part V may merely reflect excessive involvement in crime and the 1975 arrest rates by the London Metropolitan Police (Stevens & Willis, 1979) provide some evidence for this. Blacks had disproportionately high rates for all crime, but arrest rates do not necessarily correlate with rates of criminality or conviction; they may reflect police attitudes or an increase in 'arrest-prone groups'. In addition, these authors emphasise that measures of social disadvantage are crucial in determining crime rates, and these vary between ethnic groups.

There are other possible explanations for the difference. First, once in custody, West Indians may be more prone to developing mental illness than whites; we know of no evidence either for or against this. Another possible explanation of our finding is that the manifestation of mental illness in West Indians leads to arrest and criminal charges, rather than referral to a mental hospital. There are certainly reports in the literature of West Indians presenting a more disturbed or violent picture for psychotic illness in general (Hitch & Clegg, 1980; Rwegellera, 1980; Harrison *et al*, 1984), acute psychotic reaction (Littlewood & Lipsedge, 1981*b*), hypomania (Rack, 1982) and cannabis psychosis (Knight, 1976). This may lead to early police involvement, particularly if the disturbance occurs in a public place. (It is important to remember that there are many possible explanations for any increase in disturbed behaviour; one is that it is a result of a poor relationship between psychiatric and other agencies and West Indians.) Whilst it is known that police referrals to psychiatric hospitals include an excess of West Indian migrants (Sims & Symonds, 1975), it is not known how many are placed 'inappropriately' in the penal system. Evidence from the US penal system (Scheiffer *et al*, 1968) suggested that blacks needed to be more obviously ill before the police referred them to psychiatric facilities; if the illness was less overt, they were more likely than whites to be dealt with in the penal system. There has been no similar work in the UK, but such a phenomenon may contribute to our results.

These differences between the Part V and Part IV results have implications for forensic psychiatrists and merit further study. To obtain more Part V patients, it would be necessary to include more hospitals in the study, including Special Hospitals. In an attempt to answer some of the questions raised by this paper, we have recently completed a study of first admissions to the same psychiatric hospital and plan a further study in a local prison to determine psychiatric morbidity of members of ethnic minorities in custody.

Anticonvulsant Medication in a Mental Handicap Hospital: 1972–1982

L. C. SHEPPARD, B. R. BALLINGER and G. W. FENTON

The prescription sheets for all patients in a mental handicap hospital on one day in 1972 and on the same date in 1982 were examined to identify trends in anticonvulsant medication over a 10-year period. There was a reduction in size of the hospital population associated with fewer very young and milder handicapped persons. Prescription of anticonvulsants fell slightly during the decade under study with a dramatic fall in the use of phenobarbitone, and a parallel increase in the prescription of carbamazepine. Other changes included the use of sodium valproate in a significant minority of patients and the occasional use of clonazepam in 1982, while phenytoin remained a first-rank anticonvulsant throughout the period under review. The proportions of patients on polytherapy did not change over the 10-year period, though the contribution of phenobarbitone to the combined drug regimes was significantly reduced.

Epilepsy is common in mentally handicapped patients, especially the severely retarded and those who are institutionalised (Corbett, 1981). Hence anticonvulsant drugs are widely used in hospitals for the mentally handicapped. There is evidence that the latter are specially prone to become intoxicated with anticonvulsant drugs and may show side-effects, such as intellectual deterioration and psychomotor slowing with serum levels within the accepted optimum range (Reynolds & Travers, 1974: Trimble & Corbett, 1980). The probability of such complications is increased by polytherapy – the combined use of two, three or more anticonvulsants (Reynolds, 1975). Yet, surveys of anticonvulsant prescribing practices in mental handicap hospitals are scarce and most have surveyed drugs prescribed on a single day only (Spencer, 1974; Kirman, 1975; Hughes, 1977). Even fewer studies of prescribing changes over time have been carried out. James (1983) studied changes over a 9-month period following the introduction of British National Formulary prescribing guidelines and Gowdey *et al* (1984) investigated drug prescribing between 1977 and 1982 in a Canadian residential mental retardation centre.

The present investigation reviews anticonvulsant prescribing changes in a mental handicap hospital over a rather longer 10-year period, 1972–1982, a decade that witnessed significant advances in anti-epileptic drug therapy, a greater understanding of their clinical pharmacology, the development of effective serum level monitoring methods and a recognition of the therapeutic benefits of monotherapy and adverse consequences of polytherapy. In 1982, estimation of serum anticonvulsant drug levels had become routine; a decade before, such serum monitoring was not customary.

Method

The Drug Monitoring Unit at the Royal Dundee Liff Hospital was set up in November, 1969 to monitor drug prescribing and adverse drug reactions. A continuous record of all prescriptions for in-patients in the Dundee Psychiatric Service and the Tayside Region Mental Handicap Service is kept. The drug prescription sheets for all patients in Strathmartine Hospital on the following two dates were scrutinised: 31 December 1972 and 31 December 1982. Strathmartine Hospital accommodates all mentally handicapped patients within Tayside who need in-patient care.

The following data was extracted from each prescription sheet and recorded on a specially prepared data sheet: patient's name, ward, sex, date of birth, consultant's name and all drugs prescribed on the date of interest. For each drug the following information was obtained: date of commencement of the prescription, total daily dose, route of administration and whether the prescription was 'as required' or to be administered at regular intervals throughout the 24 hours.

Patients discharged on the day of interest were not included. Those on 'leave' from the hospital were. 'As required' or 'once only' prescriptions were only included if the drug was actually given to the patient on the day of interest.

The date of admission and diagnosis for each patient identified as receiving medication on the two days of interest were recorded from the medical records at Strathmartine Hospital. The severity of mental handicap was graded according to the Ninth Revision of the International Classification of Diseases. An additional Borderline category was used to describe those patients whose IQ was rated as higher than the Mild range but less than the lower limit of the average IQ range (Reid 1982). Those for whom no specific diagnostic category was available were defined as having 'unspecified mental retardation'.

The numbers of patients receiving anticonvulsants on the two dates of interest were calculated. The frequency of use of the individual drugs and common drug combinations were tabulated and compared for the two dates. The associations between severity of handicap and drug prescribing were also examined. χ^2 Tests were used where appropriate.

Results

Table I shows the total in-patient population changes. The total number of in-patients decreased from 605 in 1972 to 535 in 1982, the sex distribution remaining unchanged. Those under 20 years fell from 158 to 83 ($P<0.001$). A non-significant increase in those over 60 years was observed (50 to 72). No other changes in age distribution were apparent. There were significantly fewer patients with borderline handicap in 1982 (155 in 1972, 109 in 1982, $P<0.02$). Although there were fewer severely and profoundly retarded people in 1982 (213 as compared to 225 in 1972), they represented a slightly higher proportion of the population (37% in 1972, 40% in 1982). However, these differences were not statistically significant.

The main features of those receiving anticonvulsant medication are displayed in Table II. The total number receiving anticonvulsant medication was 179 (30%) in 1972 and 130 (24%), this decrease being significant at the 5% level. The sex distribution was similar to the in-patient population as a whole with an excess of males and did not change significantly over time. The anticonvulsant drug prescription rates increased with severity of the mental retardation. The numbers of each category on anticonvulsants are less in 1982 but this change is not statistically significant.

TABLE I

Total in-patient population changes

	1972	*1982*
Number of patients	605	535
Proportion of males	55%	58%
***Number under 20 years	158 (26%)	83 (15%)
Number over 60 years	50 (8%)	72 (13%)
Degree of handicap		
Borderline MR	29 (5%)	9 (2%)
Mild MR	126 (21%)	100 (19%)
Moderate MR	203 (34%)	208 (39%)
Severe MR	145 (24%)	137 (26%)
Profound MR	80 (13%)	76 (14%)
Unspecified MR	22 (4%)	5 (1%)

Significant differences between 1972 and 1982: $***P<0.001$.

TABLE II

Anticonvulsant prescribing changes

	1972	*1982*
*Number of patients on anticonvulsants (% total population)	179 (30%)	130 (24%)
Sex ratio		
Male	102 (57%)	77 (59%)
Female	77 (43%)	53 (41%)
Diagnoses		
Borderline MR	3 (2%)	1 (1%)
Mild MR	29 (16%)	18 (14%)
Moderate MR	56 (31%)	38 (29%)
Severe MR	47 (26%)	39 (30%)
Profound MR	40 (22%)	33 (25%)
Unspecified MR	4 (2%)	1 (1%)
Percentage of each diagnostic subgroup receiving anticonvulsants		
Borderline MR	10%	11%
Mild MR	23%	18%
Moderate MR	28%	19%
Severe MR	32%	28%
Profound MR	50%	44%
Unspecified MR	18%	20%

*Significant difference between 1972 and 1982: $P<0.05$.

TABLE III

Number of patients receiving each drug alone or in combination

Anticonvulsant	*1972*	*1982*
***Phenobarbitone	160 (89%)	63 (48%)
**Primidone	24 (13%)	6 (5%)
Phenytoin	60 (34%)	65 (50%)
***Carbamazepine	2 (1%)	52 (40%)
Sodium Valproate	—	22 (17%)
Clonazepam	—	6 (5%)
Ethosuximide	5 (3%)	1 (1%)
Sulthiame	9 (5%)	—
Beclamide	1 (<1%)	—
Troxidone	1 (<1%)	—
Paraldehyde	5 (3%)	—

Significant differences between 1972 and 1982: $***P<0.001$, $**P<0.01$.

Table III illustrates the prescribing changes between 1972 and 1982. These are as follows:

(a) A significant reduction in the number of people prescribed phenobarbitone (from 160 to 63: $\chi^2=39.5$; d.f. $=1$, $P<0.001$) and primidone (from 24 to 6: $\chi^2=9.6$; d.f. $=1$, $P<0.01$).

(b) A significant increase in the number of patients prescribed carbamazepine (from 2 to 52: $\chi^2=57.0$; d.f. = 1, $P<0.001$).
(c) An increase in the number of people prescribed phenytoin (from 60 to 65), although this was not statistically significant at the 0.05 level.
(d) The introduction of sodium valproate and clonazepam as anticonvulsants.
(e) Ethosuximide is rarely prescribed and its use is declining. Sulthiame, Beclamide, Troxidone and Paraldehyde, already unpopular in 1972, are not prescribed in 1982.

TABLE IV
Monotherapy and polytherapy changes

	1972	1982
Number of patients on one or more anticonvulsants		
One only	102 (57%)	68 (52%)
Two	66 (37%)	44 (34%)
Three	10 (6%)	13 (10%)
Four	1 (<1%)	5 (4%)
Diagnosis of polytherapy patients (% anticonvulsant subgroup)		
Borderline MR	2 (1%)	1 (1%)
Mild MR	12 (7%)	9 (7%)
Moderate MR	26 (15%)	22 (17%)
Severe MR	20 (11%)	17 (13%)
Profound MR	15 (8%)	12 (9%)
Unspecified MR	2 (1%)	1 (1%)

Tables IV and V show the changes in anticonvulsant polytherapy between 1972 and 1982. There is a slight decrease in number (77 to 62) but increase in proportion of patients prescribed two or more anticonvulsants (43–48%) over the 10-year period. These differences are not significant. Table IV illustrates the number of patients prescribed two or more anticonvulsants within each diagnostic category; around 80% were moderately, severely or profoundly retarded with little change between 1972 (79%) and 1982 (80%). Table V shows changes in certain combined drug regimes. The following significant differences between 1972 and 1982 are apparent:

(a) A significant decrease in the number of patients prescribed phenobarbitone and phenytoin together (from 48 to 21: $\chi^2=4.9$; d.f. = 1, $P<0.02$).
(b) A significant increase in the number of patients prescribed phenytoin and carbamazepine together (from 3 to 12: $\chi^2=10.5$; d.f. = 1, $P<0.001$).
(c) A significant increase in the number of patients prescribed phenytoin, carbamazepine and phenobarbitone together (from 2 to 9: $\chi^2=6.1$; d.f. = 1, $P<0.01$).

TABLE V
Combined medication changes

Anticonvulsant combinations	*1972*	*1982*
*Phenobarbitone and phenytoin	48 (27%)	21 (16%)
***Phenytoin and carbamazepine	3 (2%)	12 (9%)
**Phenytoin, carbamazepine and phenobarbitone	2 (1%)	9 (7%)

Significant differences between 1972 and 1982: ***$P<0.001$, **$P<0.01$, *$P<0.02$.

Discussion

Our anticonvulsant prescribing rates of 30% in 1972 and 24% in 1982 are essentially similar to those reported in previous surveys (Spencer, 1974; Kirman, 1975; Hughes, 1977; Gowdey *et al*, 1984).

If the assumption that most mentally handicapped patients receiving anticonvulsant medication are being treated for recurrent seizures is valid, it can be concluded that around 25% of our in-patients suffer from epilepsy, the number having fallen slightly over the 10-year period under review. These prevalence figures are in agreement with previously published series, as is the association between occurrence of fits and the severity of handicap (Corbett, 1981).

The proportion of severe and profoundly handicapped patients on anticonvulsants tended to increase slightly between 1972 (48%) and 1982 (55%). Hence the decrease in epilepsy prevalence cannot be accounted for by the accumulation of a residual pool of more severely handicapped patients in the hospital. Perhaps a more critical and conservative approach to the diagnosis of epilepsy and the use of anticonvulsant drugs explains the lower prescribing rate in 1982.

Probably the most dramatic change in anticonvulsant prescribing is the decline in use of phenobarbitone (from almost 90% of patients in 1972 to slightly less than 50% in 1982). Doubtless, these changes are a reflection of growing awareness of the adverse effects of phenobarbitone on behaviour and cognitive function (Reynolds & Travers, 1974; Reynolds, 1975; Stores, 1975; Trimble & Reynolds, 1976; Snaith *et al*, 1979). The declining popularity of primidone is almost certainly a consequence of phenobarbitone being one of its major metabolites. It also has acquired a reputation amongst influential clinicians for oversedation in therapeutic doses and for causing occasional psychotic episodes. Phenytoin has maintained its established place as a first-rank anticonvulsant, being used in 33–50% of patients.

The decline in phenobarbitone prescriptions is paralleled by a marked increase in the use of carbamazepine. Though available in 1972, it was rarely used. By 1982, its prescription (40%) was almost as frequent as phenobarbitone (48%) and phenytoin (50%). Over the 10-year period of this study, careful clinical trials have established carbamazepine as a first-rank anticonvulsant drug (Troupin, 1983). Further studies of both healthy subjects and patients have demonstrated that carbamazepine has much less effect on cognitive function than phenobarbitone or phenytoin (Dodrill & Troupin, 1977; Thompson *et al*, 1981; Thompson & Trimble, 1982; Hirtz & Nelson, 1985). The wide discussion of the possibility of a psychotropic action is also an important determinant in its use (Dalby, 1975; Ballenger & Post 1980). Another factor may be the recent local interest in using carbamazepine to control the behaviour of mentally handicapped patients (Reid *et al*, 1981).

The use of sodium valproate in a significant minority of patients in 1981 and not in 1972 is consistent with its relatively late introduction into the UK from the continent and its recognition as an effective drug in secondary generalised epilepsy (Driefuss, 1983). The foothold gained by clonazepam in 1982 is small. Can this be due to the problems of oversedation, irritability and tolerance that occur with this drug? (Browne, 1976; Schmidt, 1985). It is of interest that ethosuximide makes a minimal and decreasing contribution to anticonvulsant medication - presumably a reflection of the paucity of patients with absence seizures due to primary generalised epilepsy in a mental handicap hospital. Finally, the disappearance of sulthiame, beclamide, troxidone and paraldehyde by 1982 reflects current trends in anticonvulsant drug prescribing in epilepsy generally.

Polytherapy, the combination of two or more anticonvulsant drugs, continues to be the prescribing pattern in a substantial minority of patients; slightly less than half, a proportion that has not changed significantly over the 10 years being studied. As with monotherapy, the contribution of phenobarbitone to the drug combinations has reduced significantly (27% to 16%) and that of carbamazepine is rising (2% to 9%). Hence, even though the combinations of drugs used are changing, polytherapy persists. Indeed, the proportion of patients on three or more drugs is increasing (6% to 14%).

Is this worrying trend due to the intractible nature of epilepsy in a significant minority of the mentally handicapped with consequent greater difficulty in achieving seizure control? Certainly, polytherapy is a feature of the medication of the more severely handicapped (around 80% in those with moderate, severe or profound mental handicap). If and when satisfactory control is reached, are clinicians reluctant to withdraw drugs in the mentally handicapped because of the risk of status? Of course, intractible epilepsy in less severely impaired patients is likely to make discharge to community care difficult. This may lead to an ever-growing pool of patients with severe epilepsy who can only be managed by polytherapy. A further research project has been initiated in order to identify the characteristic features of the polytherapy patients and to investigate the questions raised in this paragraph.

A final question that requires answering is the extent to which polytherapy contributes to cognitive impairment and behaviour disorder in the mentally handicapped. Neuroleptic medication has been shown to affect adversely the daily living skills and workshop performance of mentally handicapped patients (Breuning *et al*, 1982; Heistad *et al*, 1982). Does polytherapy cause similar problems?

It should be emphasised that our data relate to a highly selected population of mentally handicapped patients due to their requiring institutional care. Therefore, the findings cannot be generalised to the anti-epileptic treatment of patients living in the community. Indeed, it would be of interest to study a community sample.

Behavioural Treatment of Life-threatening Masochistic Asphyxiation: A Case Study

P. HAYDN-SMITH, I. MARKS, H. BUCHAYA and D. REPPER

Asphyxia as a means of heightening sexual pleasure unfortunately comes to notice more often in the coroner's court than in the psychiatrist's consulting room. The victims are usually adolescent men who strangle or hang themselves while masturbating; transvestism is frequently associated with this behaviour (Simpson, 1979; Friedmann & Faguet, 1982; Mason, 1983). Few such people ask for help, and behavioural treatment in such a case has not been previously described.

Case report

A married man aged 35, with two young children, sought help when his wife discovered his deviant practice and he realised that he had come near to death on several occasions. He was trying to suffocate himself thrice weekly.

The patient's father was an aggressive man, possibly schizophrenic, who had received prolonged psychiatric treatment, including a leucotomy. His mother was very close to the patient emotionally during his early years and adolescence. He had a sister several years his senior. Early childhood was unremarkable.

His first recollection of any unusual sexual interest was of a vivid dream at age 13 that he was being swallowed and thus constricted by a snake, leading to intense sexual arousal and orgasm. He sought to reproduce this sensation by dressing in his mother's corsetry and masturbating, and later used a rubber diving suit to this end. He found that by holding his breath he could increase the intensity of orgasm and this led to his covering his face with a plastic bag.

The deviant behaviour became more complex in stages until he was routinely dressing in tight, women's clothing, securing a plastic bag over his head with a stocking and then binding his wrists in previously prepared slip knots in a length of rope so that he was not able to remove the plastic bag easily. He then achieved orgasm at an intensity far greater than with sexual intercourse, the excitement being increased by the risk that he might not be able to release his hands from the rope in order to remove the bag from his head. Indeed, on a few occasions he almost lost consciousness before succeeding in removing it.

Marital coitus occurred about twice a month, was felt to be unsatisfactory by both partners and was usually accompanied by deviant fantasies. In contrast, coitus with a mistress was frequent, satisfying and unaccompanied by deviant fantasies.

Treatment

We aimed first to reduce the patient's deviant urges and practices to such a level that he was able to resist his urges to act out the fantasy, and secondly, to improve his level of heterosexual functioning. The patient was admitted with his wife to a family flat on the ward, staying there for 6 weeks.

To reduce the deviant fantasy, two self-regulatory techniques were employed: covert sensitisation and the use of coping strategies. The patient's wife was closely involved throughout to encourage the patient and to help monitor his progress. The patient terminated the relationship with his mistress so that he could concentrate on bettering his relationship with his wife, which was good but needed some improvement.

Covert sensitisation

The patient was instructed, over 40 sessions, first in the presence of the therapist, then alone, to imagine carrying out his deviant routine. When he had a clear and strong image of the deviant fantasy, he was asked to produce an aversive fantasy which, with repeated practice, became linked with the deviant one and reduced its accompanying intensity of arousal. Several aversive fantasies were used, e.g. discovery by his children or by his boss, or of being attacked by wasps (the patient was phobic of wasps).

Coping strategies

These were taught to prevent his getting into tempting situations and later, as self-control improved, to enable him to disrupt any deviant behaviour. The first strategy was based on the fact that he stayed up late after his wife had gone to bed and then frequently masturbated with bondage and suffocation. He was encouraged to go to bed at the same time as his wife, who was encouraged to insist that he did so. Secondly, the in-patient nursing staff arranged that there would always be someone on duty familiar with the patient and prepared to talk to him whenever he felt an urge to engage in deviant behaviour. Such contact enabled him to resist carrying it out. Thirdly, a cassette tape recording was made of the voices of nurses and doctors encouraging him to resist his deviant urges and to phone the ward if they occurred when he was outside hospital. Fourthly, heterosexual functioning was improved by sexual skills training of the patient and his wife, together with marital counselling and the use of sexually educational videotapes.

After discharge from in-patient treatment, the patient maintained weekly contact by phone and was seen at decreasing intervals lengthening from weeks to 6 months. He remained greatly improved, both in his heterosexual relationship with his wife and in the reduction of his deviant fantasies and activities.

After 7 months, he suddenly developed strong urges to dress in, and suffocate himself with, a plastic raincoat. This occurred after he had watched a young woman dress in one while he was on holiday abroad and was unable to telephone the ward. He found watching this act intensely erotic, immediately bought such a garment for himself, and then

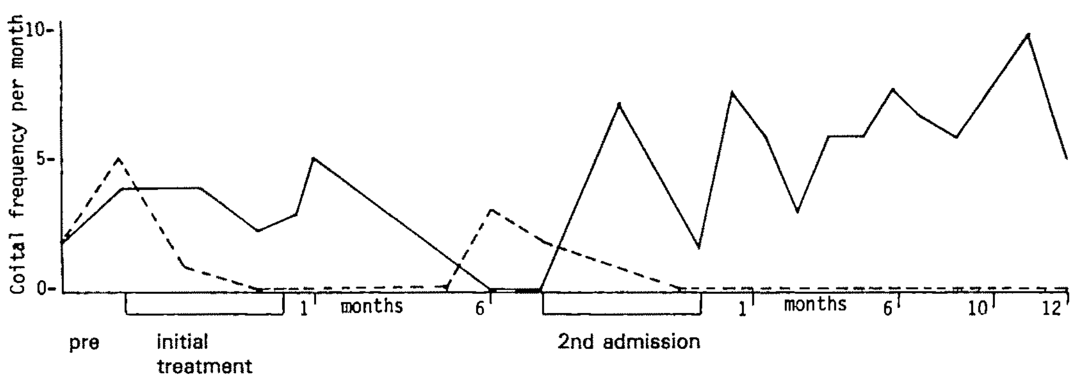

FIG. 1 The effect of behavioural treatment on frequency of coitus with (----) and without (——) deviant fantasies.

wore it, once only, back to front in a constricting manner while masturbating.

Readmission for 4 weeks was arranged for booster therapy. The patient had 45 more sessions along the lines described above and improved quickly. The swallowing fantasy disappeared for the first time. Thereafter the patient was followed up at rapidly widening intervals (6 months at the time of writing). During this time, the patient remained very well and described his marital relationship as the best it had ever been.

Outcome

As treatment progressed, the patient's attitude to his wife and to normal sex, which had been positive initially, became even more so, while his attitudes to deviant concepts became more negative. His urges to engage in deviant behaviour decreased, and the frequency of deviant fantasies accompanying masturbation diminished. The fantasy of plastic bags decreased more rapidly than that of being swallowed by a woman.

The frequency of sexual intercourse with his wife increased from once every 2 weeks prior to treatment to two or three times per week at follow-up, and orgasm during marital coitus ceased to be accompanied by deviant fantasies (see Fig. 1). Concomitantly, masturbation to deviant fantasties decreased from three times daily at pretreatment to less than once per month at follow-up.

Discussion

The patient had a combination of transvestism and masochism which is not infrequent. Of a series of transvestites, 15% had masochistic interests, and a liking of tight garments was common (Prince & Bentler, 1972).

Transvestites with features of fetishism have been treated with some success by electric aversion during fantasied and real cross-dressing, as assessed after 2-year follow-up (Marks & Gelder, 1967; Marks *et al*, 1970). However, the use of aversion in fantasy (covert sensitisation), rather than external electrical aversion, has certain advantages. It needs no special apparatus and is easier to self-administer. Electrical aversion, even if self-administered, may be seen by some patients and therapists as punishment and manipulation, while aversion in fantasy is seen more easily as a form of self-regulation. The covert sensitisation was used together with other self-regulatory methods to disrupt tempting urges, e.g. phoning the ward after discharge when the urges grew in strength, upon which the nursing staff would 'talk him down' until he felt he could cope. On such occasions he was also encouraged to talk with his wife, but only became able to do so after 1 year, even though she was extremely cooperative.

The patient's improvement requires a continuing vigilance and self-control. At 2½-year follow-up deviant urges were infrequent and could be controlled.

Classification of Parasuicide by Cluster Analysis

Types of Suicidal Behaviour, Therapeutic and Prognostic Implications

A. KURZ, H. J. MÖLLER, G. BAINDL, F. BÜRK, A. TORHORST, C. WÄCHTLER and H. LAUTER

A classification of suicidal behaviour was derived by cluster analysis from descriptive data on parasuicide patients. The grouping was meaningful in terms of clinical interpretation and had both therapeutic and prognostic implications. The sample was broken down into three groups, identified as repeated, serious and non-serious attempts. The repeated attempters had the worst prognosis at 1-year follow-up. When the sample was classified into five groups according to seriousness of the attempts, the repeater and non-serious groups were retained, while the serious attempts were split into three subtypes, which differed on nosological characteristics, treatment disposal and outcome. An excessively high successful suicide rate was found in a small group of elderly attempters.

In many investigations, attempted suicide has been treated as a uniform entity; in particular much of the research into aetiology and prediction of self-destructive behaviour has set out from this premise. On the other hand, efforts have been made to distinguish separate behavioural patterns within attempted suicide. Classifications have been proposed on the dimensions of suicidal intent (Dorpat & Boswell, 1963; Silver *et al*, 1971; Beck *et al*, 1976), seriousness of the act (Schmidt *et al*, 1954; McHugh & Goodell, 1971; Pallis & Birtchnell, 1977; Goldney, 1981) and repetitiveness (Batchelor, 1954; Buglass & Horton, 1974). A more complex typology was suggested by Wold (1971) and by Litman (1972). Clustering techniques have been applied to the classification of suicidal behaviour by only a few investigators (Kiev, 1976; Henderson *et al*, 1977; Paykel & Rassaby, 1978; Katschnig & Fuchs-Robetin, 1984). In the present report, 493 cases of parasuicide were grouped by cluster analysis and the nosological characteristics and pattern of treatment disposal examined in each group. The prognostic value of the classification was assessed by the rates of repeated suicide attempts and of successful suicides, after a follow-up period of 1 year.

Method

Subjects

The sample comprised 485 patients, consecutively admitted to the poisoning treatment unit of a large university hospital in Munich. They fulfilled the criteria of parasuicide (Kreitman *et al*, 1969). Eight cases of drug experimentation, in whom the diagnosis of parasuicide was equivocal, were also included. The patients were representative of suicide attempters in Western European cities: a detailed description has been published elsewhere (Kurz *et al*, 1985).

Collection of data

Using a pre-coded data recording form, information was gathered on demographic characteristics, psychiatric history, pre-suicidal situation, circumstances of the suicide attempt and psychiatric diagnosis. Severity of intoxication was rated in accordance with the classification proposed by Reed *et al* (1952). A severe intoxication was defined by stages IV and V of this scheme or, where the operationalisation did not apply (e.g. in alkyl phosphate poisoning), was specified by high probability of lethal outcome without medical intervention. The Inpatient Multidimensional Psychiatric Scale (Lorr & Klett, 1967) was used for psychopathological evaluation. Psychiatric diagnoses refer to the German version of the International Classification of Diseases (ICD-9, Degkwitz *et al*, 1980). A personal follow-up investigation was performed 1 year after the key admission. Information on repeated suicide attempts and on completed suicides was obtained from 421 patients (85% of the sample).

Therapeutic management

Following initial psychiatric assessment, immediate crisis intervention was offered where appropriate. In addition to this treatment, outpatient psychotherapy or psychological counselling was considered necessary for most patients. Roughly one-fifth of the cases were referred for psychiatric hospital care; few patients were discharged without a treatment proposal. An account of the therapeutic management has been given by Möller *et al* (1984).

Selection of variables for cluster analysis

The set of input variables was adapted from Paykel & Rassaby (1978): of the original 14 items, ten could be matched on item content and scaling. The variable list covered age and sex, number of previous suicide attempts, frequency of suicidal intent in the past month (rated on a four-point scale), precautions against discovery (rated on a four-point scale), severity of intoxication (rated on a three-point scale), clinician's judgement of interpersonal motivation (e.g. appeal for help, rated on a five-point scale) and clinician's judgement of auto-aggressive motivation (intent-to-die, rated on a five-point scale), depression and hostility at initial assessment (percentage scores of the factors 'anxious intropunitiveness' and 'hostile belligerence' on the Inpatient Multidimensional Psychiatric Scale).

Clustering procedures

The data were analysed with the PKM program of the BMDP statistical software (Dixon, 1983); this uses a clustering technique which establishes mutually exclusive classes (Everitt, 1974). The procedure is composed of a hierarchical (divisive) and an optimising (hill-climbing) method. Starting from the initial set of individuals, the number of clusters is successively increased by the splitting of one group, until the pre-fixed number of clusters is reached; subsequently, cases are reassigned to the groups by iterative reallocation. The sum of squared distances serves as the clustering criterion. For the calculation of distance measures, the raw data were transformed to unit variance. In Tables I and III, the clustering results were retransformed to raw means and percentages. The number of clusters was chosen to be 3, 4 and 5; the three-group solution was selected for cross-validation. The original sample was divided in two subsets, each of which was subjected to the clustering procedure separately.

Discriminant function analysis

A discriminant function analysis was performed on the three-cluster solution to determine the quality of group separation and to assess the discriminant power of each input variable. The P7M program of the BMDP statistical software was used. Three linear classification functions were computed, serving to classify each case into one of the three groups. The percentage of correct allocation was examined by comparison with the original cluster composition.

Results

Three-group classification

Characteristics of the groups (Table I)

Compared to the total patient sample, group A was characterised by low mean age, more males, more previous suicide attempts, more suicidal pre-meditation and more hostility. Group B was distinguished by above-average mean age, more males, more precautions against discovery, more severe intoxications, low interpersonal and high auto-aggressive motivation, high depression and low hostility scores. The outstanding features of group C were low mean age, more females, low percentage of previous suicidal episodes, low rates of recent suicidal intent and of concealment, less severe intoxications, and high interpersonal and

Difference between groups significant at $P<0.001$ on nine variables (analysis of variance), on sex distribution significant at $P<0.01$ (χ^2).

low self-directed motivation. Differences between groups were statistically significant on all variables.

Cross-validation

The cluster triplets obtained from each subset were very similar and consistent with the original clusters; differences between groups were statistically significant on all variables except for sex distribution in both subsets.

Discriminant function analysis

A total of 96% of all cases could be correctly reclassified into the three clusters, which indicates that the groups were well separated. The variables that contributed most to the discrimination were the number of previous parasuicide episodes, the extent of precautions against discovery and the clinician's rating of interpersonal motivation.

Psychiatric diagnosis

Since psychiatric diagnosis was not included in the set of input variables, the nosological characteristics of the clusters were examined separately. A relatively high incidence of personality disorder (31%) was found in cluster A. In cluster B, neurosis, addictive behaviour and reactive disorder were equally frequent, each of these diagnostic categories accounting for one-quarter of the patients. Cluster C was distinguished from the two other groups by a high percentage of reactive disorders (44%).

Treatment disposal

From the above, differences in the therapeutic management of the groups can be suspected. This was confirmed by comparing the major categories of treatment disposal. Admission to psychiatric hospital was frequent in cluster A (44%) and was rare in cluster C (5%).

Follow-up data

To determine the prognostic relevance of the classification, the rates of repeated suicide attempts and of successful suicides within 1 year after key admission were calculated for each group (Table II). Further suicide attempts were three times as frequent in cluster A as in the remaining groups. The suicide rate was roughly 4% in clusters A and B, compared with only 0.4% in group C.

TABLE II

Three-group classification: outcome at 1-year follow-up

	Clusters					
	A		*B*		*C*	
	n	*%*	*n*	*%*	*n*	*%*
Patients who repeated suicide attempts	13	25.0	18	8.9	20	8.4
Patients who committed suicide	2	3.8	8	3.9	1	0.4

Five-group classification

When the number of clusters was increased successively, groups A and C remained fairly stable with their respective characteristics including psychiatric diagnosis, treatment disposal and follow-up data. The clusters which corresponded to A and C on the four- and five-group levels of analysis were not considered. Subdivision occurred in cluster B: in a first step, it was split into two groups, containing 88 and 154 patients, which were difficult to interpret. In a second step, the larger group was subdivided, while the

**Differences between groups significant at $P<0.01$ (χ^2).

minor group was retained. Eventually, three different patterns of suicidal behaviour were distinguished (Table III).

Characteristics of the groups

Group B1, the smallest in number, deviated from the remaining groups by a high mean age (75 years). Group B2 was discernible by long-standing suicidal pre-meditation and by a high depression score. Group B3 was distinguished by a sex ratio of 1:1 and by almost complete absence of suicidal pre-meditation. Differences between groups were statistically significant on all variables.

Psychiatric diagnosis

Relatively high rates of organic brain syndrome (21%) and of endogenous depression (14%) were found in group B1. Neurotic disorder was the most frequent diagnosis in group B2 (35%). In group B3, one-third of the patients were given the diagnosis of substance misuse or addiction.

Treatment disposal

In groups B1 and B2, all patients were referred to outpatient or inpatient psychiatric therapy, whereas no further treatment was considered necessary for 9% in group B3. The rate of admission to hospital was high in group B2 (44%) and low in group B3 (9%).

Follow-up data

In group B1, no further suicide attempts occurred, but the suicide rate was high (7.4%). In both other groups, roughly 10% of the patients had repeated parasuicidal acts and 3% had committed suicide.

Discussion

Did the classification make sense from a clinical point of view? Cluster A contained 11% of all patients and showed the known features of parasuicide repeaters (Batchelor, 1954; Kessel & McCulloch, 1966; Buglass & Horton, 1974; Kurz *et al*, 1982). According to the differentiation between serious and non-serious suicide attempts (Schmidt *et al*, 1954; Greer & Lee, 1967;McHugh & Goodell, 1971; Pallis & Birtchnell, 1977; Torhorst *et al*, 1983), cluster B, which comprised 41% of all cases, shared the characteristics of serious acts, while cluster C, which accounted for 48% of the cohort, was identified as a group characterised by non-serious suicidal behaviour.

These results are compatible with previous cluster analysis classifications of suicide attempts. Henderson *et al* (1977) distinguished a group of alienated hostile individuals, whose acts were highly operant, from a depressed alienated group with high life-endangerment, and from a third group, which could not be interpreted clinically. Paykel & Rassaby (1978) found a group taking overdoses, showing little risk to life, little psychiatric disturbance and more evidence of interpersonal rather than self-destructive motivation; a second group made more severe attempts, with more self-destructive motivation; and by violent methods rather than overdose, while a third group had previous histories of many attempts, made relatively mild attempts and were overtly hostile. Katschnig & Fuchs–Robetin (1984) described an 'appeal' group, characterised by low mean age, female sex, first-ever attempts and mild acts motivated by interpersonal conflict. The second group was interpreted as 'failed suicides' and was distinguished by high mean age, hard methods, and motives other than interpersonal friction. The third group – the 'chronic' cluster – was comprised of relatively young repeaters. There is remarkable agreement between the data of Paykel & Rassaby, Katschnig & Fuchs-Robetin and our own findings concerning the main properties of different types of suicidal behaviour, which adds to the evidence that the classification is more than a methodological artifact.

When the original sample of patients was broken down into four and five groups respectively, the clusters interpreted as repeaters and as non-serious attempts were slightly changed in size, but their characteristics were preserved – another point in favour of the consistency of these two clusters.

The prognostic relevance of the classification can be seen from the follow-up data. The cluster of repeaters turned out to be a high-risk group with respect to future attempts and completed suicides, while the cluster of non-serious acts was identified as a low-risk group. The suicide rate was higher in the serious than in the non-serious cluster. Katschnig & Fuchs-Robetin evaluated their classification in a 10-year follow-up study and found similar results. In their sample, no suicide occurred in the 'appeal' group, the suicide rate was 10.7% in the 'failed suicides' and 13.9% in the 'chronic' group; figures on repeated attempts were not reported.

The high rate of further suicidal behaviour in the repeater group is not surprising. There is general agreement in the literature that a history of multiple suicide attempts is associated with an increased risk of repetition and of suicide (Buglass & McCulloch, 1970; Bagley & Greer, 1971; Buglass & Horton, 1974; Morgan *et al*, 1976; Pino *et al*, 1979; Siani *et al*, 1979). In the present sample, however, the 'repeater' group involved less than one-half of the patients who had a history of suicidal behaviour prior to the key attempt; the remaining repeaters were dispersed among the other clusters. From this, it may be hypothesised that there are several subtypes of parasuicide repeaters, as suggested by Bancroft & Marsack (1977).

The difference in prognosis between the serious and non-serious groups requires attention, since discrepant data have been reported on this issue. Whereas Jansson (1962) found no association between the seriousness of suicide attempts and repetition, both Beck *et al* (1976) and Pierce (1981) demonstrated an increased probability of repeated attempts in serious compared to non-serious acts. According to Rosen (1976), patients who made serious attempts were more likely to commit suicide than were non-serious attempters. However, Pino *et al* (1979) failed to confirm this finding. The results of the present study strengthen the assumption that the seriousness of self-destructive behaviour, as judged from ratings of suicidal intent and of life-endangerment, is relevant to prognosis.

The follow-up data of five groups show that the probability of suicide was not evenly distributed within the original group of serious attempts. The elderly patients did not repeat parasuicides, but had a very high suicide rate; this finding is consistent with the fact that the suicide rate increases with age, while the probability of parasuicide is reduced (Kreitman, 1981). As a group, the elderly did not score higher on depression than did the patients who had made non-serious attempts, but this does not preclude an association between suicidal behaviour in old age and depression (Barraclough, 1971; Kockott, 1981). Looking at individual cases, one of the two elderly patients who committed suicide had been given the diagnosis of endogenous depression, and the second was an alcoholic.

The classification of suicide attempts into repeated, serious and non-serious acts, which follows both from previous cluster analysis investigations and from our data, is not novel. Indeed, it is familiar to clinical experience. However, the grouping by mathematical procedures demonstrates that the typology is an objective property of the complex phenomenon of suicidal behaviour, rather than a matter of intuitive judgement. The practical importance of the classification is implied in its relation to outcome: by allocating a patient to a particular behavioural pattern, the level of probability for future suicidal acts is determined, and therapeutic measures can be taken accordingly. Since the classification can be accomplished on a minimum of information, it may be helpful in the management of parasuicide patients, when rapid decisions have to be made. Our data suggest further that the discrimination of smaller and more specific subtypes of suicidal behaviour, such as suicide attempts in old age, may be valuable. More empirical evidence is desirable on this issue.

An American Validation Study of the Newcastle Diagnostic Scale

II. Relationship with Clinical, Demographic, Familial and Psychosocial Features

M. ZIMMERMAN, W. CORYELL, B. PFOHL and D. STANGL

We completed the Newcastle Diagnostic Scale on 152 unipolar depressed in-patients: its validity was supported by the findings that endogenous depressives were, in contrast to neurotic depressives, older, more severely depressed, with better social support, fewer life events, less personality disorder, and a lower morbid risk of alcoholism and antisocial personality in their first-degree relatives. The relationship between Newcastle scores and the morbid risk for alcoholism was non-linear, such that a cut-off score of 4, rather than 5, maximised the difference between the endogenous and neurotic groups with respect to familial alcoholism rates as well as other validating variables.

In 1972, research workers at Washington University, St Louis offered a five-phase paradigm to validate psychiatric diagnoses (Feighner *et al*, 1972). Their five phases of diagnostic validity were: clinical description, laboratory studies, delimitation from other disorders, family studies, and follow-up studies. The present paper is the second in a series in which we examine the validity of the Newcastle diagnostic scale (Carney *et al*, 1965) according to the Washington University model. Previously, we focused on the second phase of validity (laboratory studies), and reported a significant association between the Newcastle scale and results of the dexamethasone suppression test (DST) (Zimmerman *et al*, 1986*c*). Here, we report our results for the first and fourth phases of validity (clinical description and family studies).

The clinical description phase of validity refers to both the signs and symptoms of a disorder, as well as to demographic characteristics such as age, education, and sex ratio, and psychosocial variables such as life events, social support, and personality disorder diagnoses. Based on our survey of the literature of the 1920s and 1930s, before the discovery of effective antidepressant treatments, and on studies during the 1960s and 1970s examining the correlates of a clinical distinction between endogenous and neurotic depressives, we concluded that a valid operational definition of endogenous depression should identify a group of patients who, in contrast to neurotic depressives, are: older; more severely depressed; less likely to make a non-serious suicide attempt during their index episode; and have a more stable and well integrated lifestyle, as reflected by lower rates of premorbid personality disorder, fewer dysfunctional attitudes, lower frequencies of stressful life events during the year prior to hospital admission, lower frequency of marital separation and divorce, and better social support (Zimmerman *et al*, 1986*a*).

From a family history perspective, the literature suggested that endogenous depressives have a higher morbid risk for depression in their first-degree relatives and a lower frequency of familial alcoholism and antisocial personality. There is more empirical support for the alcoholism prediction than for the conventional wisdom that endogenous depressives have a higher familial rate of affective disorder. Three studies found a clinical diagnosis of reactive/neurotic depression significantly associated with a family history of alcoholism (Perris *et al*, 1982; Winokur, 1983; Winokur & Pitts, 1964). In a cluster analysis study, Andreasen & Grove (1982) found a significantly higher frequency of alcoholism in the families of patients in the non-endogenous than endogenous clusters.

Method

We approached a consecutive series of DSM-III major depressives aged 18 and older, admitted to the 58-bed psychiatry in-patient unit at the University of Iowa Hospitals and Clinics between June, 1982 and June, 1983. Because the research protocol included a DST, patients were excluded if they had any of the medical or pharmacological conditions specified by Carroll *et al* (1981), had insulin-dependent diabetes, or were taking carbamazepine.

A detailed description of our diagnostic procedures is given in Zimmerman *et al* (1986*c*). Because the unipolar/bipolar distinction is related to family history of affective disorder (Gershon *et al*, 1982) and to personality (Akiskal *et al*, 1983), only the 152 unipolar major depressives are described in this report.

Measures

Two of the authors (D. S., M. Z.) completed the 17-item Hamilton Rating Scale for Depression (HAMD; Hamilton, 1967), Beck Depression Inventory (BDI; Beck *et al*, 1979), and the Global Assessment Scale (GAS; Endicott *et al*, 1976) within one week of admission ($\bar{x}=2.5$ days after admission). Sucidal ideation and behaviour during the index episode were also recorded; judgements about the seriousness of suicidal behaviour reflected both the medical lethality and seriousness of intent of the attempt. The raters (B. P., W. C.) followed the SADS (Spitzer & Endicott, 1978) guidelines and a serious attempt would be rated 4 or above on SADS items 249 or 250.

The life event instrument was the 152-item Positive and Negative Impact (PANI) life event interview (Zimmerman *et al*, 1986*b*). A unique feature of the PANI is that it incorporates all the items from the two widely used life event scales developed by Paykel *et al* (1971) and by Tennant & Andrews (1976). In the present study, we compared endogenous and neurotic depressives on the total number of events experienced on the PANI, Paykel, and Tennant scales. In addition, we compared the groups on two event subcategories that the New Haven group found to be important in distinguishing depressed patients, suicide attempters, schizophrenics, and normal controls (Jacobs *et al*, 1974; Paykel *et al*, 1975): exits from the social field (e.g. deaths, divorce, child leaves home) and undesirable events. Finally, the interviewer rated the degree to which each event's occurrence might be the result of the patient's behaviour (i.e. event independence); e.g. an event such as divorce would usually be rated as non-independent, because it could be due to the depression. Death of a spouse, in contrast, would be rated as independent of the patient's behaviour.

Personality disorder diagnoses were made using the Structured Interview for DSM-III Personality Disorder (SIDP, Pfohl *et al*, 1982). This instrument includes a 90-minute interview with the patient and a 30–60 minute interview with a knowledgeable informant – a parent, spouse, sibling, or close friend. With the SIDP, our chance-corrected inter-rater reliability (kappa) for the presence or absence of personality disorder was 0.71 in joint interviews and 0.66 in independent interviews (Stangl *et al*, 1985).

Social support was rated on the four-point scale developed by Brown & Harris (1978). The essence of this rating is whether the respondent has at least one close, confiding, intimate relationship, and if so, how frequent are the interactions between the respondent and the confidant.

We used the Dysfunctional Attitudes Scale (DAS) to assess cognitive distortion (Weissman, 1980). This is a 40-item scale designed to measure the degree to which individuals endorse the attitudes hypothesised by cognitive theory to be associated with depression (Beck, 1972).

Family history diagnoses were based upon information collected from the patient, and are described in greater detail by Zimmerman *et al* (1985). Briefly, each relative was diagnosed twice – according to both a low and a high diagnostic threshold. Our low-threshold diagnoses were based on a strict interpretation of the Family History Research Diagnostic Criteria (FH-RDC; Endicott *et al*, 1978) whilst our high-threshold diagnoses required hospital admission for depression and treatment for alcoholism.

Data analysis

Morbid risks were calculated with age-corrected denominators or Bezugsziffers (BZs) by the Weinberg shorter method. Thus, relatives over the age of risk for the particular illness were given a value of 1; those within the age risk were given a value of 1/2; and those below it given a value of 0. Limits for these ages of risk for depression, alcoholism, and antisocial personality were 15 to 59, 20 to 39, and 20 to 39 respectively (Tsuang *et al*, 1984). Morbid risks were compared according to the method proposed by Breborowicz & Trzebiatowski-Trzeciak (1976), which modifies the χ^2 statistic to accommodate the statistical artifacts introduced by age correction in the denominators of the morbid risk calculations. We used the χ^2 statistic for other categorical comparisons and the *t*-test for comparisons of continuous variables.

Results

The majority of the 152 patients were female (109/152), high school graduates (122/152), and had one or more prior psychiatric hospital admissions (103/152); one-quarter (40/152) of the sample were separated or divorced. The mean scores on the rating scales completed during the first week of admission reflect a moderate-severe level of symptoms (HRS 22.5±6.4; BDI 27.8±11.2; GAS 38.9±8.7). The Newcastle scores ranged from −2 to 12 ($\bar{x}=4.79$, S.D.=2.6). Figure 1 shows that the scores were normally distributed.

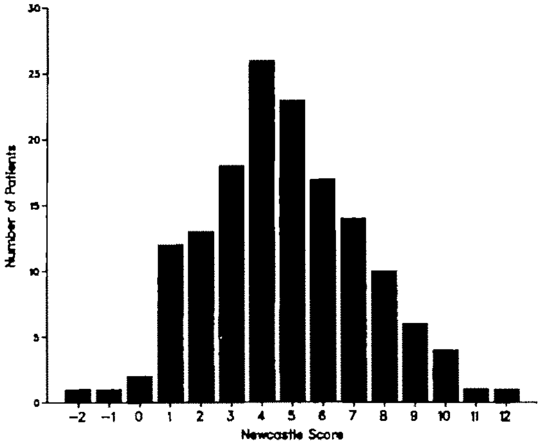

FIG. 1 Distribution of Newcastle scores in 152 unipolar depressed in-patients.

Family history

Kendell (1982) suggested that two syndromes, such as endogenous and neurotic depression, can be distinguished by demonstrating a non-linear relationship between symptomatology and some independent variable such as treatment response, family history, or a laboratory measure. The association between Newcastle scores and the morbid risk for FH-RDC alcoholism is non-linear (Fig. 2). (An identical relationship was also found with the narrower definition of treated alcoholism). This suggests that a cut-off of 4 should be used to distinguish endogenous and neurotic depression. The morbid risk for alcoholism was 2.5 times greater in the 26 patients with a Newcastle score of 4 than in the 23 patients with a score of 5 (11.7% *vs* 4.6%, $P<0.06$). The difference in familial rates of alcoholism between endogenous and neurotic depressives is greater with a cut-off of 4 in contrast to the conventional cut-off of 5 (Table I).

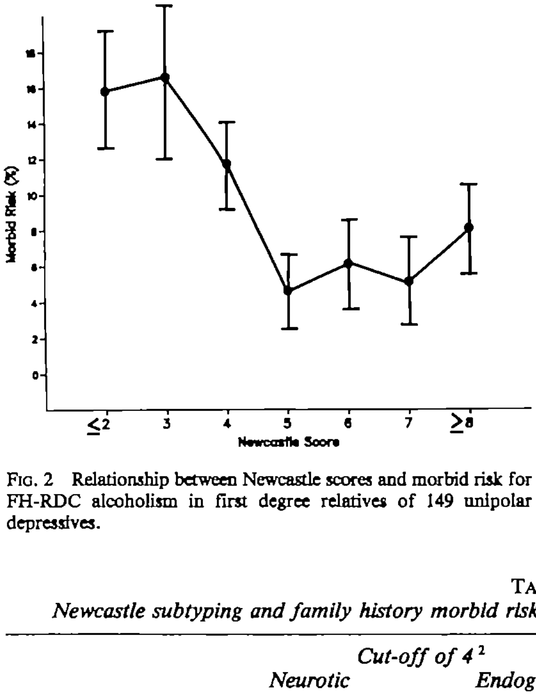

FIG. 2 Relationship between Newcastle scores and morbid risk for FH-RDC alcoholism in first degree relatives of 149 unipolar depressives.

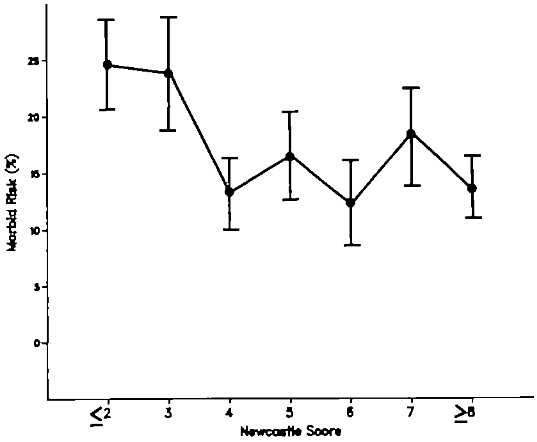

FIG. 3 Relationship between Newcastle scores and morbid risk for FH-RDC depression in first degree relatives of 149 unipolar depressives.

Inconsistent with our prediction, endogenous depressives had a *lower* morbid risk for affective disorder (Table I). Neurotic and non-endogenous depression cannot be clearly separated based on a family history of depression (Fig. 3).

Finally, we found that a family history of antisocial personality was greater in the neurotic depressives, although this was significant only when a cut-off of 4 was used (Table I). There were too few antisocial relatives ($n = 10$) to search for a point of discrimination between endogenous and neurotic depression.

In our previous report on the relationship between the Newcastle Scale and the DST, our results suggested that a cut-off of 4 was more valid than the conventional point of 5. The present findings for familial alcoholism rates are consistent with the DST analysis. In the remainder of the paper, we use both cut-offs in examining the relationship between Newcastle diagnosis and demographic, clinical, and psycho-social variables. The Newcastle-4 scale will refer to

$^{*}P<0.05$; $^{**}P<0.01$

dichotomisation about a cut-off of 4, whereas the Newcastle-5 scale refers to the traditional diagnosis based on a cut-off of 5.

Demographic and clinical characteristics

Newcastle diagnosis was not significantly associated with sex ratio or level of education. Newcastle-4 neurotic depressives were significantly more likely to be separated or divorced at the time of the index admission (34.2% *vs* 19.0%, $P<0.05$). Newcastle-5 diagnosis was similarly associated with current marital separation or divorce (31.2% *vs* 17.9%, $P<0.10$). Endogenous depressives were significantly older than neurotics according to both scales (Newcastle-4 44.4 ± 17.1 *vs* 34.4 ± 13.2, $P<0.001$; Newcastle-5 46.7 ± 17.7 *vs* 35.5 ± 13.5, $P<0.001$).

Baseline HRS and BDI scores were significantly higher, and GAS scores significantly lower (which indicates greater severity), in endogenous depressives (Newcastle-4 HRS 24.6 ± 5.2 *vs* 20.2 ± 6.8, $P<0.001$; BDI 30.1 ± 10.8 *vs* 25.6 ± 11.3; GAS 35.0 ± 6.2 *vs* 43.1 ± 9.2; Newcastle-5 HRS 25.3 ± 5.0 *vs* 20.9 ± 6.6; BDI 31.6 ± 10.8 *vs* 25.8 ± 10.0; GAS 34.1 ± 6.0 *vs* 41.7 ± 8.9). Serious suicide attempts were equally frequent in endogenous and neurotic depressives; however, non-serious suicide attempts were more frequent in neurotic depressives (Newcastle-4 39.7% *vs* 5.1%, $P<0.001$; Newcastle-5 31.3% *vs* 5.4%, $P<0.001$). Approximately 90% of the 33 non-serious suicide attempers were neurotic depressives.

Psychosocial variables

Life events

The PANI semi-structured life event interview was completed on 128 (84.2%) patients. There was no association between Newcastle diagnosis and interview completion. Neurotic depressives reported significantly more events during the year prior to admission (Table II). In general, the relationship between Newcastle diagnosis and life events was similar for both cut-offs. The relationship between subtyping and stress was stronger for non-independent events than for events independent of the patient's behaviour.

Social support

The rating of confidant support based on Brown & Harris' (1978) method was available for 142 (93.4%) patients. Individuals with an 'A' rating on this scale have a close, intimate, and confiding relationship with their spouse, boyfriend/girlfriend, or other friend with whom they are sharing a residence. Newcastle-4 endogenous depressives were significantly more likely to have an 'A' rating than Newcastle-4 neurotic depressives. The Newcastle-5 scale was not significantly associated with the rating of confidant support (Table III).

Personality disorder

Of 89 patients interviewed with SIDP, half received at least one DSM-III Axis II personality disorder. The frequency

TABLE III

Social support, personality disorder, and dysfunctional attitudes in Newcastle subtypes

	Cut-off of 4		*Cut-off of 5*	
	Neurotic	*Endogenous*	*Neurotic*	*Endogenous*
'A' rating on Brown & Harris' social support scale: %[1]	20.0	38.9**	26.4	35.3
DSM-III personality disorder: %[2]	64.2	30.5**	60.3	26.9**
Dysfunctional attitude scale,[3] $\bar{x}$: s.d.	143.9 (41.1)	144.4 (38.0)	142.4 (39.3)	146.9 (40.0)

1. Based on a cut-off of 4, 95.9% (70/73) neurotic and 91.1% (72/79) endogenous patients were interviewed.
   Based on a cut-off of 5, 94.8% (91/96) neurotic and 91.1% (51/56) endogenous depressives were interviewed.
2. Psychotic patients were not administered the SIDP. In our previous paper we reported that in contrast to neurotic depressives significantly more endogenous patients had delusions and/or hallucinations (Zimmerman *et al*, 1986*c*). Thus it is not surprising that SIDPs were more frequently administered to the neurotic patients (Newcastle-4: 72.6% (53/73) vs 45.6% (36/79), $\chi^2 = 11.4$, $P < 0.001$; Newcastle-5: 65.6% (63/96) vs 46.4% (26/56), $\chi^2 = 5.37$, $P < 0.05$).
3. Based on a cut-off of 4, 41.1% (30/73) neurotic and 35.4% (28/79) endogenous patients completed the DAS.
   Based on a cut-off of 5, 37.5% (36/96) neurotic and 39.3% (22/56) endogenous patients completed the DAS.

of each specific diagnosis is presented elsewhere (Pfohl *et al*, 1984). As diagnosed by both Newcastle scales, neurotic depressives were significantly more likely to have a personality disorder (Table III). The relationship between Newcastle subtyping and personality disorder diagnoses is partially confounded because the adequate personality item on the Newcastle scale was influenced by the SIDP results. We recomputed each patient's Newcastle score, based upon the remaining nine items. Using the same cut-offs as the ten-item scale, we found that the relationship between the corrected Newcastle diagnoses and personality disorder was still significant.

Cognitive distortion

Newcastle subtyping was unrelated to DAS scores (Table III). Several studies have recently suggested that depressives' cognitive style normalises after depressive symptoms resolve (Eaves & Rush, 1984; Simons *et al*, 1984). If the DAS is more of a state characteristic of all depression than a trait marker for certain types of depression, then the lack of association between the Newcastle scale and DAS scores should have been expected.

Discussion

Though the Newcastle diagnostic scale was published almost 20 years ago, its validity has only recently received much attention. Renewed interest in it has paralleled the growing literature on biological markers of endogenous depression. The most frequently examined biochemical correlate of Newcastle subtyping is the dexamethasone suppression test (DST). Similar to our previously reported results, six other studies found significantly higher DST non-suppression rates in endogenous depressives (McIntyre *et al*, 1981; Coppen *et al*, 1983; Kasper & Beckmann, 1983; Holden, 1983; Davidson *et al*, 1984*a*; McKeith, 1984); two negative findings have also been published (Ames *et al*, 1984; Klein *et al*, 1984). Two studies reported that endogenous depressives are older (Kiloh & Garside, 1963; Abou-Saleh & Coppen, 1984), though a third (Davidson *et al*, 1984*b*) found no age differences between the groups. Two studies found that endogenous depressives have higher symptom severity scores (Davidson *et al*, 1984*b*; Klein *et al*, 1984). The only study other than our own which examined the patients' family history of depression found no differences (Abou-Saleh & Coppen, 1984). No previous studies compared familial alcoholism rates, nor are we aware of any studies which examined psychosocial characteristics such as life events and social support.

Our results suggest that the Newcastle diagnostic scale is a valid discriminator of endogenous and neurotic depressives respectively. Consistent with our predictions, endogenous patients were characterised by greater severity of symptoms, older age, better social support, fewer life events, less personality disorder, and a lower familial rate of alcoholism and antisocial personality. In contrast, neurotic depressives were younger, less severely depressed patients who in many cases had been admitted to hospital after a non-serious suicide attempt, and had a more stormy and disruptive lifestyle, as reflected by more life events (particularly the types of events that may have been caused by the individual rather than those occurring outside of the individual's control), poorer social support, and more personality disorder, as well as a higher morbid risk of alcoholism and antisocial personality in their first-degree relatives.

Since the 1920s, European psychiatrists have debated whether endogenous and neurotic depressives are clearly distinct subtypes. These debates have often centered around the form of the frequency distribution of symptom scores – a bimodal distribution of scores being interpreted as support for the two-type thesis. A bimodal distribution of Newcastle scores has been found only by Carney *et al* (1965) and by Carney & Sheffield (1972). The unimodal distribution of scores we found is consistent with the results of other research groups (Abou-Saleh & Coppen, 1984; Bech & Rafaelsen, 1980; Kendell, 1968). Kendell (1982), however, indicated that support for typological classification is also provided by demonstrating a non-linear relationship between symptomatology and an independent variable such as treatment response, family history, or a laboratory measure. We have found two such relationships – one between Newcastle scores and the morbid risk for alcoholism in first-degree relatives, and the other between Newcastle scores and rates of DST non-suppression (Zimmerman *et al*, 1986*b*). Both analyses found that a cut-off of 4 was the optimal point of discrimination between neurotic and endogenous groups. In their study of the DST and the Newcastle scale, Davidson *et al* (1984*a*) also reported that a cut-off of 4 was superior to the conventional point of 5.

Our one major negative finding was the failure to validate Newcastle subtyping with familial depression rates: in fact, the results were contrary to initial expectation, with the neurotic depressives having a significantly higher morbid risk of depression. The conventional wisdom that endogenous depression is more genetic than neurotic depression may be incorrect. Just as there are genetic components to antisocial personality (Crowe, 1974) and anxiety disorders (Torgersen, 1983), the aetiology of neurotic depression probably involves an inherited component. Neurotic and endogenous depression may be equally genetic; but neurotic depression may be more familial. The results of our study suggest that neurotic depression is associated with more environmental chaos and disruption; therefore, perhaps we should expect a higher rate of depression in relatives of neurotic depressives because they are exposed to both genetic and psychosocial insults, whereas the relatives of endogenous depressives are only genetically predisposed. For example, the children of neurotic depressives may be psychosocially vulnerable to (neurotic) depression because their parents separated or divorced. Consistent with this, Brown & Harris (1978) found that early parental loss due to separation was associated with a clinical diagnosis of neurotic rather than endogenous depression. It will be necessary to turn to twin and adoption studies in order to better partial out the relative effects of genetic and psychosocial determinants of depressive subtypes.

An Evaluation of the Performing and Recording of Physical Examinations by Psychiatric Trainees

J. C. RIGBY and A. G. OSWALD

The physical examination on admission, as recorded in the psychiatric case notes, was assessed for 100 consecutive admissions under the age of 65. Assessment was made on the presence or absence of reference to 43 items of examination and the recording of the examinations was found to be uniformly poor. One of the authors re-examined 50 patients within 48 h of admission and the findings were then compared with the initial recorded examination. Significant unrecorded positive findings were most frequent in the neurological and locomotor systems.

It has been demonstrated that psychiatric and physical disorders occur together more than by chance combination. Herridge (1960) and Kellner (1966) have shown that physical illness often precedes psychiatric disorder and Lovett Doust (1952) found that psychiatric patients experienced more physical illness than healthy controls, with psychotic patients suffering more than those in whom the diagnosis was a neurosis or personality disorder. In a general practice survey with a cohort in excess of 14 000, Shepherd *et al* (1966) confirmed the high incidence of physical illness in psychiatric populations and Koryani (1972), found almost 50% of a study of 100 consecutive out-patient attenders to have 'significant physical illness', of which it was thought to be the direct cause in half. That this extends to psychiatric inpatients was demonstrated by Maguire & Granville-Grossman (1968) who, in 200 consecutive admissions to a psychiatric hospital found 57 with physical disorder, half of which had not previously been diagnosed.

Thus, psychiatrists often meet physical disorder in their psychiatric population, and psychiatrists in training need, and are expected to, regularly exercise their physical skills. Increasingly however, trainees begin to specialise immediately on registration and therefore have limited opportunity to consolidate these medical skills. The present study assesses how adequately physical examinations are recorded, and whether or not they satisfactorily identify physical disorder.

Method

The psychiatric case notes of 100 consecutive admissions under the age of 65 were obtained and the record of the physical examination on admission was rated on the presence, or absence, of reference to a 43-item check list based on the standard admission document of the professorial medical unit. The maximum score for each recorded physical examination was thus 43. For each individual item, e.g. finger clubbing, carotid bruits, it was then noted in how many of the 100 case notes it was referred to, thus giving a score of 0–100 in each item.

Of the 100 consecutive admissions, alternate patients were re-examined by one of the authors (J.C.R.) within 48 h of admission, and the positive findings compared with the admission record. To avoid any discomfort to the patients concerned, pelvic examination was excluded in all cases, although both external genitalia and perianal areas were examined. Measurement of blood pressure was similarly excluded, as its magnitude may be altered significantly by changing mental state, and it was felt that this would make interpretation of the findings difficult. Although none of the patients refused examination for research purposes, two were judged sufficiently psychiatrically disturbed so as to make meaningful examination impossible without sedation, and in these cases the next two consecutive admissions were examined. Thus 50 patients were examined, 21 males and 29 females.

Results

The 100 recorded physical examinations were scored using the 43-item check list, and the average number of items referred to was 20. The range was 11–37. For each item of examination the number of admission records which referred to it, either positively or negatively, is recorded in Table I. The items are grouped into the bodily systems to which they appertain, and listed in order of the frequency to which they were referred.

For the 50 patients re-examined, 54 abnormalities were found, of which 32 were recorded in the notes. Table II records, for each item of examination, the discrepancies between the number of positive findings made by J.C.R.,

TABLE I

Checklist and frequency of reference to each item in the admission record

General observation		*Cardiovascular system*	
Nodes	74	Pulse rate	100
Anaemia	62	BP	96
Cyanosis	57	Heart sounds	95
Jaundice	53	Murmurs and added sounds	76
Clubbing	41	Jugular venous pressure	63
Breasts	21	Pulse rhythm	63
Goitre	19	Dependent oedema	54
		Apex beat	27
		Carotid bruits	15
		Peripheral pulses	4
Respiratory system		*Alimentary system*	
Breast sounds	74	Scars	65
Additional sounds	69	Tenderness	59
Percussion	68	Masses	57
Trachea	53	Organomegaly	55
Chest movements	42	Rectal examination	22
Respiratory rate	12	Genitals	19
		Hernial orifices	14
		Bowel sounds	5
Neurological system		*Locomotor system*	
Pupils	86		1
Reflexes	85		
Fundi	59		
Power	59		
Sensation	54		
Tone	51		
Cranial Nerves	40		
Co-ordination	34		
Abnormal Movements	22		
Gait	6		
Meningism	0		

and those made by trainees at the initial examination.

Of those patients re-examined, general observation revealed two cases of finger clubbing and one of goitre, all of which had been noted initially, although one case of clinically apparent anaemia (subsequently confirmed by an Hb of 9g) was missed. No cases of lymphadenopathy, jaundice, cyanosis or breast abnormalities were found at either examination.

In the cardiovascular system two findings of atrial fibrillation, two cardiaic murmurs, and one of dependent oedema were made at both examinations, and one case of absent peripheral pulses was found at re-examination but not recorded in the admission record.

In the respiratory system five cases of added sounds were noted at both examinations and no other positive findings made.

In the gastronintestinal system one case of hepatomegaly was noted both on admission and at re-examination, as was one case of inguinal hernia. Another inguinal hernia was missed, and only seven of 13 abdominal scars were noted.

Neurologically, one case of unequal pupils and two of limb weakness were noted at both examinations. Although one case of tardive dyskinesia, presenting as choreoathetotic limb movements, was recorded on admission, two orobucco-lingual tardive dyskinesias were not. Concerning drug-induced parkinsonism, five cases were observed at re-examination. All had increased tone, three had tremor, and there were two with a typical parkinsonian gait. Of these, three cases of rigidity were not recorded, as were one each of tremor and gait abnormality. The diagnosis of drug-induced parkinsonism was made in only two of five cases.

In the locomotor system, re-examination revealed one case each of severely disorganised hand joints (rheumatoid arthritis), marked unilateral lower limb deformity (old trauma), hip movements markedly limited by pain, and frozen shoulder, none of which had been noted initially. Dupuytren's contracture was noted in both examinations on one occasion.

TABLE II

Discrepancies between initial examination and re-examination

Item	*Positive findings made by trainees*	*Positive findings made by J.C.R.*	*Number of discrepancies*
Clubbing	2	2	0
Goitre	1	1	0
Anaemia	0	1	1
Pulse rhythm	2	2	0
Cardiac murmurs	2	2	0
Dependent oedema	1	1	0
Peripheral pulses	0	1	1
Additional chest sounds	5	5	0
Hepatomegaly	1	1	0
Hernial orifices	1	2	1
Abdominal scars	7	13	6
Pupillary abnormalities	1	1	0
Muscle power	2	2	0
Tardive dyskinesias	1	3	2
Muscle tone	2	5	3
Drug induced tremors	2	3	1
Parkinsonian gait abnormalities	1	2	1
Other gait abnormalities	0	2	2
Locomotor abnormalities	1	5	4

Discussion

The records made of physical examinations on admission often seem to have significant deficiencies. On average, reference was made to only 20 items of the 43-item check list, and many items were regularly omitted. Breasts, goitre, carotid auscultation, peripheral pulses, respiratory rate, rectal examination, hernial orifices, bowel sounds, abnormal movements, gait, meningism, and the locomotor system were items particularly seldom referred to.

Where positive findings are not made, it is of some importance to have documented that they have at least been looked for. Only by such documentation may the line be drawn between negligence and clinical error. Not only for such medicolegal reasons is recording of negative findings as important as that of positive findings, but also for purely medical reasons. Should positive findings be made, it is of importance to know whether these are of recent onset, or long-standing and present at previous examinations.

In this study, re-examination was carried out in most circumstances under optimal conditions, with no pressure of time, and on patients who were probably more co-operative than they had been at the time of the initial examination. Although the re-examination was carried out without reviewing the admission record first, i.e. it was blind, no abnormality of any system was found on the first occasion that was not noted on the second.

The discrepancies between the initial examination and the re-examination were most marked in the neurological and locomotor systems. Drug-induced parkinsonism had not been noted in three of five cases, and tardive dyskinesia in two of three cases. On none of these occasions had medication been altered between the time of the initial examination and the re-examination, and the discrepancies are therefore likely to have resulted from a failure to recognise the clinical signs. Of four significant gait abnormalities, (two resulting from parkinsonism, and two from other locomotor abnormalities) found at re-examination, only one was documented at the initial recording. In the examination of the neurological system, trainees clearly need to pay more attention to muscle tone, gait, and the presence of abnormal movements.

The discrepancies in the findings of the locomotor system seem to have resulted from failure to examine joints, to test movements adequately, and again from inadequate observation of gait.

Comparing Table II with Table I, it would seem that, for the neurological and locomotor systems particularly, low rates of recording, e.g. of muscle tone, abnormal movements, and gait, are accompanied by significant discrepancies between the initial examination and the re-examination. This also remained true for the other systems for, with the exception of anaemia and abdominal scarring (both of which were well recorded), discrepancies occurred in those areas least well documented e.g. peripheral pulses and hernial orifices.

It appears therefore, that it is among the more poorly recorded items that positive findings are most often missed. The encouraging of a more complete recording may thus also encourage a more complete and therefore successful examination. Further work is required to investigate whether, for example, the provision of a standard typed record, allowing space for the description of signs in each system, would achieve this end.

Five Risk Factors for Depression

A. ROY

Significantly more of 300 patients with non-endogenous depression compared with 300 matched controls were unemployed and had a poor marriage before the onset of depression, had a first-degree relative who had been treated for depression, had experienced separation for one year or more from a parent before 17 years of age and had three or more children under 14 years of age at home. However, significantly more of 44 patients with endogenous depression, than their 46 controls, also had a poor marriage before the onset of depression and 43% of them had a first-degree relative who had been treated for depression. Thus a family history of depression and a poor marriage before the onset of depression are associated with both non-endogenous and endogenous depression but unemployment, separation for one year or more from a parent before 17 years of age, and having three or more young children at home may be risk factors for non-endogenous depression.

In a community study, Brown & Harris (1978) described four vulnerability factors which increased the chances of a woman developing depression in the presence of a life event or difficulty. They were: lack of full-time or part-time employment, lack of a good marital relationship, the presence of three or more children under 14 years at home, and parental loss before 17 years of age. In psychiatric patients, when compared to medical patient controls, these four factors along with a fifth – depression in a first-degree relative – have been previously reported to be significantly associated with non-endogenous depression (Roy, 1978, 1981*a*,*b*). However, the specificity of these factors for the non-endogenous subtype of depressive disorder has not been examined. Thus the purpose of this final report is to examine these risk factors in subtypes of depressive disorder by presenting the data as found in (a) this large gradually accumulated series of 300 patients with non-endogenous depression compared to their 300 matched normal controls and in (b) a consecutive series of 44 patients with endogenous depression compared to 46 normal controls.

Method

From July 1976 to June 1982 300 white patients meeting DSM-III criteria for a major depressive episode (MDE) without melancholia were seen (Diagnostic and Statistical Manual of Mental Disorders, 1980). Before DSM-III draft criteria became available the International Classification of Diseases (1965) category 3000.4, depressive neurosis was used. All of these patients would have met DSM-III criteria for MDE without melancholia and, in fact, had to have had a duration of depression of at least one month to be studied – twice the duration criterion in DSM-III. Few patients were seen with bipolar or psychotic depression or melancholia ('endogenous' depression) and thus were excluded as were patients with secondary depression. These 300 patients are the 'non-endogenous' sample.

The first 84 patients were all female patients seen at the Maudsley and Dulwich Hospitals in London. The remaining 216 depressed patients were seen at the Clarke Institute of Psychiatry, Toronto. All 300 patients were matched for age (within 5 years), sex, marital status, social class and country with non-depressed and never-depressed gynaecological and orthopaedic patients seen at Dulwich Hospital or clinics of the Wellesley or Orthopaedic and Arthritic Hospitals, Toronto. The General Health Questionnaire (GHQ) (Goldberg, 1972), followed by a short psychiatric interview, was used to screen out potential controls with depression or other psychiatric disorder.

From July 1982 to June 1985 a consecutive series of 44 white in-patients with endogenous depression (296.2, ICD) who met DSM-III criteria for a major depressive episode with melancholia was collected at the National Institute of Mental Health (NIMH), in Bethesda, Maryland, and are the 'endogenous' sample. They were compared with (a) 46 normal controls recruited through the NIMH normal volunteer office; and (b) with the 27 of these 46 controls with whom they could be matched for age, sex and marital status. Controls were interviewed with the Schedule for Affective Disorders and Schizophrenia (SADS-L) (Endicott & Spitzer, 1979) and had no past, current or family history of psychiatric disorder.

All 690 subjects were asked by the same interviewer about age, marital status, the occupation of the head of the household, whether they were in full- or part-time employment (at the onset of depression), about early parental loss because of death or separation for one year or more between 0 and 17 years of age, whether there was a first-degree relative treated for depression by a psychiatrist, and whether there were three children under 14 years of age at home (earlier papers reported three children 14 years or younger). The duration of depression and the Hamilton depression score (1960) were recorded. For married (or cohabiting) subjects a semi-structured marital interview was performed, using the method of Quinton *et al* (1976), covering the year before the onset of depression (or the year before for controls). Ratings 1–3 were called 'good marriage' and ratings 4–6 'poor marriage'. Two reliability studies of the marital interview were performed (Roy, 1978, 1981*a*). (The marriages of the first 16 depressed patients were not assessed.) Social class was determined using the occupation of the head of the household and the classification of occupations of Goldthorpe and Hope (1974); 1–22 was called middle class and 23–36 working class.

In the statistical analysis the χ^2 and Fisher's exact test were used and possible interactions were examined for using linear model analysis (Grizzle *et al*, 1969).

Results

The demographic data and clinical variables are shown in Table I.

Non-endogenous depression

Unemployment before onset of depression

Significantly more depressed patients than controls were unemployed before the onset of depression (104 vs 57, $P<0.0001$) (Table II). Significantly more of both the total group of Canadian ($n=216$) and British ($n=84$) depressed patients than controls were unemployed (71 vs 39, $P<0.01$; 33 vs 18, $P<0.0006$, respectively). Significantly more of both the total group of working-class ($n=129$) and female working-class ($n=88$) depressed patients were unemployed (63 vs 31, $P<0.0001$; 50 vs 24, $P<0.0001$, respectively).

Poor marriage before onset of depression

Significantly more depressed patients than controls had a poor marriage before the onset of depression (94 vs 13, $P<0.0001$) (Table II). Significantly more of both the total group of working ($n=53$) and middle-class ($n=51$) female depressed patients than controls had a poor marriage (36 vs 6, $P<0.0001$; 33 vs 2, $P<0.0001$, respectively).

Among the married English depressed 14 of 32 (44%) working-class and four of 16 (25%) middle-class patients were unable to confide in their spouse compared with 0 and 0 of controls ($P<0.0001$ and NS). Among the married Canadian depressed 16 of 36 (44%) working-class and 14 of 55 (26%) middle-class patients were unable to confide in their spouse compared with 1 (3%) and three of controls ($P<0.0001$ and $P<0.008$, respectively).

Three or more children under 14 years at home

Significantly more depressed patients than controls had three or more children under 14 years of age living at home (17 vs 8, $P<0.05$) (Table II).

Depression in a first-degree relative

Significantly more depressed patients than controls had a first-degree relative treated for depression (77 vs 30, $P<0.0001$) (Table II).

Early parental loss

The detailed data about early parental loss because of permanent separation or death has been previously

TABLE I
Demographic data and clinical variables

	Non-endogenous depressed patients (n=300)	*Endogenous depressed patients (n=44)*	*Controls for endogenous patients (n=46)*
Female	207 (69%)	37 (84%)	28 (61%)
Male	93 (31%)	7 (16%)	18 (39%)
Married	155 (51.7%)	31 (71%)	29 (63%)
Single	91 (30.3%)	4 (9%)	13 (28%)

Non-permanent separation from parent(s) for at least one year or more before 17 years of age	33	8	<0.0001	9	2	NS	42	10	<0.0001

TABLE III

Risk factors in patients with endogenous depression compared to normal controls

	Total groups			*Groups matched for age, sex, and marital status*		
	Depressed (n=44)	*Controls (n=46)*	*Sig. P*	*Depressed (n=27)*	*Controls (n=27)*	*Sig. P*
Unemployed before onset of depression	19	7	<0.007[1]	9	3	NS[1]
Poor marriage before onset of depression	15/31	4/29	<0.009	10/20	3/20	<0.04
Three children under 14 years	2	5	NS	2	4	NS
Depression in first-degree relative	19	NA[2]		14	NA[2]	
Parental death before 17 years of age	5	5	NS	3	3	NS
Permanent separation from parent(s) before 17 years of age	2	1	NS	2	1	NS
Non-permanent separation from parent(s) for at least one year or more before 17 years of age	1	2	NS	1	1	NS

Mean age of matched depressed patients, 20 female and 7 male, was 41.3 years and of controls 40.6 years; six patients and four controls were working class.

[1] Fourteen of the total 46 and 9 of the 27 matched controls were hospital employees.

[2] NA is not applicable. Controls were selected for biological studies thus those with a family history of psychiatric disorder were excluded. However, 30 of the 300 non-endogenous controls (10%) had a depressed first-degree relative (Table II) and if 10% of these controls had such a relative there would be significant differences.

published (Roy, 1983, 1985). Significantly more depressed patients than controls had permanent separation from a parent before 17 years of age (66 vs 19, $P<0.0001$) (Table II). In 14 patients (4.7%) this was separation from both parents compared with three controls (1%) ($P<0.01$). There were no significant differences for early parental death.

Significantly more depressed patients than controls had non-permanent separation of or from parents for at least one year or more before 17 years of age (42 vs 10, $P<0.0001$). Sixteen of these 42 depressed patients and three of these control patients also had experienced a permanent loss (either parental death or permanent parental separation). Thus only 26 of the depressives with non-permanent loss had experienced no permanent loss as had seven of these ten controls ($P<0.001$).

The linear model analysis revealed no significant interactions between any of the five factors in any group.

Endogenous depression

Unemployment before onset of depression

There was no significant difference in the matched comparison.

Poor marriage before onset of depression

Significantly more depressed patients than controls in both total and matched groups had a poor marriage before the onset of depression ($P<0.009$ and $P<0.04$, respectively) (Table III).

Three or more children under 14 years at home

There were no significant differences (Table III).

Depression in a first-degree relative

Nineteen of the total 44 (43.2%) and 14 of the 27 (51.9%) matched depressed patients had a first-degree relative treated for depression. However, their controls were selected for biological studies and those with a family history of psychiatric disorder were excluded (Table III).

Early parental loss

There were no significant differences for either parental death or permanent or non-permanent separation before 17 years of age (Table III).

Discussion

This final study reports on 344 depressed patients and 346 controls seen over 9 years by one investigator. Significantly more non-endogenous depressed patients than controls were unemployed and had a poor marriage before the onset of depression, had a family history of depression, had three children under 14 years of age at home, and had experienced permanent separation from a parent before 17 years of age. Only two of these five factors, poor marriage before the onset of depression and a family history of depression, were found significantly more among patients with endogenous depression than controls.

Being unemployed before the onset of depression was significantly associated only with patients with non-endogenous depression. Unemployment was high in both British and Canadian depressed patients (39.3% and 32.9%). Significantly more of both British and Canadian female depressed patients were unemployed as were significantly more male depressed patients. In the total group of patients unemployment was significantly associated only with the working class, and was found in 47.3% of them. Tennant *et al* (1982) found that being employed was highly protective for the mental health of both men and women.

A poor marriage before the onset of depression was found in significantly more of both non-endogenous and endogenous depressed patients. It was found in 67.6% of married non-endogenous and 48.4% of married endogenous depressed patients—percentages similar to the 69.2% of neurotic and 36.0% of endogenous depressed patients reported by Birtchnell & Kennard (1983a,b) to have marital maladjustment preceding the onset of depression. Other studies have also found that a poor marriage was associated with non-endogenous depression (Weissman & Paykel, 1974; Paykel *et al*, 1980; Kumar & Robson, 1984; Watson *et al*, 1984; Hallstrom & Persson, 1984; D'Arcy & Siddique, 1984). Assortative mating and the stresses induced by recurrent episodes of affective disorder may also play a part in causing a poor marriage (Brodie & Leff, 1971; Hoover & Fitzgerald, 1981; Merikangos, 1984).

Quinton *et al* (1976) developed the marital interview assessment technique used here. They, and others, found that marital ratings can be performed reliably. Goering *et al* (1986) examined whether expressed marital dissatisfactions and criticisms were merely reflections of the depressed state but found no correlation between severity of depression and the patient's report of the premorbid marital relationship, but there was a strong correlation between premorbid marital ratings obtained from separate interviews with depressed patients and their spouses. Crowther (1985) also found highly significant correlations between depressed patients and spouses for their scores on the Locke-Wallace Marital Adjustment Test and between depressed patient's scores and their therapists rating of marital adjustment. Similarly Waring & Patton (1984) reported general agreement between spouses and depressed patients about the degree of marital intimacy. Thus these studies suggest that depressed patients are able to give a reasonably undistorted account of their premorbid marital relationship.

Having three or more children under 14 years of age at home was significantly associated only with non-endogenous depressed patients—but was found in only 5.7% of them. Brown *et al* (1975) identified this risk factor in depressed working-class women in London, and Campbell *et al* (1983) reported similarly from Oxford. Tennant *et al* (1982) found that having young children at home was not directly associated with psychiatric disorder but through the effect on unemployment, as having young children prevented married women being employed.

A first-degree relative treated for depression was found in more of both non-endogenous and endogenous depressed patients. Weissman *et al* (1982, 1984) also found a familial aggregation of non-bipolar depression in first-degree relatives of non-bipolar depressed patients when compared with controls. In the present study the percentage of patients with a depressed first-degree relative was higher among endogenous than non-endogenous depressed patients (43.2% vs 25.7%) which conforms with the view that the evidence for genetic transmission is less clear for non-endogenous depression than for endogenous depression (Kidd & Weissman, 1978). However, another interpretation of these data is that families transmit a depression-proneness culturally rather than genetically, and that when, as with non-endogenous depressions, current circumstances as well as past family culture contribute to onset, the effect of the latter will be diluted by the former.

Early parental loss because of permanent separation from a parent before 17 years of age (but not because of death) was significantly associated only with patients with non-endogenous depression (discussed in Roy, 1985). Non-permanent separation for at least one or more years was also significantly associated with the non-endogenous depressed patients, as found by Brown *et al* (1977). However, among endogenous depressed patients there were no significant differences, compared to controls, for either early permanent or non-permanent separation or death.

Social risk factors for depression may best be identified from studies of general population samples rather than from studies of the minority of depressives who are referred to hospital psychiatrists. Thus, it is possible that the differences in the present study between endogenous and non-endogenous depressed patients and their respective controls are not genuine differences but the product of differences in the 'filters' determining who consults a doctor, whether that doctor refers the patient to a psychiatrist and whether the psychiatrist admits the patient to hospital. Also, the distinctions found in the present study between the non-endogenous patients (from London and Toronto) and the endogenous patients (from NIMH in Maryland) may be confounded by national, cultural and temporal differences. However, all the depressed patients were matched with controls from the same country, and DSM-III criteria were used by one investigator which prevented study variables (e.g. job loss, marital disharmony) influencing diagnoses of non-endogenous or endogenous depression. Furthermore, the endogenous sample contains significantly more middle-class patients than the non-endogenous sample and this social class difference may possibly confound interpretations of the endogenous/non-endogenous distinctions reported here.

In summary, all five factors studied were significantly associated with non-endogenous depression: unemployment before onset, a poor marriage before onset, separation for one year or more from a parent before 17 years of age, having a first-degree relative treated for depression, and having three or more children under 14 years of age at home. No significant interactions were found. Patients with endogenous depression were found to have two of these five factors: a poor marriage before onset and depression in a first-degree relative. Thus the present study suggests that three social factors - unemployment before onset, separation for one year or more from a parent before 17 years of age and having three or more children under 14 years at home - are risk factors for non-endogenous depression but that depression in a first-degree relative and a poor marriage before the onset of depression are found in both non-endogenous and endogenous depression.

The Effect of Sodium Valproate on Tardive Dyskinesia – Revisited

G. G. FISK and S. M. YORK

As a treatment for tardive dyskinesia, sodium valproate was tested in a double-blind placebo-controlled parallel group trial, with 6-week base-line observation period followed by 6 weeks of treatment. Sodium valproate was not found to be an effective treatment for either tardive dyskinesia or drug-induced Parkinsonism, and did not affect mental state or behaviour.

At present, there is no satisfactory or uniformly effective treatment for tardive dyskinesia (TD) (Mackay & Shepherd, 1979; Jeste & Wyatt, 1982); the initial success of many treatment strategies has not been maintained on replication (Jeste & Wyatt, 1979). There are difficulties in defining TD and in assessing it with respect to both reliability and validity (Gardos *et al*, 1977); Barnes & Trauer, 1982). This and the possibility that there are a number of neuropharmacological subtypes of TD (Casey, 1976; Fann *et al*, 1977; (Moore & Bowers, 1980) complicate an already confusing array of trial data.

Nevertheless, there has been growing evidence for the usefulness of drugs facilitating γ-aminobutyric acid (GABA) in the treatment of TD (Jeste & Wyatt, 1979, 1982). Although the GABAergic system is not fully determined in neuroanatomical terms, it is thought that GABAergic striato-nigral neurones modulate the activity of dopaminergic nigro-striatal neurones (Kelly & Beart, 1975), and interplay with extra-pyramidal and limbic cholinergic systems (McGeer & McGeer, 1976). It has been found that GABA facilitators inhibit dopamine (DA) turnover and impulse flow (Andén & Stock, 1973; Walters *et al*, 1973; Andén & Wachtel, 1977). The findings of reduced concentrations of GABA and of the synthesising enzyme glutamic acid decarboxylase (GAD) in the caudate nucleus, putamen, globus pallidus and substantia nigra in Huntington's chorea and in Parkinson's disease (Lakke & Teelken, 1976; McGeer & McGeer, 1976; Enna *et al*, 1977), together with reports of reduced GABA receptor binding in the former (Lloyd *et al*, 1977), have helped inspire research into the effects of GABA facilitators in TD. Attempts have been made to correct a postulated relatively hypo-GABAergic balance between DA and GABA systems.

Sodium valproate (SV), considered to be a GABA facilitator, has been the subject of a number of clinical trials, but its mechanism of action is still the subject of research. The evidence that SV enhances the concentration of GABA in the brain, inhibiting the breakdown of GABA by inhibition of GABA transaminase, has recently been updated by reports that this drug enhances the sensitivity of GABA post-synaptic membrane receptors (Hammond *et al*, 1981; Meldrum & Chapman, 1983).

However, the evidence for the efficacy of SV provided by past clinical trials is equivocal: the first trial that claimed it to be of value fell short of critical standards of significance (Linnoila *et al*, 1976). Gibson's (1978) single-blind trial, using unskilled raters with no valid or reliable instrument for measuring TD, obtained negative findings. A further single-blind trial used a cross-over design comparing three drugs (Chien *et al*, 1978): the findings were equivocal and interpretation was complicated by the small number of patients. Nair *et al* (1980) found SV ineffective when used on its own, but effective when combined with small (and, by themselves, ineffective) doses of haloperidol, but the small numbers and single-blind design made this trial also unsatisfactory. Casey & Hammerstad (1979) obtained a positive result in a single-patient study. More recently, SV has been found to exert an antidyskinetic effect in eight patients considered to have TD, in a single-blind study attempting to look at the drug's effect on akathisia (Friis *et al*, 1983), but the result was not significant. The methodological short-comings of these trials to date has left the question of the efficacy of SV still inadequately answered.

We have aimed to overcome some of these methodological inadequacies. The particular focus of attention in this trial was whether SV is an effective treatment for TD in a chronically psychotic population maintained on antipsychotic drugs. Discontinuation of antipsychotic medication before the trial was not considered, since it would not have been a desirable clinical step for most of the patients. We were particularly interested in an antidyskinetic treatment which could be effective when used alongside existing antipsychotic medication, in the manner that antiParkinsonian agents are used for drug-induced Parkinsonism. We also wanted to avoid the methodological problem of discontinuation of antipsychotic medication prior to the trial effecting *per se* (Gardos *et al*, 1978).

Method

Patients

This was a double-blind placebo-controlled parallel group study. Patients were drawn for three mental hospitals: Pastures and Kingsway in Derby, and Mapperley in Nottingham. Patients with chronic functional psychotic illness and diagnosis of at least 6 months of TD, defined by a score of two or more on the central portion of the Barnes & Kidger (1979) rating scale, were included in the study if they were under the age of 70, had been maintained for at least 1 year on antipsychotic drugs, were physically fit, without evidence of liver disease, and with absence of acute or chronic organic brain syndromes (including dementias, tumours, epilepsy, cerebrovascular lesions, demyelinating disorders). Informed consent was obtained.

Design

Trial entrants were randomised between SV and placebo treatment groups, with stratification for age, sex, hospital, in-patient or community-based status, and high or low pretrial TD, using a computer program giving these factors differential weightings. (High TD was defined as a trial score of five or more on the Barnes & Kidger scale.) Double-blind procedures were used throughout.

Medication was prepacked and labelled with the patient's name. There were two dose regimes: either a stepwise build-up over 6 days to a fixed dose of 1500 mg/day, or for patients weighing less than 50 kg, a similar build-up to 1200 mg/day. Adjustments to this final dosage were made for some patients because of side-effects. Maintenance antipsychotic medication, together with any other existing maintenance psychotropic or antiparkinsonian medication, was continued and kept constant throughout the trial.

Hospital pharmacists acted as coordinators of treatment dispensation with emergency access to treatment allocation. Compliance was monitored by records of tablet returns.

The trial lasted for 12 weeks, consisting of a 6-week base-line period, followed by 6 weeks of treatment. The base-line period was included because it was considered appropriate to control for the effect of attention *per se* in this group of patients, which invariably receives comparatively little attention. Assessment were carried out at 0, 6, 9 and 12 weeks.

Assessment

Patients were assessed, using the Barnes & Kidger rating scale (Kidger *et al*, 1980), the Simpson & Angus (1970) scale for extrapyramidal side-effects and the Krawiecka *et al* (1977) assessment scale for rating mental state and behaviour in chronic psychotic patients. The Barnes & Kidger scale gives a total TD score and also a central and peripheral score. In addition to a 'live' TD rating, each patient was videotaped simultaneously, as described by Barnes & Kidger (1979) and by Kidger *et al* (1980), the only modification being the replacement of a portion of standard prose by that of the daily newspaper. Thus, each patient was videotaped in a standard environment and was given a standard task. The videotapes were used to provide two further blind TD ratings by experienced independent raters.

In addition to the rating scales, a standardised question concerning side-effects was used, and physical examination performed, as appropriate. At the first assessment, venepuncture was performed for liver function tests, full blood count, urea and electrolytes, and was repeated after 3 weeks of, and at the end of, the treatment phase together with serum SV levels. All medication administered was monitored.

Analysis

Comparisons between groups made use of the Mann–Whitney *U* test on either actual scores or change scores; within-group comparisons used the Wilcoxon matched pairs signed ranks test. Contingency tables based on operational definitions of clinical change were evaluated using χ^2 and the Fisher exact probability test. Clinically significant change in TD was defined, using the Barnes & Kidger scale, as a change of two or more on the central subscale or two or more on the peripheral subscale with one on the central. Clinically significant change in extrapyramidal symptoms was defined as a change in score of six or more on the Simpson & Angus scale. Clinically significant change in mental state was defined as a mental state score of three or more using the Krawiecka scale. Change in each case was measured from the base-line score average to the final assessment. For inter-rater reliability, the Kendall coefficient of concordance was employed.

Results

Patients

Sixty-two patients entered the trial (Table I). They had an average age of 54 years, with ten under the age of 50, 21 between 50 and 60, and 31 between 60 and 70. A total of 49 were maintained on anticholinergic antiparkinsonian medication and 14 on benzodiazepines. A check on randomisation showed no significant difference between SV and placebo treatment groups for age, sex, in-patient *vs* community-patient status, diagnosis, duration of antipsychotic treatment, maintenance medication level and type of medication.

During the base-line period, three patients were withdrawn because of ill-health, and a further patient on SV for 2 weeks was withdrawn because of pneumonia. Nine patients defaulted or failed to comply (five on SV, four on placebo) and in two patients, background medication was unstable. Therefore, 15 patients failed to complete the trial.

The profile of the remaining 47 patients is shown in Table I. There were no significant differences between this group and trial entrants for age, sex, placement, diagnostic distribution, duration of pre-trial antipsychotic medication, or current medication; 22 of these patients were allocated to SV, 25 to placebo, and a further randomisation check revealed no significant profile differences.

Inter-rater reliability

Concordance between two 'live' ratings, carried out on a sample of 25 patients, for TD (total, central and peripheral scores), extrapyramidal symptoms and the mental state was significant. (Kendall coefficient of concordance: $P<0.001$, respectively.)

TABLE I
Profile of the population studied

	Trial entrants (n=62)	*Trial completers (n=47)*	*Sodium valproate (n=33)*	*Placebo (n=29)*
Age: years				
Mean	54	58	58.1	57.6
s.d.	8.86	8.27	8.83	9.05
Sex: *n*				
M	42	34	21	21
F	20	13	12	8
Status: *n*				
In-patient	31	27	17	14
Community	31	20	16	15
Diagnosis: *n*				
Schizophrenia	56	43	32	24
Manic-depressive	3	3	1	2
Recurrent depressive	3	1	0	3
Duration of antipsychotic medication: years				
Mean	15.75	15.88	17.4	14.6
s.d.	7.95	8.1	7.51	7.76
Antipsychotic dosage: *n*				
<300 mg/day (Chlorpromazine equivalents)	21	18	12	9
300–900 mg/day (Chlorpromazine equivalents)	29	18	17	12
>900 mg/day (Chlorpromazine equivalents)	12	11	4	8

Concordance between 'live' and the two video-ratings for TD (total, central and peripheral scores), based on the trial population, was significant (Kendall coefficient of concordance: $P<0.005$, respectively). This allowed these three ratings to be reduced to the one 'modal' score as described by Barnes & Kidger (1979).

Results of treatment

Sodium valproate and placebo groups were compared; first, using all scores available for comparison at each assessment point and, secondly, confining the analysis to the scores of all 47 patients completing the trial.

Tardive dyskinesia

All scores

There were no significant differences between the assessments at the beginning and at 6 weeks, within either the SV or placebo group. On the first assessment, the SV group had significantly higher scores than had the placebo group for central scores (Mann–Whitney: $P=0.02$), with a similar trend for total and peripheral scores failing to reach significance. Although there were no significant differences between treatment groups after 6 weeks, because of the disparity found initially, the remaining analyses were carried out on change scores.

Between the 6-week assessment, at which point the different treatments were introduced, and the 9-week assessment, both the SV and placebo groups improved non-significantly, with no significant difference in the score changes between them. There were no significant differences in score changes between the 6- and 12-week assessments (i.e. the complete period of treatment), but there was a trend towards improvement in placebo relative to SV for total TD scores, nearly reaching significance (Mann–Whitney: $P=0.06$). From the half-way treatment point, at 9 weeks, to 12 weeks, the score changes between treatment groups differed significantly for total scores (Mann–Whitney: $P=0.05$) and central scores (Mann–Whitney: $P=0.01$). This reflected the SV group's greater tendency to return to base-line scores.

Completers (Fig. 1)

There were no significant differences between SV and placebo initially or at 6 weeks, except for significantly lower central scores for the placebo initially (Mann–Whitney: $P=0.02$). There were no differences at 9 weeks (i.e. 3 weeks after treatment commenced). At 12 weeks, placebo had significantly lower total scores (Mann–Whitney: $P=0.03$) and central scores (Mann–Whitney: $P=0.05$). Score changes were used again because of the slight base-line disparity. Between 6 and 12 weeks, the period of treatment, change scores for SV and placebo groups were significantly different for central scores (Mann–Whitney: $P=0.02$), but this just failed to achieve significance for total scores (Mann–Whitney: $P=0.06$); this reflected a relative improvement in the placebo group. While score changes between 6 and 9 weeks did not differ significantly, between 9 and 12 weeks, a greater tendency to return to base-line scores in the SV group resulted in significant differences for total scores (Mann–Whitney: $P=0.03$) and central scores (Mann–Whitney: $P=0.01$).

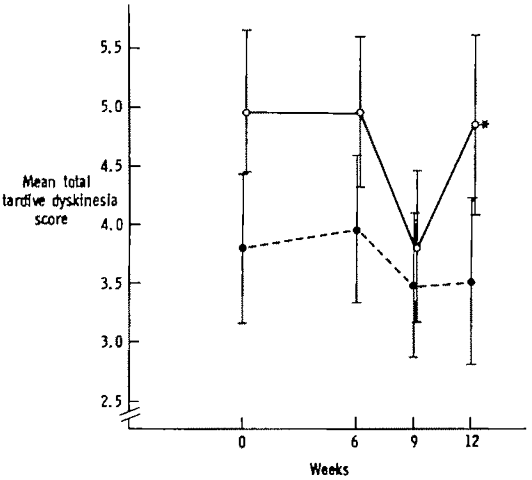

FIG 1. Total tardive dyskinesia scores for those completing the trial on sodium valproate (O——O) and placebo (●——●). The asterisk indicates that the score change was significantly different from that for placebo between weeks 9 and 12 ($P=0.03$).

Seven patients showed clinically significant improvements (four on SV, two on placebo) and eight patients showed deterioration (six on SV and two on placebo). There was no significant trend, but a trend towards no change, whether improvement or deterioration, being associated with placebo; this failed to reach significance. ($\chi^2=3.77$; $P>0.05$).

Extrapyramidal symptoms

There were no significant differences within treatment groups during the base-line period, and no differences between SV and placebo groups during the base-line period. At the 9- and 12-week assessments, placebo had significantly lower scores than had SV (Mann–Whitney: $P=0.03$ and 0.012, respectively). This held for all scores available for comparison at each assessment point and for the 47 completers. Within the SV group, there was no evidence of deterioration during treatment.

During the trial, three patients improved clinically, two of them being on SV, while one patient on SV deteriorated. These trends did not reach significance.

Mental state

There were no differences between base-line assessments within each treatment group, or between treatment groups. There were no significant differences between SV and placebo during treatment. Three patients improved clinically, all of whom were on SV; three patients deteriorated, two on SV and one on placebo. These trends did not achieve significance.

Serum sodium valproate

There was no significant association between clinical outcome for TD and serum SV levels.

Side-effects

Twenty-one patients reported side-effects. Of these, 11 complained of sedative side-effects; seven were on SV and four on placebo. The sedation was mild, and not clinically noticeable in all but one 69-year old chronic schizophrenic in-patient on SV, who experienced heavy sedation, ataxia and faecal incontinence after 10 days of SV. All side-effects disappeared when the dose was cut to 500 mg daily. In four patients, three of whom were on SV, reduction of dosage to 500 mg *b.i.d.* successfully removed mild sedative side-effects.

Ten patients reported mild non-sedative side-effects, from headache to irritability; six of these were on SV. One patient self-administered SV erratically and became restless and socially disruptive. He was found to have a serum SV level of 1074 μmol/litre and was withdrawn from the trial.

There was no overall trend towards side-effects, whether sedative or non-sedative, being significantly associated with SV. There was no association between serum levels of SV and side-effects. There was no trend towards abnormal blood tests with SV.

Subcomponents of tardive dyskinesia

Finally, we used our data to investigate whether central and peripheral TD score changes within patients on SV were significantly different. Using score changes in the treatment period, we found no significant difference.

Discussion

After 6 weeks of SV treatment, there was no evidence of any improvement in TD: the non-significant improvement found after 3 weeks of SV was not significantly different from that found for placebo and was not maintained, unlike that for placebo. This effect after 3 weeks of SV is of interest, because a similar trend was noted by Chien *et al* (1978) in their single-blind cross-over trial. The findings of Linnoila *et al* (1976) of a non-statistically significant improvement in TD after 2 weeks in a double-blind cross-over trial may also be due to this effect. This suggests that the positive results from their trials are a transient placebo effect.

The findings at the end of the trial – that placebo did significantly better than SV did, both in terms of direct comparison and in terms of relative change from the pretreatment base-line – underline the ineffectiveness of SV; TD was relieved more successfully by placebo.

The improvement in Parkinsonian-type extrapyramidal symptoms, found after 3 and 6 weeks of placebo, was not produced with SV. Although Parkinonism was relieved more successfully by placebo, there was no tendency for SV to exacerbate Parkinsonian symptoms, which is broadly in line with the trial carried out by Friis *et al* (1983).

The suggestion has been made by Lautin *et al* (1980) that SV can cause a deterioration in chronic schizophrenic symptoms; however, their patient numbers were small, the trend could not be disentangled from the effect of neuroleptic discontinuance and the results did not achieve significance. We used a similar dose range, and found no evidence of improvement or deterioration in mental state. There have been reports of GABA facilitators being sedative, particularly in the elderly (Gerlach, 1977; Gerlach *et al*, 1978; Casey *et al*, 1980), and even the suggestion that their efficacy in TD is secondary to such sedation, but we have not confirmed this in the population we studied. However, there is the possibility that this reflects our younger age group, and that the elderly may be more sensitive.

This trial provided additional evidence for the usefulness of the Barnes & Kidger rating scale for TD. The levels of concordance between 'live' ratings, and between 'live' ratings and two independent videoratings, both for total scores and for central and peripheral scores, support its reliability. The significant association between score changes for central and peripheral TD during treatment adds weight to the view that oro-facial and peripheral subsyndromes of tardive dyskinesia, while separable, are related phenomena.

Brief Reports

Cousin Marriages and Schizophrenia in Saudi Arabia

The rate and degree of consanguinity in the parents of 143 schizophrenics who satisfied the DSM-III diagnostic criteria, was compared in the same number of controls matched for age, sex and socioeconomic class. A family history of disorders suggestive of schizophrenia in the offspring of consanguineous parents who were schizophrenic, was compared with the incidence of a similar history in the schizophrenic offspring of non-consanguineous parents. There was no statistically significant difference in the former, but there was in the latter. This finding supports the theory of a familial tendency towards schizophrenia and the possibility of recessive or a multigene pattern of inheritance.

The study of genetic theories of schizophrenia can be divided into three categories: the incidence of schizophrenia relative to the degree of consanguinity in relatives of known patients; the concordance rate in twins and studies on adopted twins.

Since Rüdin's report in 1916, there have been numerous similar studies but using increasingly more sophisticated methods: Schultz in 1932, Kallman in 1938, Zerbin-Rüdin in 1967 and Slater in 1968. All reported a significantly higher prevalence of schizophrenia in the families of schizophrenic patients than in the families of non-schizophrenics, but their studies only show that schizophrenia is a familial trait and not that it is necessarily genetic.

Twin studies by Tienari in 1963, Gottesman & Shields in 1966, Kringlen in 1967, Pollin *et al* in 1969, and Fischer in 1973, reveal a three-fold increase in the monozygotic concordance rate as compared with the dizygotic rate. This is not unexpected because when the lifestyles of twins are examined closely, there is frequently found a more intense bond between monozygotic twins than between non-twin siblings or dizygotic twins (Jackson, 1960). This argument, however, has been countered by schizophrenic twins reared apart.

The Danish adoption studies by Kety *et al* in 1975, which reported a significantly greater prevalence of schizophrenic spectrum disorders among the relatives of schizophrenic adoptees than among those of non-schizophrenic adoptees, certainly support the genetic theory of schizophrenia. However, Benjamin (1976) criticised the statistical analysis used in that study, and indicated that an alternative method of analysis leads to a conclusion that violates the principle of genetic effect increasing with greater consanguinity. So Kety's studies may be flawed, but the sequel to them, the current Danish adoption study of Jacobsen, is finding the same results.

The Arabian culture provides the opportunity to investigate this matter from a different angle, that of the rate of consanguinity of parents of schizophrenics compared with that of controls. Only three similar studies are found in the literature. The Sudanese study (Ahmed, 1979) used a large number of subjects but was very brief, did not include data from family histories, did not differentiate between acute, remitting cases and chronic cases, and there were no well-defined diagnostic criteria. Another study was done in Azerbaijan, Russia (Skoblo, 1975) and indicated an increased frequency of sporadic schizophrenic patients in comparison with the average; the abstract did not give the statistical significance of this difference. The study is in Russian and not available for comment. In the third study, by Prasad in 1985, only 15 schizophrenic patients were compared with patients with affective disorders. The author said that the inference of the results should be accepted guardedly, and that more controlled studies are needed.

The nature of the study presented here is such that it will not resolve the argument of familial versus inherited nature of schizophrenia, but it will add to the data available and help to correct a deficiency in the medical literature.

Method

During one year, 143 randomly selected patients who satisfied the DSM-III diagnostic criteria for schizophrenia, were interviewed individually by the two authors. Patients with a diagnosis of schizophreniform psychosis, schizo-affective disorder, or affective disorder were not included in the study. Complete demographic data were taken; also data were obtained on type and duration of illness, number of stays in hospital and out-patient visits, dosage of neuroleptic drug used to maintain control; and history of schizophrenia in siblings, parents, and siblings of parents identified by the patients or family by similarity of signs and symptoms and the requirement of long-term psychiatric care. The degree of parental consanguinity was accurately tabulated into marriage of first cousins, second cousins, and distant relatives; the later included marriage between members of the same tribe and was called third-degree consanguinity.

TABLE I
Occurrence of schizophrenia in families of cousin-marriages and non-consanguineous marriages

Degree of consanguinity in patients' parents	*No family member affected*	*One family member affected*	*Two family members affected*	*Three or more family members affected*	*Total*	*Control*
First cousins	12	7	3	1	23	17
Second cousins	6	4	2	1	13	10
Distant cousins	26	3	2	1	32	15
Non-consanguineous	56	10	7	2	75	101
Total	100	24	14	5	143	143

Saudi Arabia maintains no public records of birth, marriages and deaths, therefore there are no official data available on the rate of consanguinity in the general population. Therefore, the companions of the patients, who were unrelated but of the same socioeconomic class and who attended the clinic with the patients, were asked the same questions as the patients and thus comprised the control group in this study.

Results

Of the 143 patients studied, 105 were males and 38 were females; their ages ranged from 16 to 70 years, with a mean of 31.6 years and standard deviation of 11.0 years. There was the same number of controls and they were matched for age, sex and socioeconomic class. Twenty-three patients were the offspring of first-cousin marriages, 13 were the offspring of second-cousin marriages, 32 were of distant-cousin marriages and 75 reported no parental consanguinity. The respective numbers for the controls were 17, 10, 15 and 101 (Table I). Although these figures indicate a higher rate of parent–consanguinity among the patients than among the controls, a statistical significance was not demonstrated ($\chi^2=1.65$, $P=0.20$). Of the 75 patients with no parental consanguinity, 56 had no family history suggesting a schizophrenic disorder, 10 had one family member (family member for this purpose is defined as sibling, parent or sibling of parent only) who was affected, seven had two family members who were affected, and two had three or more family members who were affected. Of the 32 patients who were the offspring of distant cousins, the distribution of family history suggestive of schizophrenia was 26, 3, 2 and 1 respectively, and for the 13 who were the offspring of second cousins was 6, 4, 2 and 1 respectively and for the 23 offspring of first cousins was 12, 7, 3 and 1 respectively. The scatter of these figures was too wide to give a statistically significant conclusion.

However, combining the patients from distantly related parents with those of no consanguinity, and combining patients who were the offspring of first- and second-cousin marriages, an interesting, statistically significant, conclusion is reached (Table II). The offspring of first and second cousins are far more likely to have a positive family history suggestive of schizophrenia than similar patients who are the offspring of distantly related and non-consanguineous parents ($P=0.005$).

TABLE II
Occurrence of family history of schizophrenia in families of close and distant (including non-cousin) cousin marriages

	With negative family history	*With positive family history*	*Total*
Distant cousin or non-consanguineous marriages	82	25	107
First and second cousin marriages	18	18	36

$\chi^2=7.866$, d.f. $=1$, $P=0.0059$

Several attempts were made to identify the demographic differences of these two subgroups; the type of schizophrenia e.g. paranoia, undifferentiated or simple; the chronicity and severity of illness identified by unremitting status, duration of more than 10 years, more than three stays in hospital and unemployment. In none of these parameters was there a statistically different distribution in either of the subgroups.

Discussion

Intermarriage was once a matter of pride and honour among the Bedouin tribes (Hasanien, 1984) but it has declined considerably in inverse proportion to their rising socioeconomic status in recent years. Even today, however, there are families who would in no circumstances let their women marry out of the family; this would be demeaning and show a disregard for their blood line. Hence it was important to have a carefully matched control for this study.

We found there was no statistically different rate of intermarriage between the parents of the patient group and the parents of the control group, although the rate was relatively higher in the former. It is possible that the result is affected by the small size of the sample groups; however, our results are in agreement with the Sudanese study (Ahmed, 1979), but not with the Russian study (Skoblo, 1975).

The finding of a significantly higher rate of positive family history in patients of consanguineous parents than in the other groups of patients, indicates a definite familial tendency of schizophrenia and possibly an inherent pattern of a multiple gene type, since it is well known that in-breeding will promote the appearance of a multi-gene trait of recessive character. Our data support the genetic theory of schizophrenia. The fact that neither the type nor the clinical course of schizophrenia have taken any specific pattern in this study, conforms with the concept that schizophrenia is single disorder with various clinical courses and differing presentation.

In conclusion, although this study does not resolve the argument of familial versus hereditary nature of schizophrenia, it does support the later and provide an evidence to suggest association with recessive genetic disorders, where two copies of any aberrant gene are required for expression of the disorder, or a polygene nature of the disease.

Electrodermal Response as a Monitor in Electroconvulsive Therapy

A study comparing the use of electrodermal response with the cuff technique and clinical judgment as monitors in electroconvulsive therapy is reported. A sensitivity of 90.5% and a specificity of 41.7% were found and it is, therefore, suggested that this method is not used routinely.

The administration of electroconvulsive therapy (ECT) in the UK was reported on in 1980 (Pippard & Ellam, 1980) with some disturbing findings. It is generally accepted that a convulsion is required for the therapeutic benefit (Kendell, 1982), but it is not always obvious to those administering ECT that a convulsion has, in fact, occurred. Various methods have been used to determine this although observation for convulsive muscular movements seems the most common. The use of EEG monitoring is the surest way to measure seizures, but both EMG and the cuff technique have also been widely used (Fink, 1983). In the cuff technique (Addersley & Hamilton, 1953) a sphygmomanometer is inflated to above systolic blood pressure before the administration of suxamethonium. This is left on during the ECT and that arm subsequently has an unmodified seizure. This method of monitoring has the advantage of being simple, safe and universally available. Other measures used have been dilatation of pupils (Addersley & Hamilton, 1953), ECG (Goffen, 1984) and electrodermal response (EDR). The latter was reported in a small study (Watkins-Pitchford & Reynolds, 1984) comparing EDR on 15 administrations of ECT with clinical twitching of the muscles, which is the unreliable measure under question. Therefore a study was designed to compare the sensitivity and specificity of the EDR with the cuff technique whose validity has been demonstrated (Fink & Johnson, 1982).

Method

The EDR was measured using the simple apparatus described by Watkins-Pitchford & Reynolds (1984). Two electrodes on non-adjacent fingers were connected to the apparatus. A light-emitting diode (LED) was then illuminated by adjusting a pre-set resistor. This was turned down until the light was just extinguished to give the pre-ECT baseline. A successful convulsion increased the skin resistance and re-illuminated the LED. The cuff technique was performed on the other arm with the cuff kept at 260 mmHg from before the suxamethonium was administered to after the seizure had finished.

Forty-eight patients consented and 117 administrations of ECT were monitored. All were given bilateral ECT using an Ectron Duopulse constant current apparatus. Anaesthesia was induced using methohexitone; suxamethonium and atropine were also given. After preoxygenation and insertion of a mouthpiece, ECT was given. The administering psychiatrist noted whether or not a tonic-clonic convulsion had occurred. The convulsive response of the isolated arm and the EDR change were recorded. The psychiatrist was working blind regarding this last measure.

Results

Interestingly we found that the EDR was positive in nearly all patients during initial current application. A positive response was, therefore, only recorded if a subsequent EDR occurred sufficient to illuminate the LED after the current had ceased. This coincided with the expected convulsion.

On three occasions the cuff technique was negative when there was an obvious bilateral convulsion in the rest of the body. This must have been due to poor technique and shows limitations of this method. Since the results of the cuff technique are highly correlated with the EEG method of monitoring (Fink & Johnson, 1982), we decided to use the cuff technique, and clinical observation to be the measure of convulsion occurrence.

The results using this method are displayed in Table I. Of 105 patients who had a convulsion, a positive EDR showed in 95 of them. This gives a sensitivity of 90.5%. Of the 12 patients who did not have a convulsion, seven showed a positive EDR. This gives a specificity of 41.7%.

TABLE I

EDR compared with a combination of the cuff technique and clinical judgment on the occurrence of convulsions

	Cuff and clinical	
EDR	*Convulsion occurred*	*Convulsion not occurred*
Convulsion occurred	95	7
Convulsion not occurred	10	5

Discussion

The EDR is not a simple measure as it is determined by many variables (Venables & Christie, 1980). In this study a simple apparatus has been used as a gross indicator of change in skin resistance (illumination of LED). Skin resistance is determined by the sympathetic nervous system's stimulation of sweat glands which have cholinergic post-ganglionic innervation. As atropine is given intravenously it will presumably block this effect as it has been shown to do when given by iontophoresis (Lader, 1970). It is, therefore, not surprising that the use of EDR has been shown in this study to have poor validity. The cuff technique, in contrast, is simpler and has been shown previously to correlate well with the EEG (Fink & Johnson, 1982). In this study only three patients (2.6%) showed a discrepancy between the clinical and cuff technique and this must have been due to the patients' blood pressure rising above 260 mmHg during the convulsion. The clinical opinion in this study took the cuff technique into consideration as the psychiatrists were not working blind and this is the reason for the high level of agreement between them.

It is suggested from this study that the EDR is not yet a useful technique to monitor the occurrence of convulsions during the ECT and that the cuff technique should, therefore, be used until further development has taken place.

A Schoolgirl with Onset of Anorexia Nervosa during a Concealed Pregnancy

In anorexia nervosa, amenorrhoea and endocrine disturbance make pregnancy unlikely while the patient's weight is low. Bulimics may conceive at quite a low weight, and anorexics who have regained weight may become pregnant but typically relapse following delivery (Crisp, 1980). Anorexia has also been reported following termination of pregnancy (Thomas & Harris, 1982). Cases of onset of anorexia nervosa with weight loss during pregnancy are rare in the literature, although there are isolated reports (e.g. Weinfeld *et al*, 1977; Strimling, 1984). Strimling described a treated anorexic who restarted dieting during pregnancy in response to weight gain before she realised that she was pregnant. We report on a schoolgirl who became pregnant at 14 years, whose anorexia began when she was 5 months pregnant and whose pregnancy was not discovered until she was in labour.

Young schoolgirls tend to delay seeking advice about pregnancy (Russell, 1983). In a series of patients requesting late termination of pregnancy in Tower Hamlets, Savage (1985) found that the major reason for late presentation was the youth of the patients, often associated with denial of pregnancy. Denial of pregnancy is described (Finnegan *et al*, 1982) as sometimes extending to (and beyond) delivery. It may involve the patient's relatives and doctors. It may prejudice the mother's acceptance of the baby after birth.

Case history

The patient 'Gill' was an only child of a shop assistant. Her birth weight was 2.33 kg at 37 weeks gestation. Her mother developed a post partum embolus resulting in a 2-week separation from Gill and advice against further pregnancy.

Gill's early years were unremarkable, but her later friendships were restricted by her parents; she remembers being locked in a garage to prevent her playing with neighbourhood children. She and her friend were known as 'Laurel and Hardy' because Gill was plump. The menarche occurred before she left primary school. At 11 years 7 months her weight was 50.5 kg (over the 97th Percentile) and her height was 146 cm (over the 50th Percentile).

She failed the 11-plus examination and was unhappy at her secondary school. She was seen by a child psychiatrist at 14 years, giving a history of depressive symptoms for 1 year and weighing 63.5 kg. She was treated with dothiepin for a month but this was discontinued when she developed 'fits' which were not thought to be epileptic. They rapidly ceased and her mood improved.

When she returned to school, parents and head-teacher agreed that a girlfriend was 'unsuitable' and discouraged the friendship. Gill formed a friendship with a boyfriend 'John' and when she was 14 years 9 months they had sexual intercourse once. Two further periods occurred before menstruation ceased. At 15 years 1 month (4 months pregnant) she was taken by mother to the GP complaining of headaches and vomiting. Gill estimates that at this time she weighed between 57 and 64 kg. She wondered if she was pregnant, but thought this impossible because her periods had continued after intercourse. She concealed the amenorrhoea from her GP who diagnosed migraine. After being teased at school, she decided to diet, weighed herself twice daily and lost 0.45 kg daily whilst vomiting but later up to 1.82 kg per week when the vomiting stopped. She has said 'I put the possibility of pregnancy to the back of my mind', and was convinced that if she lost weight she could not be pregnant. When she was 6 months pregnant her parents felt that her mood had improved. She cooked for others but only ate one small kipper daily and drank orange juice. She pretended to eat her meals but secretly fed them to the dog. A month later the school became concerned at her loss of weight and tried to persuade her parents to take her to their GP, but father claimed she was eating well. At a school medical inspection when she was 8 months pregnant, the doctor suspected anorexia nervosa and thought Gill was depressed and anxious. The pregnancy was not noted. She weighed 49 kg, said that her periods were regular and refused to see her GP.

She was upset because she had gained 0.45 kg and took no more solid food until she presented in Casualty 3 days later with abdominal pain. She weighed 46.3 kg (height 154.9 cm). She was in the second stage of labour and was delivered by forceps of a healthy female child, weighing 2.4 kg, estimated maturity 37 weeks. Gill and her parents denied all knowledge of the pregnancy and the baby was fostered at the parents' request.

Taking the lowest estimate of original weight, 57 kg and allowing for an average expected weight gain in pregnancy of 10.9 kg, Gill had probably lost about 32% of expected body weight prior to her delivery. She was transferred to an Adolescent Psychiatric Unit. She weighed 43.64 kg, was refusing carbohydrate and fat, and considered herself too fat, especially around the hips and thighs. She remained resistant to a feeding programme, was weight phobic and took exercise whenever possible. While Gill was an in-patient, the relationship with John continued and he spent most of his free time in her parents' house. After treatment, with individual and family therapy, Gill was discharged after being prescribed oral contraceptives, at 15 years 7 months weighing 46.8 kg.

Two months after discharge, when the adoption of the baby was completed, Gill weighed 50 kg. Six months later she started to diet, made herself vomit and took laxatives. She denied bingeing and weighed 47.73 kg on readmission. She was grieving the loss of her child and hostile towards her parents for insisting on adoption. She was unable to accept her own ambivalence about keeping the baby. She became engaged to John on the baby's first birthday, took CSE exams, obtained work as a shop assistant and was discharged at 16 years 8 months weighing 50.45 kg. Three months later her Eating Attitudes Test score (EAT 40, Garner & Garfinkel, 1979) was 91 (anorexic range more than 30) and her weight was 54.09 kg. At 17 years 2 months, her parents accused John of disrupting their family and Gill left home to live with John's parents. Gill's mother became depressed and sought psychiatric help.

Two months later Gill presented to an ante-natal clinic weighing 65.4 kg. The couple moved to a rented flat and Gill gained weight steadily during pregnancy to 81.3 kg. Her EAT 40 score fell to 8 in late pregnancy. She says that she 'wanted to tell everybody' about this pregnancy, unlike the previous one. She was delivered of a male child, weighing 4.06 kg, estimated maturity 40 weeks, and bottle fed the baby. She was noted to be eating all meals provided in hospital and contacted her parents to show them the child before her discharge.

At her post-natal examination Gill weighed 70.01 kg and the baby weighed 5.17 kg. Her EAT 40 score had risen to 50 and she was unhappy about her weight. She lost 2.73 kg in 2 weeks. She is now refusing to be weighed.

Discussion

At the end of her first pregnancy this patient fulfilled the DSM-III criteria for anorexia nervosa.

Why does anorexia nervosa rarely present for the first time during a pregnancy? Maternal protective feelings for the unborn child perhaps prevent pregnant women from dieting excessively. We note that in a case reported by Strimling (1984) the anorexic patient tried to resume more regular eating habits after the discovery of her pregnancy. Also, in pregnancy, weight gain is clearly anticipated and a pregnant woman may feel temporarily absolved from the pursuit of thinness. However, if the pregnancy is denied this may make anorexia nervosa psychologically possible.

The aetiology of anorexia nervosa is discussed by Hsu (1983). Individual and family theories both involve the concept of failure to complete adolescent developmental tasks. As the only child of over-controlling parents our patient had never established independence in her relationships. In common with many anorexics she was a plump child whose puberty came early, but she was not from the upper social classes, was of average intelligence and non-competitive and her parental expectations of academic achievement were not high. She first presented with depression, but the stress of her first sexual experience followed by pregnancy at a young age precipitated anorexia nervosa. The development of anorexic symptoms may have been assisted by the vomiting of pregnancy. The onset of anorexia with weight loss fostered the conviction that she was not pregnant and the weight gain of pregnancy disguised the anorexia.

Pregnancy normally necessitates maturational progress for a patient, and her family. The patient adopts a clearly defined adult role which involves some degree of separation from parents, who are themselves offered a new role as grandparents. Pregnancy in a young teenager results in the sudden, unprepared precipitation of the teenager into an adult role and of her parents into a different relationship with their child.

As this girl's first pregnancy was not acknowledged until delivery, these adjustments did not occur, and could have been unacceptable. The subsequent removal of the baby returned the family to their previous situation without evident maturational progress. The parents' resistance to separation involved incorporating the patient's boyfriend into the family as a second child when they failed to divide him from the patient. A second pregnancy, 2 years later, was conceived deliberately and the patient left home. Increasing maturity with age and therapeutic interventions may have contributed to the patient's ability to deal more normally with her second pregnancy but anorexic symptoms returned after delivery and neither her separation nor her eating problems are fully resolved.

'Imposed Psychosis'

A Case Variant of the Gaslight Phenomenon

In 1969 Barton & Whithead described the Gaslight Phenomenon. In this condition a presentation of mental illness is found, on further enquiry, to have been induced or imposed on the patient by some other person for that other person's gain. Amongst these gains is removal of the patient to a hospital. Previous reports have highlighted the malicious intent of the exploiter (Barton & Whitehead, 1969; Smith & Sinanan, 1972; Tyndal, 1973; Lund & Gardiner, 1977).

The phrase 'Gaslight Phenomenon' was derived by Barton & Whitehead (1969) from the play *Gaslight* (Hamilton, 1939). In that play the victim's husband manipulated the gaslight in a way which made his wife's complaint about it seem as if she was going insane. His aim in doing this was to remove her from the scene and gain for himself her property.

We wish to report on a case of imposed illness, but one in which the intent of the inducer was not primarily malicious.

Case descriptions

Mrs A is a 52-year-old widow who first presented in the Accident and Emergency Department. She expressed distress about the sudden disappearance, 3 months previously, of her 22-year-old daughter. On further enquiry she stated that over a period of 6 years her late husband had returned in spirit to the house. He had brought flowers for her and her daughter. He often rearranged the contents of the cupboards, at times criticising Mrs A for her unsatisfactory housework. On occasion he had struck Mrs A on the head and pushed her by the shoulder. He took her daughter's clothes out of the cupboard and laid them on the bed for her. He had daily engaged her and her daughter in conversations. At times he created a great deal of noise in the house by banging on doors and cupboards. Mrs A claimed that these events had also been witnessed by her daughter. However, since her daughter's disappearance her husband's spirit had not appeared again.

In her history Mrs A claimed that her daughter worked for famous private doctors. She stated that her daughter had spoken, on the doctors' car radios, with Prince Charles and Princess Diana, and that her daughter and Princess Diana were good friends. She claimed that her daughter had met Prince William when he was 6 weeks old.

Mrs A was presented at a psychiatric case conference 1 week after her admission. The general view expressed at the meeting was that her symptoms were suggestive of a psychotic illness, possibly paraphrenia. The day of her admission into hospital Mrs A commenced chlorpromazine in a dose of 50 mg 8-hourly, both in view of her mental state presentation and her level of distress.

In view of Mrs A's concern about her daughter an attempt was made to contact the daughter by letter through the DHSS. Concern by the staff had also been expressed about the daughter's mental state.

Two weeks after the DHSS enquiry the daughter, Miss B telephoned the hospital to enquire about Mrs A's health. She insisted, however, that Mrs A was not told of her whereabouts as she wanted to build up her own life away from home. She claimed that Mrs A had prevented her from leaving home and had stopped her from claiming unemployment benefit. In the year before she left home Miss B had begun to claim her unemployment pay, informing Mrs A that this money was from work she did for private doctors. To direct questioning, Miss B stated that her father's spirit had been in the house and that he had spoken to both Mrs A and herself. She also confirmed her mother's contention that he had rearranged various articles in the house.

During a further telephone conversation with Miss B she was asked about Mrs A's reference to Prince Charles, Princess Diana and Prince William. Miss B stated that she herself had never met them, but that she had told Mrs A that the doctor she worked for knew them. Miss B agreed that she may have conveyed the impression to Mrs A that she knew them personally as well. Miss B admitted that in fact she had never worked for private doctors.

Miss B was invited to attend the out-patient department for a fuller discussion of the situation, to which she agreed. At that meeting a detailed psychiatric history was obtained from Miss B and the opportunity was taken to elicit further information about Mrs A. Toward the end of the meeting Miss B was asked specifically about her father's spirit. Initially she reiterated that her father's spirit was there, and also added that on occasion he left notes of instruction to Mrs A. However, after being asked to confide in us and after being assured that what she told us would be held in the strictest confidence, Miss B suddenly became distressed and tearful: she then admitted that she had, over the years, been speaking in her father's voice to make it appear as if her father was talking to Mrs A and to herself. She also admitted rearranging things in the house and to leaving notes for Mrs A, ostensibly written by father. The following reasons were given by Miss B as to why she did these things: she was afraid of Mrs A and felt she could not cope with Mrs A by herself; she needed more freedom for herself from Mrs A and in the notes supposedly written by her father explanations were given for Miss B's absence from home during the day time.

Formal assessment of Miss B, using the Research Diagnostic Criteria (Spitzer *et al*, 1978) revealed no formal mental illness. She was of average intelligence, had an appropriate affect, and a good rapport was established with her.

An outline of Miss B's developmental history showed this to have been a highly stressful one. Her earliest childhood memories were of her parents shouting at each other, not infrequently this culminating in violence. This continued until her parents separated when Miss B was 8 or 9 years old. Her father died 2 years later of a brain tumour. Miss B stated that she cried after her father died, although before he died she had experienced feelings of anger toward him for the way he had treated Mrs A. However, her father had never mistreated her and after his death she would remember the holidays she used to spend with him. With regard to Mrs A, Miss B stated that after her parents separated Mrs A would often blame her for having prevented her from obtaining a job, despite many applications. When Miss B was 11 or 12 years old Mrs A began threatening to put her into a Children's Home because then she would be able to get a job and sell the house and move away if necessary.

With regard to Mrs A's own developmental history, she recalled that starting school and separating from her own mother was extremely difficult. Mrs A, as a child, was only able to remain at school with the reassuring knowledge that her mother would visit the school gates to see her at both break and lunch-time. She recalled how her father would do some of the housework at weekends because her mother was extremely tired. Her mother's fatigue was seen as further evidence of tireless dedication to attending and caring for her. At the age of 11 Mrs A refused to sit her 11-plus examination which both her elder sibs had passed. She recalled being terrified of failing, although she was unable to connect this with her mother's stated hopeful desire and hopeful expectation that her children should do well in life.

When Mrs A's daughter, Miss B, was born she was nursed in an incubator for the first 2 weeks of life, during which time Mrs A was constantly afraid that Miss B would die. Mrs A went to visit Miss B but was unable to hold her and recalled returning to her hospital room in tears. She never really understood what was wrong with her baby and has held a grudging resentment toward the medical profession for the way she was treated at that time.

Mrs A stated that when Miss B wished to leave home in her late teens she was totally unable to understand why she would want to do so, other than to marry or to find employment.

It is of particular importance that Mrs A's mother was a spiritualist who attended seances. During her late teens Mrs A would go with her mother to the spiritualist meetings where attempts were made to contact the dead.

Within a few days of her admission into hospital, Mrs A began to wonder whether what she had been told by her daughter was true, and she started to have doubts about the return of her husband's spirit. She was puzzled by the disappearance of her husband's spirit the moment her daughter left home. Mrs A's subsequent history has shown her to be free of all psychotic phenomena, but she remains angry and deeply embittered to the point of tears about Miss B not wanting to establish contact with her, though she had been informed that Miss B had telephoned the hospital on a number of occasions to ask the staff to reassure Mrs A that she was well.

Discussion

Mrs A's life history shows that she has had severe difficulties in the process of individuation and separation (Mahler, 1972). She experienced marked difficulty in starting school, and separating from her mother, who was idealised as being totally devoted to her, while her teachers were seen as frightening authority figures. Mrs A continues to idealise the mother/daughter relationship as one in which there is little or no room for separateness. Mrs A's object relations are typified by a rigid idealised self/object representation maintained by excessive splitting and projective identification (Klein, 1975*a*,*b*; Jacobsen, 1964). She only seems associated with idealised relationships. Feelings associated with the unsatisfactory side of her relationships are warded off, denied, or projected into others who are attacked as bad – with loss of any good or loving feelings for them. This is illustrated by her apparent absence of feeling when talking about her husband's behaviour prior to their separation; her husband apparently left her for another woman but Mrs A did not reveal this, such information being revealed by Miss B. Mrs A was totally unable to accept anything about her late husband which did not fit into her idealised view of him. She similarly described an absence of feeling for her mother who remarried late in life, but feelings of anger, resentment and sadness are denied.

Mrs A seems to have retained an ambitiousness throughout her life, something which she connected with her mother's desire that she should get on in life. She did not want to start a family as this would interfere with her own ambitions and financial goals in life. Following her husband's death she had wanted to start a new life by going out to work, but felt unable to do so because of Miss B. Here can be seen the nature of her envious rivalry with Miss B who she saw as potentially having a life denied herself. Currently she enviously attacks Miss B's independent life, with the resultant loss of any good feelings for her, though her attitude to Miss B throughout life has always been extremely ambivalent and the envious feelings have been denied (Klein, 1975*a*,*b*).

With regard to the belief that her husband was visiting the house from the grave, this would seem to serve the function of attempting to provide a solution to a complex dilemma for both Mrs A and Miss B. The 'voices' appear to provide both mother and daughter with comfort, serving as a defence for both of them against depressive anxieties to do with loss and separateness.

Two further factors seem to contribute toward understanding why Miss B invoked the idea of a return of her father's spirit. When Miss B was 14 years old Mrs A had mentioned that a spirit must be in the house because an article of clothing was in a place she had not placed it. Mrs A had thought that this spirit was either that of her own late mother (who had died the year before) or of her husband (who had died 4 years previously). The second factor was that Miss B had heard from a schoolfriend of that friend's experience of her own late mother's spirit rearranging things in the house and of the comfort which this spirit had brought to her.

Consensus Statement: Panic Disorder

SIR: We wish to draw the attention of readers to a recent initiative concerning the topic of panic. In November 1986 an informal meeting was held in the UK to discuss anxiety and panic, with particular reference to diagnosis and classification. The participants, listed below, came from several academic and clinical centres in the UK and represented a wide range of expertise and specialist interests within this area of psychiatry. Various topics were outlined in order to focus the subsequent discussions.

The concept of anxiety neurosis was established nearly 100 years ago, and has emphasised at several times since the somatic, particularly cardiovascular, symptoms. 'Panic' originally implied collective and excessive fear reactions, but the term has come to have somewhat different psychiatric implications, stressing individual physiological response. Cardinal features are the rapid rate of onset of the attack and the feeling of loss of personal control. Recently, attempts have been made to separate panic and anxiety as diagnostic entities, both in the proposed ICD–10 and in the DSM–III classification system of the American Psychiatric Association.

The epidemiology of panic attacks and disorders varies according to the sample studied and the criteria used: population studies, surveys of general practice attenders, and out-patient studies provide very different prevalences of panic. In one American study, prevalences were: Generalised Anxiety Disorder 2.5%; Phobic Disorders 1.5%; and Panic Disorders 0.5% of the general population. One study suggests a low use of psychiatric services; others, a higher use of general practice services. Distinct diagnostic categories probably give arbitrary estimates of prevalence. An approach regarding severity of panic attacks as an important dimension gives more realistic estimates: for example, in a recent UK study occasional panics were present in 1 in 10, whereas frequent disabling panic attacks were reported by only 1 in 50 of the adult population. Alcohol can be involved in a vicious circle of panic leading to problem drinking leading to withdrawal leading to panic, although this is less common in the community than in out-patient psychiatric practice. The natural history of panic either as a cluster of symptoms occurring alone or forming part of another psychiatric illness has not been established.

Family studies show that anxiety neuroses are familial, and the data from twin studies suggest a genetic contribution. This is more obvious in Panic than in Generalised Anxiety Disorder, and this has led some to suggest a specific genetic contribution to the former but not the latter. However, more general genetic predispositions are likley to be important: personality, neuroticism, autonomic lability, and biochemical factors. Multifactorial or polygenic explanations may, therefore, fit the data better.

In the study of anxiety and panic, reliable measures are important, and self-reports must remain a key feature; several dimensions should be taken into account. These include severity, duration, and frequency of attacks as well as type, e.g. 'spontaneous' as opposed to 'situation-related' panic attacks. The diary method is very useful. Intensity is best assessed by the disruptive effects of the attack on normal on-going activities. Other aspects of the psychiatric condition should be rated, such as phobias and levels of generalised anxiety and depression. The natural history of the panic attacks should be documented, for example whether the attacks follow an episodic, cyclic, or clustered pattern.

Views on the psychological aspects of panic attacks currently focus on the cognitive hypothesis. This proposes a cycle in which a trigger stimulus, internal or external, gives rise to perceived threat, apprehension, and in particular to bodily sensations which are misinterpreted in a catastrophic fashion and thereby reinforce the perceived threat. These misinterpretations involve perceiving these sensations as indicating immediate and severe physical or mental harm. In cognitive therapy these misinterpreted bodily sensations are identified, and by suggesting and testing alternative non-catastrophic interpretations panic and anxiety levels are reduced. There is some evidence, stemming from studies on cognitive abnormalities, that panic can be differentiated from generalised anxiety disorders.

The bulk of morbidity in anxiety disorders is encountered in general practice, but there are problems with current diagnostic schemes. Patients may present with anxiety, phobic, panic, and depressive symptoms in various combinations. As symptom-clusters are not stable over time, there are often changes in appropriate diagnostic labels; somatisation is common, so that patients who experience panic attacks often complain of bodily rather than psychological symptoms. This may lead either to failure of recognition or inappropriate referral.

The treatment of panic disorders is varied. Most of the evidence comes from studies which included agoraphobic patients with panic attacks, and concurrent behavioural treatments were usually given. Tricyclic antidepressants, such as imipramine and clomipramine, have an established place in the prevention of panic attacks. Where panic occurs without significant depression some workers have evidence to support the use of low doses of antidepressant drugs, but others have suggested the use of high doses. There is also disagreement about the time of onset of the therapeutic effect, some workers reporting prompt onset, others noting substantial delays. Some panic patients appear very sensitive to unwanted effects of these drugs. Reponse at low doses may suggest a mechanism of action distinct from the antidepressant action seen at higher doses. Although improvement may be maintained for some time after stopping the drugs, over the longer term the outcome is more uncertain. A few benzodiazepines used in doses above the usual anxiolytic ones (e.g. alprazolam, clonazepam, diazepam) have been shown to prevent panic attacks; the evidence for this is most clear for alprazolam, and further studies are in progress. Such response to benzodiazepines is, however, less convincing than that to the tricyclic antidepressants, and there is a danger of dependence. Alternative drugs include the MAOIs and β-adrenoceptor blockers; the latter are of limited usefulness. All of these treatments can be used in conjunction with behavioural and cognitive therapies. Indeed, preliminary evidence suggests the efficacy of cognitive therapy alone in patients with panics. High consultation rates and limited time in general practice emphasise the need for simple, pragmatic therapies.

Panic attacks can be regarded as a cluster of symptoms which can occur alone or as part of another disorder which has its own place in the classificatory scheme. Controversy attends the nosological status of disorders in which the symptoms of panic occur in conjunction with other disorders (agoraphobia, generalised anxiety, or depression). In the American classification (Revised DSM–III) panic attacks are given primacy and are thought to delineate a separate diagnostic entity (called Panic Disorder). The proposed revision of the ICD uses the term 'Panic Disorder (episodic anxiety)' to describe a disorder in which panic attacks occur as the major feature in the absence of significant anxiety between attacks and a depressive disorder. The meeting preferred the latter convention, as it is unclear whether panic attacks which occur in association with significant generalised anxiety are best considered as a separate disorder or as a more severe form of generalised anxiety disorder.

The meeting also recognised that for research purposes the individual symptom clusters should be considered independently, and it urged longitudinal studies to clarify their natural history and outcome.

The consensus of the meeting was that it is useful descriptively to recognise the symptom cluster of panic attacks which can be defined operationally in terms of features and content. Frequency is a useful, albeit arbitrary, indicator of severity. It was recognised that patients are encountered in whom panic attacks occur in the absence of other significant symptoms. The status of panic disorder as a separate entity was not strongly supported by available clinical and scientific evidence. Finally, although some evidence suggested that panic attacks often represented a severe form of more generalised anxiety, it was premature to attempt to describe the relationships between the various symptom clusters.

Senile Dementia and Parietal Lobe Dysfunction

Sir: Gilleard *et al* (*Journal*, January 1987, **150**, 114–117) miss the point of the paper by McDonald (1969), whose findings they claim to have disproved. Since the latter's hypothesis was essentially a predictive one which was vindicated by follow-up and confirmed by others (Naguib & Levy, 1982) it is difficult to see how a purely cross-sectional study with no follow-up can be strictly relevant to the issue. Furthermore, Gilleard *et al* claim that McDonald did not exclude cases suggestive of a vascular aetiology, whereas the 1969 paper states that such exclusion did occur: "If there was a history of strokes or epileptic seizures or if there were focal neurological signs the patients were excluded as being suspect arteriosclerotic dementias".

It is true that age and age of onset may no longer be regarded as reliable predictive factors in view of the somewhat contradictory results reported by different authors (Huff *et al*, 1987), but the sinister prognostic significance of visuo-spatial dysfunction must be considered as one of the most robust findings in the clinical literature on Alzheimer's disease. Its relationship to dysphasia and other focal features on the one hand and to overall severity on the other is a complex one which my group is trying to unravel in the course of a prospective study.

Gluten Sensitivity in Schizophrenia

SIR: Singh & Kay (*Journal*, January 1987, **150**, 130–131) make telling points in their criticism of our study of gluten sensitivity in schizophrenia, most of which we have already made and accept. We hardly perceived ours as the critical experiment; such experiments are difficult to perform in any science and very difficult in clinical psychiatry. They are usually misreported simplifications of the history of science. Indeed, we experienced, as others will, considerable problems in getting psychotic people to co-operate convincingly in accepting dietary controls, and so the attempt, which is what we report, was of short duration and in a special hospital. We certainly don't wish to deter others from performing more adequate work, but in our limited study the major changes occurred in the patients before they had a gluten-free period. We were pleased that, fortuitously perhaps, the *Journal* published Singh & Kay's letter after one by Wing suggesting "very impaired patients" were "not impervious to social stimulation", as seemed obvious in our study.

In addition, though, we are blamed for not considering the heterogeneity of the syndrome, while in fact we discussed it and concluded that gluten-free diets may be of value to some schizophrenics. We could go on at length over details of interpretations, but perhaps it would be wisest to concede that Singh and Kay have done an immense amount of work in this field, which we took seriously enough to examine and to try to confirm. Hence we are sorry if our inability to support them in our short-term and necessarily imperfect study can be read as wishing to dismiss their efforts and their approach completely. Far from it – we want, with them, to see what other studies can demonstrate, but we needed to report what we found.

We note, though, that Singh & Kay have written several similar letters criticising other peoples' failures to confirm their hypothesis (Singh, 1979; Singh & Kay, 1983).

Sub-cortical Dementia

SIR: In his review of sub-cortical dementia (*Journal*, December 1986, **149**, 682–697) Cummings makes the statement: "Sub-cortical dementias are characterised by psychomotor retardation, whereas the cortical dementias" (among which he includes Alzheimer's disease) "manifest a normal psychomotor speed through most of the clinical course", and supports this with reference to Cummings & Benson (1986). Although it is true that this view has become something of an orthodoxy in neurological texts, it flies in the face of much evidence from other sources. For instance, it is clear that on the Digit Copying Test (DCT) component of the Kendrick Battery (Kendrick *et al*, 1979) groups of patients with dementia predominantly of the Alzheimer type were significantly slower than non-demented subjects. Evidence of slowing also comes from other sources using quite different techniques. Thus slowing is also found in Alzheimer patients when they are asked to identify pictures presented tachistoscopically (Neville & Folstein, 1979) or when they carry out tasks using a peg-board (Miller, 1977). This issue is discussed by Woods (1982), who suggests that a critical point may be the degree of cognitive load in terms of choices available. Another important variable which may be seen as a form of cognitive load is the delay involved before the subject is expected to respond. In a study using a computerised visual matching to sample task with variable delay

(Morris *et al*, 1987; Sahakian *et al*, 1987) we found that patients with relatively early Alzheimer disease only reacted as rapidly as controls when an immediate response was required (i.e. with a zero second delay). The data show that when the test stimulus is delayed the Alzheimer patients respond a good deal more slowly than the age-matched controls, and that in this respect they perform far worse than recently diagnosed patients with Parkinson's disease who showed much smaller differences from their own controls on this task.

We suggest that psychomotor speed is a complex variable, and that contrary to belief it is not a useful way of differentiating between cortical and subcortical dementia.

Dementia in Parkinson's Disease

SIR: Oyebode *et al* (*Journal*, December 1986, **149**, 720–725) present data about dementia in 43 patients with Parkinson's disease, and draw conclusions concerning the prevalence of this. Their population was drawn from patients attending an illustrious neurological centre. Perhaps the area served contains patients with Parkinson's disease who were not referred to the centre, but were looked after by general practitioners, geriatricians, or psychiatrists. There might have been a tendency to fail to refer the bedridden, the incontinent, and the demented.

Anorexia Nervosa or Dysmorphophobia?

SIR: An alternative diagnostic formulation is possible (*Journal*, December 1986, **149**, 780–782). As Hay (1970) points out, dysmorphophobia is a non-specific symptom often indicative of a 'sensitive personality development', or occasionally early schizophrenia. The phenomenological distinction between the overvalued idea and the delusion depends in part on external evidence of physical abnormality and adverse environmental experience, often in the form of teasing in childhood. This girl was clearly obese at the age of 12, was instructed to lose weight by two professionals, and had previously been teased by family members. The positive family history of a transient psychotic episode in her brother with no further deterioration would support the formulation of a constitutionally-based sensitive personality prone to neurotic elaboration. While the patient meets the criteria for both agoraphobia and social phobia, she apparently never lost enough weight or persisted long enough in her dieting to qualify as a case of anorexia nervosa by DSM–III criteria, but would be more appropriately labelled as having atypical eating disorder.

These diagnostic distinctions may have significant clinical relevance for treatment. Slade and others have documented the variability in body size estimations of anorexics who, as a group, have a tendency to over-estimate certain body part dimensions. Unfortunately, no body image measurements are reported in this case. In contrast, body image measurements have been described in dysmorphophobic patients which might help differentiate them from the anorexic group. Jerome (1980) described a group of patients with dysmorphophobia requesting cosmetic rhinoplasty who were *more* accurate than normal controls in estimating their own nose size, and spent more time looking at this particular feature of their appearance in mirrors. The data suggested that dysmorphophobics may be utilising a 'perceptual defence' of over-focusing on specific aspects of their body image. This contrasts with the clinical findings in anorexia nervosa, which suggest an avoidance of observation of their own bodies with parallel mirror avoidance and a relative over-estimation of specific body parts in comparison with controls. Furthermore, a recent article by Norris (1984) suggests that anorexics might show clinical improvement following mirror confrontation.

In contrast, preferred treatment for dysmorphophobia might involve the reverse behavioural approach. Support for this hypothesis comes from clinical accounts of patients who report themselves much improved after cosmetic surgery when objective ratings of their appearance indicate no significant change.

The patients who do well have a supportive confidant, an optimistic attitude, and have been prevented from looking at the particular body part, which is shrouded in dressings after surgery. This arguably may allow the dissolution of the distorted body image, which in part may be a manifestation of heightened cognitive awareness for, and the preferential visual scanning of, the body part in question. A similar cognitive-behavioural approach could be envisaged for over-focused dysmorphophobic patients.

Organic Factors in Catatonia

SIR: Though Wilcox & Nasrallah (*Journal*, December 1986, **149**, 782–784) note that catatonia has been reported in non-schizophrenic individuals, they fail to mention that in a study of 55 consecutively admitted catatonic patients Abrams & Taylor (1976) found a preponderance of cases with manic (34) and depressive (5) disorders but only four with schizophrenia. Similarly, of the 25 cases studied by Barnes *et al* (1986), ten were idiopathic and nine had a depressive illness. There was a single case of schizophrenia. Both the idiopathic and the affective groups had a high incidence of recurrent episodes and a family history of catatonia. These findings confirm Kahlbaum's original description of catatonia as a non-specific syndrome, rather than a disease entity, with a wide range of causes, of which affective disorders appear to be the most common.

The undue emphasis on the association of catatonia with schizophrenia is also pertinent to the tragic patient reported by Ainsworth (*Journal*, January 1987, **150**, 110–112). In view of the striking affective changes in her patient's mental state (as well as the family history of depression and mutism), an affective disorder, possibly mania, seems a more appropriate diagnosis than catatonic schizophrenia. Though reported as a case of Stauder's lethal catatonia, no evidence is presented of its characteristic features, i.e. mounting fever and extreme hyperactivity progressing to stuporous exhaustion and death. Clinically it resembles the more familiar benign variety of Kahlbaum (Mann *et al*, 1986).

Ainsworth raises several questions which have an important bearing on the treatment of such patients. Though amylobarbitone sodium interview is reportedly helpful in distinguishing catatonia of psychiatric origin from that with a toxic-metabolic or neurological basis, its value in the lethal variety is uncertain. Whether a putative affective disorder developed subsequent to a sub-clinical viral encephalitis or predisposed her patient to increased infection is a moot point (Wilson, 1976), but the brief return to normality after i.v. diazepam would argue against the usefulness of such techniques rather than render a diagnosis of encephalitis less probable in light of the clinical and pathological findings. Orthostatic hypotension due to the high doses of chlorpromazine could have caused the patient to fall, and while the cause of death seems unrelated to the catatonia, a viral encephalitis may well have compromised her gag reflex, resulting in fatal aspiration. The outcome for patients with benign catatonia, whether of psychiatric or other origins, is described as excellent and most recover spontaneously or rapidly after ECT, although a high rate of recurrence has been reported, particularly among those with a family history of catatonia (Barnes *et al*, 1986). In patients with lethal catatonia ECT may also be dramatically effective, and perhaps lifesaving (Mann *et al*, 1986).

Finally, several authors have commented on the similarities between lethal catatonia and the neuroleptic malignant syndrome, which may well be a drug-induced variety of the former. Because of the dangers posed by neuroleptic treatment in iatrogenic and other forms of lethal catatonia, as well as evidence that some patients develop stupor and fever only after the initiation of such treatment, a prudent approach would be to discontinue its use in benign catatonia too. In view of its efficacy, ECT would appear to be the treatment of choice in catatonia, although in some cases of the lethal variety other agents, e.g. dopamine agonists such as bromocriptine or dantrolene, may be necessary initially.

SIR: Wilcox & Nasrallah (*Journal*, December 1986, **149**, 782–784) suggest that the reason why catatonia has become something of a rarity is that brain injury in childhood, which the authors postulate as predisposing to catatonia, has declined in frequency.

I work in the field of mental handicap, in which brain damage is considered, in many instances, to be at the root of the handicap, particularly in profoundly affected patients. I have seen hardly any mentally handicapped individuals suffering from catatonia, although only recently I have been treating someone with this condition. If my experience is shared by other psychiatrists practising mental handicap, this would be an argument against the hypothesis that an organic brain condition is a forerunner of catatonia, unless one were to say that in the mentally handicapped catatonia, for reasons to do with the level of intelligence, is not a feature.

A survey of the incidence of catatonia in the mentally handicapped would throw light on the attractive theory put forward by Wilcox & Nasrallah.

A Case of Resistant Schizophrenia

SIR: I wish to comment on the treatment of this unfortunate young man (Mr A) (*Journal*, December 1986, **149**, 789–793). The record of therapeutic failure includes a trial of electroconvulsive therapy: "He was treated with six ECT for a possible affective component to his disorder, but with little benefit." Such a course of electroconvulsive therapy was probably inadequate.

Prior to the introduction of neuroleptic drugs, ECT was commonly used in the treatment of patients with schizophrenia. The comparative studies of the 1960s did not demonstrate a failure of ECT; rather, they demonstrated the equivalence of group results between those patients treated with ECT and those with neuroleptic drugs. The ease of administration, lesser expense, and assumed greater safety of psychotropic drugs, however, led to their replacement of ECT. Recent concerns about tardive dyskinesia, neuroleptic malignant syndrome, and other hazards of neuroleptic drug use (as well as therapeutic failures) have led some clinicians to re-examine the application of ECT in the treatment of schizophrenia.

Friedel (1986) recently reported the successful use of the combination of thiothixene and ECT in eight of nine patients who were non-responders to extended courses of neuroleptic drugs. We have treated nine schizophrenic patients who were neuroleptic and multi-drug treatment failures with the combination of ECT and fluphenazine. Of these, seven have been functioning well in the community for at least one year, and we are encouraged enough to undertake a random assignment trial. However, these patients required an average of 15 ECT in their treatment course, a number greater than is ordinarily given to our depressed patients.

The report by Brandon *et al* (1985) of the results of schizophrenic patients treated in the Leicestershire study and that of Taylor & Fleminger (1980) also encourage the use of ECT in schizophrenic patients. These findings were recently endorsed by the NIH Consensus Conference (1985) and by van Valkenberg & Clayton (1985).

If Mr A is still psychotic, a repeat trial of ECT should be considered with a minimum of 12 induced seizures, preferably with bilateral electrode placement, and with minimum durations of 25 s for each peripheral seizure (30 s central seizure). These treatments should be given while the usual dosages of neuroleptic drug therapy are continued.

Panic Attacks and Hyperventilation

Sir: Snaith (*Journal*, November 1986, **149**, 794) takes issue with Gelder's suggestion (*Journal*, September 1986, **149**, 346–352) that lowering of arterial pCO_2 may be a contributory factor in the development of a panic attack, and cites four pieces of evidence that fail to support such a view. However, Snaith has misrepresented Gelder, who did *not* state that hyperventilation *per se* causes panic. The psychological model proposed by Gelder is that hyperventilation induces panic *only* when the bodily sensations which it induces are (a) perceived as unpleasant, and (b) interpreted in a catastrophic fashion (Clark, 1986). In this respect hyperventilation is but one of a number of various pharmacological and physiological agents (such as caffeine, yohimbine, and CO_2 inhalation) which have been shown to provoke panic in susceptible individuals (Margraf *et al*, 1986). Thus the "overwhelming fear of dying or of becoming insane", which Snaith regards as the pathognomonic feature of a panic attack, is simply (in the cognitive model) a consequence of the misattribution of hyperventilation-induced somatic sensations to a life-threatening illness. Ley (1985) provided support for this view when he found that panic patients frequently report that the *first* thing they notice during an episode of anxiety is a physical feeling, most commonly breathlessness.

It is important to note that hyperventilation is neither a necessary nor sufficient prerequisite for panic anxiety. However, it is important to identify the sub-group in whom it may be a necessary condition, i.e. those in whom the symptoms of hyperventilation lead to panic, for the following reasons: firstly, the symptoms which cause panic can usually be reproduced by asking the patient to overbreathe; and secondly, the patients' fears and beliefs about the symptoms can be modified using a therapeutic technique that has been shown to be effective in reducing panic attack frequency (Salkovskis *et al*, 1986). We therefore need to know how this sub-group differs from those patients in whom hyperventilation does not play a role in panic.

Snaith remarks that not all patients who hyperventilate become anxious. This is certainly the case, as we have shown, but such a finding is not unexpected, since it is known that correlation between measures of physiological arousal and subjective reports of anxiety is not robust. It is also consistent with the cognitive model of anxiety. Although it has not been demonstrated that non-anxious hyperventilators do not report anxiety precisely because they do not appraise their somatic symptoms as frightening, this proposition is testable.

Snaith also points out that the administration of CO_2 to patients *induces* anxiety rather than the reverse, and argues that such a finding is not consistent with the hyperventilation theory. But whether CO_2 inhalations are anxiolytic or anxiogenic depends on the individual's cognitive set, i.e. on the instructions that are given before the inhalation. This observation emphasises the importance of cognitive factors in determining the affective state produced by manipulation of CO_2 (Clark, 1986).

I agree with Snaith that there is a lack of consensus about the definition of panic. It is not clear whether panic is quantitatively or qualitatively distinct from other forms of morbid anxiety, and the word has been used to describe both a psychological and a physiological experience. Some authors have introduced additional behavioural criteria such as fear of death, fear of losing control, fear of going crazy, or an urgent need to run, in addition to DSM-III symptoms.

It should be noted that the 'hyperventilation theory' has gained ground not because of the ideology of those committed to a psychogenic rather than a biogenic explanatory model, but because of studies that have revealed the importance of not only cognitive processes, but also specific physiological abnormalities such as hypocapnia in patients with anxiety disorders (Bass, 1985). Laboratory studies using phobic imagery and other provocations may help to further clarify the relationships among cognitive, physiological, and behavioural variables in patients with panic anxiety. Finally, it is worth recalling that the impetus for splitting panic disorder from the body of anxiety disorders arose from the observation that tricyclic drugs had a specific anti-panic effect. The evidence for this 'biogenic' theory of panic is not compelling (Margraf *et al*, 1986).

Sir: I am grateful for the opportunity to respond to the letters from Snaith (*Journal*, November 1986, **149**, 794) and Bourne (*Journal*, February 1986, **150**, 265–266) about my article on panic attack. In his letter in the December issue, Snaith argues that panic attacks are not caused by hyperventilation, and implies that I take the opposite view. He has misunderstood my position, for I did not conclude that hyperventilation is the most important cause of panic. The misunderstanding centres round two statements in Snaith's letter and these require a response.

Firstly, Snaith writes that the effect of cognitive treatment "supposedly supports the argument that lowering arterial CO_2 is an essential component in the development of a panic attack". This is not the case: the effects of cognitive therapy support a different argument, namely that patients who experience panic attacks have a particular tendency to misinterpret bodily sensations, ascribing them to causes that are more serious than the real ones. For example, palpitations may be interpreted as evidence of heart disease. This view of panic attacks is consistent with the idea that on some occasions the misinterpreted sensations have been produced by hyperventilation, but it is not suggested that they always arise in this way. Equally, the cognitive hypothesis does not suggest that all those who hyperventilate will experience panic – only those people who have the particular tendency to misinterpret bodily sensations.

Secondly, Snaith writes that "the evidence points to the conclusion that raising, *not lowering*, arterial CO_2 induces anxiety". In fact, raising as well as lowering CO_2 can induce anxiety in some people (Van den Hout & Griez, 1984). At first this finding seems paradoxical, but it is easily explained by the cognitive hypothesis. Thus, either an increase or a decrease in pCO_2 can – through different mechanisms – cause unpleasant bodily sensations, and people who misinterpret these bodily sensations will be made anxious by either kind of change.

Returning to my own article, I did not single out hyperventilation as a frequent or major cause of panic attacks. Indeed, I concluded that it is unlikely that all panic attacks will turn out to have a single cause. I also suggested that 'biological' factors (including hyperventilation) have been overemphasised in the recent literature, and that more attention should be given to the investigation of psychological factors in these patients.

Bourne criticises me for failing to give a fuller account of Freud's views. However, he writes as though the subject of my paper were the aetiology of anxiety neurosis; in fact, it was the more specific problem of why some patients with anxiety neurosis develop panic attacks while others do not. My selective quotation from Freud was chosen to show how carefully he had described the clinical phenomena of anxiety disorders including panic attacks. I included this quotation because I agree with Bourne that some of Freud's early papers contain penetrating observations about clinical phenomena. I also agree that these observations are of great interest to present day practitioners of cognitive therapy. It is in their interpretation of the phenomena that analysts and cognitive therapists differ and, more importantly, in the kind of treatment that they have developed. Time will decide which approach is more fruitful: cognitive treatment for panic disorder is now being tested in controlled trials, but we still await reports of a comparable evaluation in which psychoanalytic treatment is compared with other methods.

Use of Paraldehyde

Sir: The generally unfavourable discussion on the modern use of paraldehyde by Linter & Linter (*Journal*, November 1986, **149**, 650–651) cannot go unchallenged. The patient reportedly received 40 ml of paraldehyde intramuscularly over 12 hours. This is more than double the recommended maximum i.m. dose of 30 ml per 24 hour period (McEvoy & McQuarrie, 1986). Paraldehyde is a drug with a disagreeable smell and special storage requirements, but over 100 years of anecdotally safe use is precisely why "Its current use is limited to psychiatric units, particularly those without resident medical cover" (Linter & Linter, 1986): an important factor in those parts of the world that are short of doctors. Intermittent claims that paraldehyde is outmoded usually include a pharmacologically erroneous comparison with modern sedative/anxiolytics such as the benzodiazepines and phenothiazines and their derivatives. Paraldehyde belongs to the class of drugs including ethinate, clomethiazole, methyprylon, and ethanol (Goodman & Gilman, 1985) that act by membrane transport inhibition due to high lipophilicity and produce dose-related sedation devoid of the autonomic side-effects common with those drugs that act putatively via neurotransmitter mechanisms. While it is probably correct to state that the high potency benzodiazepines such as clonazepam and lorazepam have superceded paraldehyde in the parenteral treatment of status epilepticus, it remains useful as a sedative/hypnotic adjunct in hyperaroused states such as established delirium tremens, psychotomimetic 'street-drug' toxicity, and extreme mania, complementing the actions of neuroleptics of high anti-psychotic potency (but low sedative rating) that are usually administered concurrently. In these cases paraldehyde in normal doses does not produce the marked hypotension common with equi-sedative doses of the low potency sedating phenothiazines such as chlorpromazine which have marked anticholinergic and alpha-adrenergic blocking actions (Hollister, 1977). The patient reported by Linter & Linter arguably received an overdose of a drug no longer indicated for the condition concerned. These two errors should not be extrapolated to adversely influence the continued use of a drug still regarded by many as the standard against which other agents must be measured (McEvoy & McQuarrie, 1986), which has limited but highly specific indications and which currently has no exact pharmacological equivalent.

Autocastration in Ontario Federal Penitentiary Inmates

Sir: With regard to the report by Waugh (*Journal*, November 1986, **149**, 656–658), the summary asserts that autocastration usually occurs in men with chronic paranoid schizophrenia. The evidence for this is not clear in the text, and it seems to contradict our experience, with an admittedly selected population, at the Regional Treatment Centre (Ontario). The Treatment Centre provides in-patient psychiatric care for the approximately 3000 federal penitentiary inmates of the region. The following brief case studies cover seven cases of attempted or successful autocastration on record since 1980.

Case reports: (1) A 23-year-old inmate was incarcerated for life for the second degree murder of his mother, which occurred during an argument about his transsexual behaviour. In 1980 he inserted foreign bodies into his genitalia as an attempt to force surgical castration. During reparative surgery his physique caught the attention of the urologist, and subsequent tests confirmed an XYY karyotype. In 1983 he lacerated his scrotum, intending castration, as part of a suicide attempt in protest at prison authorities' refusal to finance sex reassignment surgery. Final psychiatric diagnoses were of transsexualism and schizoid personality disorder.

(2) A 50-year-old Hungarian immigrant, also serving life for murder, in 1981 cut his scrotum, removed his testicles, and flushed them down the toilet, then swallowed the razor blade. He revealed that he did so to pre-empt a Mafia inspired scheme for other inmates to crush his testicles in punishment. Final diagnosis was of paranoid schizophrenia.

(3) A 38-year-old inmate, serving two years for theft, with earlier convictions for prostitution, in 1984 lacerated his scrotum, removed the right testicle, and by stuffing the cavity with cigarette ends, forced a complete surgical orchidectomy. Diagnoses were of transsexualism and antisocial personality disorder.

(4) A 41-year-old man lacerated his scrotum as part of a suicide attempt after revocation of his parole. He had served ten years of a composite 24 year sentence for a series of rapes. While out on parole and because of impotence he had refused continued provera treatment, which in turn lead to the revocation. Diagnoses were of adjustment disorder with depressive features, and antisocial personality disorder.

(5) A 40-year-old transsexual, who had castrated himself in 1979, slashed at his penis in 1980 and again in 1983 in protest at being placed in a male, rather than female, institution after his conviction for a series of armed robberies. Diagnoses were of gender dysphoria and personality disorder, unspecified.

(6) A 34-year-old serving ten years for six counts of robbery in 1984 almost completely severed his genitalia and slashed his wrists, intending suicide. He did it, he said, to punish himself. His sexual orientation was normal; diagnoses were of substance abuse and borderline personality disorder.

(7) A 27-year-old transsexual serving a 15-year composite sentence for assault and attempted murder in 1983, under the influence of "brew" and illicit drugs, attempted castration to force sex reassignment surgery. Diagnoses were of transsexualism, substance abuse, and personality disorder, unspecified.

Of these seven patients, three of them successful, only one was diagnosed as having a psychosis. The others all showed personality disorder of various kinds. Almost all had a previous history of self-mutilation, slashing of the wrists, or previous suicide attempts. The largest group, four patients, consisted of long-standing transsexuals whose disturbed personalities had possibly suggested a poor prognosis for sex reassignment surgery, and who consequently had been refused such surgery by the various specialists they had encountered. Of interest in a generally young population is the higher than average age of the group. While the high proportion of personality disorders may simply reflect the catchment population, which may also account in part for the low number of psychotic patients, this report serves to emphasise that such behaviour is not necessarily, nor particularly often, associated with paranoid schizophrenia. The most common associations seem to be a disturbance of sexual identity, a previous history of self-mutilation, and personality disorder.

Ethnic labels in South Africa

SIR: We refer to the correspondence regarding the use of South African Population Registration Act categories as a basis for psychiatric research (Sashidharan & Lipsedge, *Journal*, April 1986, **148**, 484; Teggin *et al*, *Journal*, November 1986, **149**, 667–668; Graham, *Journal*, November 1986, **149**, 669). During the time that we were working at the MRC/University of Cape Town Clinical Psychiatry Research Unit this was a major issue of debate. The labels "Black", "Coloured", "Indian" and "White" as used in South Africa are fundamentally political, and do not refer in any scientific sense to discrete ethnic or cultural groups (Sharp, 1980). The important way in which these labels are "real" is that they dictate vastly differing access to resources of all kinds, including housing, education, employment, and health care.

The Continuum of Psychosis and the Gene

SIR: Crow attempts to replace the Kraepelinian dichotomy between manic depressive psychosis and schizophrenia with a continuum of psychosis (*Journal*, October 1986, **149**, 419–429). We agree that data such as those obtained by Kendell *et al* support the conclusion that a symptomatic continuum exists. However, the evidence for a genetic continuum of the form envisaged by Crow is less persuasive.

Crow's model is based on several studies from the older literature reporting an excess of individuals with schizophrenia among the offspring of patients with affective disorder while failing to observe the converse. None of these studies employed modern diagnostic criteria, and it is possible that misclassification occurred. Indeed, studies (quoted by Crow) using modern methods have failed to show an increase in schizophrenia among the relatives of probands with affective disorder. Crow also argues that similarities in season of birth effects point to an underlying commonality of genetic mechanisms. However, the season of birth effect in schizophrenia is associated with an absence of a manifest genetic predisposition, suggesting a relationship with environmental factors (Boyd *et al*, 1986).

In contrast, evidence that schizophrenia and affective disorder are based on two independent genetic diatheses is more compelling. Firstly, as Crow acknowledges, the two major functional psychoses by and large breed true. Secondly, bipolar affective disorder appears to have a stronger genetic component than schizophrenia. Crow's hypothesis would appear to predict the converse. Thirdly, Elsässer (1952) found an equal prevalence of the two psychoses in the children of marriages between an affective and a schizophrenic individual. A greater prevalence of schizophrenia than affective disorder is predicted by Crow's hypothesis. Finally, Crow's model also fails to take into account the existence of "schizophrenia spectrum disorders", or the evidence that minor depression and depressive and cyclothymic personality disorder are genetically related to affective disorder. These findings suggest that there are separate phenotypic spectra related to the schizophrenic and the affective genotypes which are orthogonal to the phenomenological continuum that exists between the two disorders.

Given this evidence for independent genotypes, where does this leave the nosological status of schizoaffective disorder which occupies the intermediate position in the symptomatic continuum? One possibility is that it consists of both affective and schizophrenic types of illness. However, as Crow reminds us, the concept arose out of the failure to demonstrate such a division. Secondly, it might be a genuine interform between schizophrenia and affective disorder (Kendell, 1983). This implies that both illnesses are polygenic, with the presence of some elements from each genotype predisposing to schizoaffective disorder. A third possibility, which does not imply polygenic inheritance of both Kraepelinian psychoses, is that it represents the presence of both the schizophrenic and the affective genotypes in the same patient: it occurs in individuals who, in genetic terms, have both illnesses. It has been argued by Kendell (1983) that this is unlikely because schizoaffective disorder is more common than would be expected given that "the chance coincidence of two illnesses each affecting around one person in a hundred is one in ten thousand".

We disagree with such a conclusion on several grounds. Firstly, there is no reason to suppose, as Kendell does, that for schizoaffective disorder to occur a genetic diathesis to schizophrenia would have to exist with one for bipolar rather than unipolar affective disorder. The morbid risk for all types of affective disorder combined is much greater than 1%, and therefore Kendell's expected figure would be larger. Secondly, assortative mating might take place to increase the likelihood of both genotypes being present in combination. Thirdly, Kendell assumes that possession of one genotype will not affect expression of the other. On the contrary, it seems likely that schizophrenic symptoms will trigger the onset of affective illness in a predisposed individual and vice versa. Moreover, it is quite possible that *subclinical* expression of one genotype increases the likelihood of the other being expressed in a predisposed individual. For example, possession of an affective diathesis might render an individual with a schizophrenic genotype more likely to develop a psychotic reaction to stressful life events. Such a psychosis might be expected to show both schizophrenic and affective features.

In summary, we suggest that the symptomatic continuum reflects phenotypic interaction rather than the relationship proposed by Crow.

Procyclidine Abuse

Sir: In reporting five more cases of procyclidine abuse, Fenech & Khoosal (*Journal*, October 1986, **149**, 524) pointed out that the latest edition of the *British National Formulary* (BNF) did not mention the potential for abuse of that drug. Pullen *et al* (1984*a*) drew attention to the fact that the BNF omitted reference to the abuse of any anticholinergic.

At last the BNF (Number 11, 1986) does include one sentence on abuse in its section on the use of antipsychotic drugs (p. 139), although there is still no mention of this danger in the main section on anticholinergics (pp. 182–184). These preparations continue to be freely prescribed, and there still seems to be continuing ignorance about these significant drugs of abuse (Pullen *et al*, 1984*b*).

Neurological Factors in Obsessive-Compulsive Disorder

Sir: In their article on obsessive-compulsive disorder (OCD) (*Journal*, September 1986, **149**, 315–319), Kettl & Marks emphasise the case for organic precipitants, probably operating 'downstream' from the primary mechanisms initiating the condition. Whether cognitive abnormalities in OCD attributed to these organic precipitants could be intrinsic or secondary features of the condition is not assessed. This remains unclear in the recent studies quoted (Behar *et al*, 1984; Flament & Rapoport, 1984), which showed computerised tomogram and cognitive abnormalities in adolescents with OCD. Brain injury was not used as an exclusion criterion in the group concerned. Some patients had histories of head trauma and birth injury, and one is mentioned as having tardive dyskinesia.

I have studied 19 DSM-III-diagnosed obsessive-compulsive patients, none of whom had neurological impairment, psychosis, alcoholism, or a history of head injury (Harvey, 1986). They were given tests of frontal lobe functions and sub-tests of the Weschler Adult Intelligence Scale (WAIS). Using matched normative data for Nelson's Modified Wisconsin Card Sorting Test (MWCST), the obsessionals were shown to perseverate significantly more than normals ($t=2.80$, $P=0.01$). Their mean percentage perseveration (50%, s.d. = 31) was greater than for patients with gross frontal lobe damage (42%, s.d. = 25). Obsessionals with or without significant perseveration were comparable on age-scaled sub-tests of the WAIS. Perseveration correlated with degree of obsessionality on the Leyton Obsessional Inventory (Spearman's $r=0.50$, $P=0.01$), which also correlated, negatively, with alternating category verbal fluency (ACVF) ($r=-0.62$, $P=0.002$). This latter test and the MWCST assess cognitive set-shifting ability, a specific frontal lobe function.

Although OCD could affect cognitive tasks, such as the ACVF test, via impaired performance efficiency, it seems unlikely that a qualitatively distinctive error, such as perseveration, would occur on this basis. An overall impairment of performance would seem more likely, although this was not evident from the WAIS sub-tests. Whether or not idiopathic OCD is associated with frontal impairment therefore needs to be looked at as a specific issue. It should not be assumed that such impairment necessarily implies the presence of a known brain injury.

Gamma Glutamyl Transpeptidase and Mean Cell Volume in Alcoholics

SIR: Latcham (*Journal*, September 1986, **149**, 353–356) suggests that measurement of serum gamma glutamyl transpeptidase (GGT) and red blood cell (RBC) mean corpuscular volume (MCV) are of "little value in the assessment of patients admitted to psychiatric beds for problem drinking".

Macrocytosis in alcoholics has at least four different causes, some of which are independent of the duration of drinking habit. Lindenbaum (1980) comments that alcoholics' enlarged RBC can be secondary to liver dysfunction, reticulocytosis in response to blood loss, or folate vitamin deficiency, as well as "the macrocytosis of alcoholism".

Nearly a quarter of Latcham's male subjects and a sixth of the females were not clinically diagnosed as alcohol-dependent. What differences were there, in the correlations reported, between those diagnosed as alcohol-dependent and those diagnosed as suffering from alcohol abuse?

If only 143 male subjects had GGT assays performed then the maximum number of subjects in his Table III should be the same.

His data suggest that a considerable proportion of the male subjects had been abstinent for two or more weeks. This is long enough for mildly elevated GGT levels to settle to 'normal'.

The upper limit of normality for GGT of 50 i.u./litre is probably excessively high. We have recently shown (Hambridge & Jones, in preparation), that an upper limit of 40 i.u./litre is probably more clinically valid. Also, many clinicians will have experience of assessing younger, fitter alcoholics with high consumption and minimal damage – however defined.

I suggest that Latcham has not proven his case and that the measurement of GGT, RBC, and MCV remain of considerable value in assessing and managing alcoholics, when considered with the full clinical picture.

Neuroleptic Malignant Syndrome or Lithium Neurotoxicity

SIR: I refer to the comments made by Lowe & Batchelor (*Journal*, September 1986, **149**, 385–386) on the review of the neuroleptic malignant syndrome (NMS) by Abbott & Loizou (*Journal*, January 1986, **148**, 47–51).

Their criticism regarding omission of the original report by Cohen & Cohen (1974) seems to be founded on inconclusive evidence. The descriptive picture in the four patients has been found to be similar to NMS (Frankel & Spring, 1982), but there have been divergent opinions regarding the interpretation of the cause of the clinical picture. It has been suggested that these patients have persistent neurological after-effects of acute lithium neurotoxicity (Donaldson & Cuningham, 1983; Schou, 1984). A detailed analysis of the patients described by Cohen & Cohen reveals that all were on high doses of lithium carbonate (1165 mg/day to 1800 mg/day). The maximum serum lithium ranged from 1.48 mmol/litre to 2.45 mmol/litre during the acute phase of lithium toxicity. All four patients were female. A preponderance of females has been reported in patients with persistent neurological sequelae of lithium (Donaldson & Cuningham, 1983; Schou, 1984), unlike NMS (Shalev & Munitz, 1986).

Moreover, each of the four patients was left with permanent brain damage (two became grossly demented, two had persistent dyskinesias). NMS, despite a mortality rate of 20%, is an acute condition and generally regresses without sequelae. Shalev & Munitz (1986) reviewed 120 patients with NMS and could identify only four with permanent sequelae. In one of these, permanent brain damage was probably due to brain anoxia during ECT given in the course of NMS and not due to the condition itself. In contrast to this, I have identified 48 patients with long-lasting sequelae of lithium intoxication (either alone or in combination with other drugs) in the literature.

Although there is controversy about lithium/haloperidol interaction (Cohen & Cohen, 1974; Frankel & Spring, 1982) it is well established that lithium intoxication at times resolves leaving persistent neurological sequelae (Donaldson & Cuningham, 1983; Schou, 1984). Since NMS is only a descriptive term, superficial resemblance may be seen with any other descriptive syndrome, e.g. lethal catatonia and some cases of lithium neurotoxicity.

Gilles de la Tourette's Syndrome in Down's Syndrome

SIR: Karlinsky *et al* (*Journal*, May 1986, **148**, 601–604) speculate on a possible causal link between these two conditions. They appear to have neglected a more straightforward aetiology for the Tourette's syndrome.

It is reported that the patient developed seizures at the age of 24 years. Age-related epilepsy, with an onset in adult life, is a well recognised complication of Down's syndrome (Veall, 1974; Tange, 1979). The patient was being treated with carbamazepine two years later, at the onset of the Tourette's syndrome. Carbamazepine has recently been recognised as one of a number of pharmacological compounds (including dextroamphetamine, methylphenidate, and other adrenergic agents) which may precipitate tics, (Gualtieri & Evans, 1984). This tends to fit in with the dopaminergic theory of Tourette's syndrome, mentioned by the authors of the paper. Although, as they also point out, tics may be missed in people with mental retardation, there is as yet no clearly established link with any particular syndrome.

Precipitation of the tics by carbamazepine may account for the late onset of Tourette's syndrome in this patient, and seems a more likely explanation than those proposed by the authors. It is an iatrogenic complication of which psychiatrists should be aware.

Mianserin and Blood Dyscrasias

SIR: It is with some concern that I note that manufacturers of mianserin (Norval, Bencard and Bolvidon, Organon) have written to the profession in the UK advising of changes in the Data Sheet concerning bone marrow depression and blood dyscrasias, the changes having been instituted at the insistence of the Committee on Safety of Medicines. The essential change is that a full blood count is recommended every four weeks during the first three months of treatment. This action follows concerns highlighted in a recent CSM update (1985).

There appears to be confusion between a drug-related depression in the white cell count and drug-induced agranulocytosis. Many psychotropic drugs are known to be able to produce changes in the white cell count. Tricyclic antidepressants, phenothiazines, and carbamazepine are all recognised as being able to depress the white cell count. Lithium, on the other hand, is associated with a leucocytosis. On the whole these findings are benign, usually incidental results with no clinical manifestations, and reverse on cessation of the drug (Kaplan & Sadock, 1985). Agranulocytosis with the features of opportunistic infection, however, is a more serious condition, commoner in older females and arising 4–6 weeks after initiation of therapy, which in the case of chlorpromazine can carry a mortality of 30% (Kaplan & Sadock, 1985). This condition arises very quickly and appears unpredictable; thus many authorities believe that routine blood counts are unhelpful and that the doctor should rely on the associated symptoms and signs (Kaplan & Sadock, 1985; Gregory & Smeltzer, 1983).

Actual numbers of patients with these drug-related adverse events are extremely difficult to ascertain. The criteria for reporting a finding as a particular reaction are themselves usually idiosyncratic, depending on the physician's expertise, and there are few guidelines provided to standardise such reports. These problems are compounded by a methodology that is essentially anecdotal, with no control groups. Thus comparisons are difficult and often misleading, with doctors being more likely to report events with newer drugs than with older established compounds. Perhaps the most clinically iniquitous practice, however, is that the reports appear to be acted upon in isolation and out of the context of the overall risk-benefit ratio of the particular drug, and it is the overall mortality from exposure to the drug that should be considered.

Combining data from the Office of Population Censuses and Survey for England and Wales for 1982–84 with similar data from the General Register Office for Scotland over the same period, there were 1029 deaths in which tricyclics either alone or in combination were implicated. This compares with 55 in which mianserin either alone or in combination were implicated. Even allowing for the difference in rates of prescription, the overall mortality associated with mianserin is substantially less than with the tricyclics. Considering deaths resulting from antidepressant drug overdoses alone, the differences are especially striking, with mianserin accounting for only 15 such fatalities per million patients compared with 388 per million for the tricyclics and bridged-tricyclics (Leonard, 1986).

Practising geriatric psychiatry in Canada, I am restricted to using toxic and problematical antidepressants in the elderly which themselves can produce serious blood dyscrasias. For example, with amitriptyline 83 cases were reported in Britain between 1964 and 1981, with 18 deaths (Clink, 1983).

Therefore, it is far from clear that amendments to the Data Sheets for mianserin will achieve an improvement in the treatment or outcome of depressed patients. Routine blood monitoring is not likely to detect the uncommon event of a blood dyscrasia, and may well confuse the picture further as there are no controlled data with which to compare results of such testing. The likely outcome is that many doctors will be put off using mianserin, especially in patients who are particularly at risk from the tricyclic antidepressants such as the elderly. Ironically, the CSM may be contributing to increasing the risks of treatment.

Psychological Complications Following a Mis-diagnosis of Deafness

Sir: The differential diagnosis between hysteria and organic illness is important and fraught with pitfalls. Emphasis has been placed on ensuring that organic conditions are not mis-diagnosed as hysterical with consequent delay in treatment (Slater, 1965); however, it has also been recognised that protracted physical investigations and delay in psychiatric referral may worsen the prognosis for true hysterical symptoms (Goodyer, 1981).

Hysteria in childhood is uncommon, and is reported as not occurring in children under five years of age (Goodyer, 1981). We report a case of chronic hysterical deafness presenting at the age of two years with delay in the exclusion of any organic pathology until the age of fourteen years.

Case report: A fourteen-year-old boy presented to the adolescent psychiatric unit with a six-month history of increasingly poor peer and family relationships. He displayed a marked speech impediment, and communication was complicated by an apparently variable and selective deafness. Otherwise, physical examination was found to be normal. Although of average intelligence, his educational attainments were assessed as being at the eight-year level, as were his behavioural, emotional, and social abilities.

The history revealed that at the age of two years he was referred to a child psychiatrist with disturbed behaviour. His language was delayed and he appeared not to respond to noises or speech. At ENT referral, examination of the ear drums was normal but hearing tests suggested he was profoundly deaf. The diagnosis was supported by a history of otosclerosis in the immediate maternal family. He was given post-aural aids, and at follow-up there was improvement in his language and behaviour. Repeated audiometry between the ages of two and fourteen confirmed the diagnosis, although the degree of deafness was inconsistent. Doubt about the diagnosis was expressed, but dismissed when response to spoken sounds improved with more powerful hearing aids.

He attended educational establishments for the deaf until at 13 years of age he was integrated into an ordinary high school. Although he has always displayed various behavioural difficulties at home and at school, it was not until at high school that an educational psychologist noticed that the degree of deafness appeared to vary with his psychological state; at times his hearing appeared normal. Auditory evoked brain stem potentials were performed which showed normal hearing in the right ear with only a 40 dB loss in the left ear.

In the six months following the revised diagnosis his behaviour deteriorated dramatically. It has since been revealed that at eighteen months old he witnessed his father severely assault his mother, following which he hid in a cupboard for two days with his hands over his ears. The boy's mother thinks that the deafness dated from that time. Despite having been an in-patient in an adolescent psychiatric unit for five months both he and his family are still finding it difficult to adjust to the change in diagnosis.

This case illustrates the danger of mis-diagnosing psychological symptoms as being due to organic illness, and shows that when the correct diagnosis is delayed the sequelae can be severe with significant resultant morbidity. Psychological symptoms are commonly found among the deaf population; the rates appear to be 3–10 times higher than for comparable groups of children with normal hearing (Meadow, 1980). Presumably this was one reason why our patient's behaviour was accepted for so many years. The importance of considering deafness in a young child with behaviour disorders or language delay is well documented (Illingworth, 1983; Williams, 1968). We suggest that where there is any doubt as to the validity of the diagnosis of deafness, a diagnosis of hysterical conversion disorder should be considered.

CORRIGENDA

Journal, January 1987, **150,** 43–48 (M. W. P. Carney *et al*). The following co-authors names were omitted from the title page: James Edeh, B. K. Toone and C. Thomas.

Journal, February 1987, **150**, 161–163 (J. A. O. Besson *et al*). In Fig. 1 (page 162) the labels "Schizophrenics ($n=6$) without TD" and "Schizophrenics ($n=15$) with TD" should be interchanged.

A HUNDRED YEARS AGO

French Lunatic Asylums

The supervision of French lunatic asylums appears, if recent accounts be true, to be exceedingly lax. It will be remembered that a short time ago a man was released from an asylum, having been forty years previously confined by his relatives in order to secure his wealth. The escape of another man is now reported, who, although sane, was confined for a year in an ill-lit room, bound hand and foot. Such treatment is strictly forbidden by law, and the matron and two keepers of the establishment have been fined, and the medical superintendent condemned to a fortnight's imprisonment. Such regrettable and scandalous incidents would be impossible if any control were exercised by the authorities; and although our Gallic friends may manage things in general better than we do in England, their most ardent admirers will be compelled to admit that the protection of lunatics and the supervision of asylums do not redound to their credit.

Book Reviews

Editor: Sidney Crown

Divided Consciousness: Multiple Controls in Human Thoughts and Actions (expanded edition). By ERNEST R. HILGARD. Chichester: John Wiley & Sons. 1986. Pp 313. £18.50.

This book, by one of the most distinguished figures in modern psychology, first appeared in 1977. The current edition contains a ten-page addendum which brings the reader up-to-date with more recent developments in research and theory. The book is a wide-ranging and thorough review of the phenomenon of dissociation. The author adopts a broad definition, including instances of human activity in which some thought, experience, and behaviour, normally performed consciously, takes place largely or exclusively outside of the person's awareness. Defined thus, dissociation is something which can be understood from everyday experience and which has been extensively studied by psychologists working in the field of attention. However, the author concentrates mainly on the more striking manifestations of dissociation which may be observed in the clinical field, and in demonstrations of the capacities of virtuoso hypnotic subjects.

The first chapter is a short history of the study of dissociation, from Janet in the late nineteenth century, through its demise in the 1930s with the influence of behaviourism, to a revival of interest among psychologists from the 1960s onwards. The second chapter examines possession states, fugues, and multiple personalities; this is followed by chapters on hypnotic age regression and amnesia. Subsequent chapters deal with dreams, hallucinations, imagination, creativity, dissociation of motor activity, and automatic writing. The remaining chapters are concerned with the nature of hypnosis and suggestion, and in the final chapters the author expands on his neodissociation theory.

The nature of the material makes this a fascinating book, and the reader's interest is sustained throughout by the author's clear and honest style. His approach is eclectic and undogmatic, but he insists at all times on impeccable standards of logic and scientific rigour. The text is well referenced and illustrates the work of experimental psychologists at its best – not least the contributions of the author himself, which span over half a century.

Hilgard has set the definitive standard for scientific writings on the nature of human consciousness. For any serious student of the human mind this book is obligatory reading.

M. HEAP, *Principal Psychologist and Senior Lecturer, University of Sheffield*

Alzheimer's and Parkinson's Diseases: Strategies for Research and Development. Edited by ABRAHAM FISHER, ISRAEL HANIN and CHAIM LACHMAN. New York: Plenum. 1986. Pp 710. $95.00.

This volume contains papers presented at an international conference held in Israel under the auspices of the Israel Institute for Biological Research in March 1985. It seems to have been an unusually busy meeting, for the contributions number 73 and cover almost 700 pages of small print. This reflects the current clinical and research interest in these major degenerative CNS disorders.

The material is arranged in six sections, covering anatomy, pathology, and biochemistry; clinical and diagnostic aspects; aetiology and genetics; biological markers; experimental models; and new drug development and innovative experimental approaches. As might be expected, there is wide variation in standard and general interest. Many papers report highly specialised animal experimental work, but there are also some valuable review articles of wider interest. For example, Wisniewski provides a useful summary of the clinical and neuropathological diagnostic criteria for Alzheimer's disease and argues in favour of an infective aetiology in genetically susceptible subjects. Edwardson *et al* review neurotransmitter changes and senile plaque morphology in Alzheimer's disease, with particular reference to the recent identification of alumino-silicates at the core of the plaques. Bowen *et al* remind us that, as well as the cholinergic deficit, serotonin receptors are also consistently reduced in Alzheimer's disease, and Groner *et al* report on chromosomal investigations into the fascinating association between Down's syndrome and early onset Alzheimer's disease. The recently identified Parkinsonian syndrome induced by MPTP, a toxic derivative of meperidine, is covered thoroughly by Kopin *et al.*

Accounts of the investigation of Alzheimer's and Parkinson's diseases by magnetic resonance imaging, computerised tomography, positron emission tomography, and regional cerebral blood flow estimations are exciting, if rather technical.

Basic research produced an effective therapy for Parkinson's disease, so one can look forward, with some degree of confidence, to a similar outcome to the massive research effort by various disciplines in Alzheimer's disease, exemplified by this volume. It is a useful sourcebook for researchers into Alzheimer's or Parkinson's disease, but of limited value to clinicians who can obtain the same information elsewhere at less expense.

KENNETH DAVISON, *Consultant Psychiatrist, General Hospital, Newcastle upon Tyne*

Somatization and Hypochondriasis. By ROBERT KELLNER. London: Praeger. 1986. Pp 401. £60.00.

Hypochondriasis has been greatly neglected by psychiatrists, whose writings have been largely based on highly atypical patients seen in hospital or private practice. It is only recently that they have extended their interest to attenders at general hospitals and in primary care. An additional and major obstacle to understanding is classification. 'Hypochondriasis' is used loosely as a comprehensive term, and also as a specific category within what DSM–III christened 'somatoform disorders'. There are advantages to using *somatisation,* another word with a long history, as the general category covering all the psychological mechanisms that cause somatic symptoms, including anxiety, depressive, and adjustment disorders as well as somatoform disorders.

In this major review, Kellner prefers the term 'functional somatic symptoms' for somatic symptoms which do not have a physical cause. This enables him to take a broad view which draws on evidence from general hospitals as well as specialist psychiatry. He emphasises that most symptoms are transient and minor, and that few persist following investigation and reassurance.

The organisation of the book is straightforward. An initial chapter on history is followed by reviews of prevalence, aetiology, the many specific syndromes, principles of diagnosis, psychological tests, and treatments. Psychotherapy is particularly well described. However, even though each chapter is clearly divided by sub-headings there is much repetition, and it becomes difficult to follow consistent themes. It is therefore a book for the already knowledgeable rather than for psychologists or psychiatrists who are unfamiliar with the literature.

Kellner may have taken on an impossible task. Certainly, most previous reviews are unhelpful, much of the evidence unsatisfactory, and the best classification (DSM–IIIR) is arbitrary and tentative. I found his book useful and irritating at the same time. It is copiously referenced, has told me many things I did not know and contains valuable clinical insights, but I had to work hard turning from chapter to chapter and making the maximum use of the index. There are also a number of gaps, too little on anxiety disorders and on behavioural management and rather perfunctory reviews of important syndromes such as hyperventilation and atypical chest pain.

It is a pity that Kellner did not have the nerve to impose a clearer structure on his book and to take a more ruthlessly critical view of his subject. This is a useful, but very expensive, reference work which is best seen as a sourcebook of the background rather than a guide to new ideas.

RICHARD MAYOU, *Clinical Reader in Psychiatry, University of Oxford*

The Reality of Mental Illness. By MARTIN ROTH and JEROME KROLL. Cambridge: Cambridge University Press. 1986. Pp 128. £22.50 (hb), £7.95 (pb).

That such a book as this seems necessary should give psychiatrists serious cause for thought. Is our professional standing and function still, after the hefty buffeting of the 1960s and 1970s, in serious doubt? Do the views disseminated by Szasz over the past 25 years continue to persuade people that mental illness is a myth and not a reality? Do contemporary social and political opinions require a re-examination and re-statement of the nature and relevance of psychiatry? This book makes it clear that answers to these questions are indeed needed and that it is a debate in which each psychiatrist should have his views.

The polemical writings of Szasz, Laing, Foucault, and Basaglia are trenchantly taken to task for their simplistic responses to highly complex issues and the destructive consequences their application may bring. Their views are also criticised, in the context of a valuable and informative historical perspective in which psychiatry is firmly established as part of medicine, for the selectiveness of their choice of evidence.

The eternal problem of the proper boundaries of mental disorder is examined, in particular the uncertainty of the relationship of neurosis and personality disorders to normal feelings and behaviour. However, the reliability of psychiatric diagnosis is found to be comparable to that of electrocardiographic and radiological assessments.

Minor reservations relate to the lack of an index, the absence of biographical information about the authors, and the absence of a clear indication of which readership the book is aimed at.

This reviewer would hope that members of the Mental Health Act Commission involved in re-drafting the Draft Code of Practice will read and carefully consider the final chapter, in which involuntary hospitalisation and the plea of insanity defence are discussed with erudition and elegance. For psychiatrists, the book provides a rousing and reassuring *raison d'etre.*

ALAN KERR, *Consultant Psychiatrist, St Nicholas Hospital, Newcastle upon Tyne*

Alcoholism: Development, Consequences, and Interventions (3rd edition). Edited by NADA J. ESTES and EDITH M. HEINEMANN. Oxford: Blackwell Scientific Publications. 1986. Pp 466. £16.00.

This multi-authored textbook is designed principally for nurses and other health professionals working with alcoholics. The book illustrates two of the major differences between Britain and the USA in their approach to alcohol problems. The first is the high level of seriousness and investment devoted in the USA to professional training in the management of alcohol-related problems;

the second is the primacy given to the concept of 'alcoholism' as a disease entity, which in contrast to the UK incorporates a whole range of health and social consequences that arise out of injudicious as well as addictive drinking.

Despite the title, which suggest a rather narrow focus, the book in fact addresses a wide range of other alcohol-related topics such as epidemiology and the effects of alcohol on the body systems. A further section of the book is devoted to alcohol problems in 'special groups' such as young people, women, the elderly, and the American Indians. An interesting chapter is concerned with drinking problems within the nursing profession, a much-neglected topic.

Counselling a person with alcohol problems is perceptively described in a chapter which contains much good sense and immediately reveals that whatever the rhetoric which surrounds issues such as diagnosis on either side of the Atlantic, the skills required of the sensitive and experienced counsellor are universal. Group and family therapy receive considerable attention, as do the perspectives of AA and Al-Anon, but there is little space devoted to the organisation and co-ordination of services. Chapters on cognitive and behavioural approaches describe more recent developments. Work and research from outside the United States receives scant mention, and the book is designed principally and rightly for its own culture. This will make it of limited usefulness to readers in the UK, although there are undoubtedly chapters which will stimulate and inform. Perhaps its principal value is as a reminder to health professionals in this country that we should take postgraduate training in the management of alcohol problems much more seriously than we do at present.

BRUCE RITSON, *Consultant Psychiatrist, Royal Edinburgh Hospital*

Investigating Abnormal Behaviour. By EDGAR MILLER and STEPHEN MORLEY. London: Weidenfeld & Nicolson. 1986. Pp 336. £9.95.

Miller and Morley have set out to produce a volume on abnormal psychology which is radically different in concept and content from texts designed for American undergraduate courses. While most books in this field examine each clinical disorder in turn, or evaluate the various models of abnormal behaviour, these authors have set themselves a more ambitious task: their aims are to present this branch of psychology as a coherent scientific discipline and to illustrate how its investigative techniques can be used to provide answers to at least some of the major questions relating to the nature, aetiology, and treatment of psychiatric disorders. Consequently, they have departed from the rigid structure of a conventional textbook on abnormal psychology and have selected certain topics which serve to demonstrate the width and scope of this discipline.

This strategy is both the strength and weakness of the book. An advantage of the approach is that it has enabled the authors to confine themselves to specific issues which they feel highlight the contributions made by abnormal psychology, while disregarding those areas where psychological research has not proved so fruitful. Not surprisingly, therefore, models of depression are cited throughout, while references to the genesis of schizophrenia are relatively sparse. Similarly, the chapters on process and outcome research in psychotherapy deal exclusively with well-established behavioural techniques, while the newer family therapies receive no mention. Thus, although the authors may have achieved their principal aim of demonstrating the special contributions which abnormal psychology can make to the field of psychiatry, many readers will find the topic selection somewhat arbitrary and the content rather disjointed. However, in view of the thoroughness with which each of the selected issues is examined, postgraduate students will find it a useful complement to the standard textbooks in this field.

DOUGAL MACKAY, *District Psychologist, Bristol and Weston Health Authority*

Tranquillisers: Social, Psychological, and Clinical Perspectives. Edited by JONATHAN GABE and PAUL WILLIAMS. London: Tavistock. 1986. Pp 311. £25.00.

There is a difference of opinion between profession and public about tranquillisers. This work, concerned largely with minor tranquillisers, concentrates on personal and social aspects rather than on pharmacology. There is a rich variety of facets, and after a historical account of the use of tranquillisers the remaining topics fall loosely into four groups.

Three studies on the long-term use of tranquillisers cover the process and effects of withdrawal, the duration of treatment with psychotropic drugs, and a pharmacological view. The second part, which deals with factors concerned in obtaining and using tranquillisers, looks at sex differences and the effect of family environment. A more peripheral paper of general practitioner's methods of enquiry and management concludes that "... the observable behaviour of the general practitioners is best understood as the implementation of familiar and trusted techniques by means of which they seek to impose order in the consulting room". The section on alternatives is particularly topical, including papers on withdrawing tranquillisers, not prescribing them, and self-help groups. A further section deals with social and symbolic aspects of the problem, and the social meanings: tranquillisers as a resource and as social control. The concluding chapter, by the editors, discusses future trends in research on tranquilliser use and draws attention to the need for better international communication.

There is much to be learned from this book, but as 12 chapters are reprinted and these are, on average, over five years old, it is an expensive message. The breadth of topic and approach could suggest difficulty in integration, but this is fully overcome by the introductions to each section and by the forewords which give a comforting perspective to this rapidly changing chemical and social scene. It is a work worthy of priority reading.

JOHN POLLITT, *Medical Director, Hayes Grove Priory Hospital, Kent*

Systematic Family Therapy. By LUCIANO L'ABATE. New York: Brunner/Mazel. 1986. Pp 319. $30.

What is systematic family therapy? Family therapy, like any recently introduced therapeutic form, demands that each expert introduces a brand, or different mixture of the product. There are many forms of family therapy described, including structural family therapy, systemic family therapy, strategic family therapy, contextual family therapy, behavioural family therapy, and now systematic family therapy. There are overlaps and unique features to each. L'Abate is convinced that the field of family therapy is characterised by gurus who have produced schools "based on little or no empirical evidence". He points out that evidence of the gurus' "sensitivity, ingenuity and cunning is not founded on external criteria but on some vague impression and conviction". L'Abate presents an approach that is in his own words "systematically eclectic, systematically empirical, and systematically sequential". "Systematic" therefore refers to a rationale based on classifiable ordered plans and methods.

L'Abate is concerned about two very different world views which have caused controversy in the family therapy field. One he described as represented by the researcher/investigator/empiricist/pragmatist, and the other by the artist/dialectician/aesthetician/impressionist. L'Abate is keen to show that both these activities can be performed in parallel with each other, not distinct from the other. He describes four stages of therapy, the first to do with crisis intervention and stress reduction, the second with skills training and education with the use of homework assignments. Issues of termination are the third stage, and the fourth phase is the follow-up.

In going through the various stages he describes his approach to dealing with crises by the use of paradoxical intervention and, by contrast, the use of confrontation support and control. He introduces a variety of familiar issues to the field, to do with life roles, triangulations, positive reframing negotiation and aspects of family emotional life, competence, feelings, awareness, issues of intimacy, and aspects of various therapeutic approaches. L'Abate is well read, and appears able to find ways of linking many current ideas in the family therapy field. However, his volume is surprisingly thin on case histories in comparison with other works. The evidence he gives of particular interventions seem limited and unconvincing. There is something in L'Abate's thesis about gurus who appear convincing by demonstrating therapeutic work that appeals to the intuitive sense of clinicians. L'Abate's work, while constructing a set of theories and ideas, does not have the same power to convince the clinician, which is a pity since some of his work on the use of paradoxical approaches to therapy is interesting – if he is able to present some research to show that the pragmatist and the impressionist can together produce better outcomes he will have helped the field. There is certainly a need to integrate and make sense of the bewildering varieties of wares on offer to the neophyte family therapist. This in my view is not the definitive conceptual answer.

ARNON BENTOVIM, *Consultant Psychiatrist, Hospital for Sick Children, London*

Essential Papers on Depression. Edited by JAMES C. COYNE. New York: New York University Press. 1968. Pp 507. US$50.00 (hb), US$22.50 (pb).

These papers form part of a series collectively titled "Essential papers in psychoanalysis", a title which belies the much wider aim of the editor of this volume. The opening chapter, a careful and workmanlike review by the editor of the different theoretical approaches to the problems of classification and aetiology of depressive illness, is followed by a section on psychodynamic approaches to depression, including original papers by Freud, Abraham, and Fromm-Reichmann. However, the scope of the book then widens beyond the psychodynamic. The section on behavioural and cognitive approaches features, among other authors, Seligman's model of learned helplessness and Beck's views on maladaptive cognitive structures. Interpersonal and social approaches are well covered, including chapters by George Brown and Ernest Becker. Nor are biomedical approaches ignored, with contributions from Winokur, Dunner, and Baldessarini. The value of this book lies in the wide range of topics covered, mostly in original contributions from key workers in their respective fields. The emphasis is not on integrating differing and often opposing views, but on providing a richly differentiated overview of the theoretical perspectives currently being developed in the search for understanding of depression. The wide range of significant writing included could almost be said to justify its title. The major objection one might have is that all the contributions are available elsewhere, and some (for example Freud's *Mourning and Melancholia*) very widely. Specialists in the field will be familiar with the writings of the contributors to this volume, if not with these particular contributions, and the more general reader may well not have sufficient interest to pursue this volume through the reference library. If this were a reasonably priced, freely available paperback I would recommend that anyone working in the field of mental health might benefit from owning a copy, but doubt from the American prices whether many copies would be sold outside libraries. Nonetheless, this book is a valuable collection of thoughtful and thought-provoking material, as well as an excellent source of references.

GRAEME MCGRATH, *Lecturer in Psychiatry, University of Manchester*

Handbook of Schizophrenia Vol I: The Neurology of Schizophrenia. Edited by HENRY A. NASRALLAH and DANIEL R. WEINBERGER. Amsterdam: Elsevier. 1986. Pp 416. $92.50.

This excellent book is the first of five volumes dealing with various aspects of schizophrenia. In it the authors set out to present the scientific evidence for the neurological basis of the disorder. The first chapters are presented in roughly the same order as that of a neurologist's clinical examination, and cover history, neurological examination, differential diagnosis, laboratory tests, etc. The core of the book reviews the findings from brain imaging techniques (computerised tomography, magnetic resonance imaging, computerised mapping of electrophysiological data, cerebral blood flow studies, and positron emission tomography). There follow several chapters covering theoretical models of schizophrenia based on current neuropathological findings.

The basic premise of the work, and this runs coherently through the various contributions, is that schizophrenia is a manifestation of a brain disease in a final common pathway for many disorders or genetic or acquired origin. This leads to attempts firstly at defining possible sub-types of the syndrome and, secondly, at relating phenomenological findings to disorders of brain structure and function as revealed by neuropathological and *in vivo* brain imaging techniques. It is clear that providing the impetus for much of this research is the advance in computer technology, allowing development of these non-invasive brain imaging techniques. This in turn has renewed interest in, and to some extent allowed reinterpretation of, many phenomenological observations in schizophrenic patients. Hence, such interesting chapters as those by Manschreck on motor abnormalities, Nasrallah on cerebral asymmetries, and Shelton & Weinberger on X-ray computerised tomography are complimentary without being merely reiterative.

Such attempts at relating structure to function can only be preliminary. The authors resist the temptation to construct over-elaborate theoretical models that outstrip their empirical foundation, and overall the presentation is critical, well referenced, and contains clear discussions of the methodological shortcomings of the various techniques mentioned. Perhaps, given the conceptual framework of the book, it would have been more appropriate for the editors to follow Bleuler's example and title it 'The neurology of the schizophrenias'.

STUART MCLAREN, *Clinical Research Fellow, Unit of Human Psychopharmacology, The London Hospital*

Understanding Psychological Testing in Children: A Guide for Health Professionals. By STEWART GABEL, GERALD D. OSTER and STEVEN M. BUTNIK. New York: Plenum Medical. 1986. Pp 184. £26.50.

Many medical people feel that psychological testing is well within their capability, with or without training, and it is unlikely that this book will alter those opinions. It is aimed at primary health care professionals, who are often concerned with behavioural and emotional problems of childhood. In a brief, dry style it describes how psychologists assess children, choose their batteries of tests, and reach their therapeutic conclusions. There is a brief introduction to how tests work, and a spot of insight into concepts and jargon. There is also instruction on how to choose the appropriate private psychologist.

This American book was first published in 1943 and, though doubtless re-edited, has some glaring gaps. For example, the Raven's Progressive Matrices, a test used world-wide, is not even mentioned; nor are Cattell's various personality inventories, although the TAT, the Rorschach, and the much queried Draw-a-Person (which used to be Draw-a-Man) are given great prominence. Descriptions are given of American tests of perception, social/adaptive skills, educational achievement, and neuropsychological procedures, and the text is well supplied with succinct case histories. However, there is no name index.

The approach is not so much as a guide as a euphemistic listing, as all the tests, including intelligence tests such as the Stanford-Binet, are presented without a whiff of criticism. Because of this lack of direction and discussion the book fails both the readers' latent curiosity and the rich variety of valuable test material in use.

JOAN FREEMAN, *Honorary Tutor, Department of Education, University of Manchester*

Recent Advances in Epilepsy – 3. Edited by TIMOTHY A. PEDLEY and BRIAN S. MELDRUM. Edinburgh: Churchill Livingstone. 1986. Pp 315. £38.00.

This is the third volume of a series entitled "Recent advances in epilepsy", edited by two well-known researchers in the field, one more interested in experimental aspects of epilepsy, the other a clinician. To some extent this reflects the mixture of topics covered in the book, although in this volume clinical chapters predominate. Of particular interest for psychiatrists will be the chapter by Wieser on psychomotor seizures of hippocampal-amygdalar origin, in which some of the elegant studies carried out with implanted depth electrodes are summarised, including the clinical correlates of mesio-basal limbic system seizures. The chapter by Quesney on seizures of frontal lobe origin is clinically important in the sense that these seizures are probably commoner than recognised, on account of diagnostic difficulty and confusion with non-epileptic (pseudo) seizures, or because of the psychopathological accompaniments of the condition. Toone provides one of the best reviews of sexual disorders in epilepsy that is to be found, and includes a summary of his own work on recent hormonal investigations in patient populations. Finally, Stores provides an interesting chapter on non-convulsive status epilepticus in children, again a problem which child psychiatrists see from time to time and whose evaluation can be difficult but rewarding.

The other chapters provide a pot-pourri of information with much recent research for those with a wider interest in epilepsy. Neurocytology and chemistry, genetics, ambulatory monitoring, benign focal epilepsies of childhood, and the progressive myoclonic epilepsies are some of chapter topics. It is a pleasure to have Professor Aicardi provide an up-to-date review of the syndrome that is named after him, and the topic of toxicity of anticonvulsant drugs is reviewed by Schmidt, although the neurocognitive and behavioural sequelae of these is covered in another volume. There is an update of ethosuximide and the barbiturates, and reviews of the use of ambulatory EEG monitoring and of the benign focal epilepsies of childhood.

The quality of the production and the editorial control is as high as that of the previous two volumes, and the book can be recommended to psychiatrists who have an interest in epilepsy and who would wish to keep up-to-date with advances in the area. This reviewer would encourage the editors to press on with Volume 4.

MICHAEL R. TRIMBLE, *Consultant Physician in Psychological Medicine and Senior Lecturer in Behavioural Neurology, The National Hospitals for Nervous Diseases, London*

Paediatric Perspectives on Epilepsy. Edited by EUAN ROSS and EDWARD REYNOLDS. Chichester: John Wiley. 1985. Pp 163. £17.50.

1985 was a vintage year for books on childhood epilepsy. *Paediatric Perspectives* summarises a symposium held in 1984, and gathers together an easily digested, indexed overview of (largely British) attitudes to various key issues. The contributions are succinct and go beyond diagnosis and drug treatment to a consideration of the child and his family.

Many children with problematic epilepsy are managed by neurologists, and Ross and Reynolds have edited a book that should appeal not only to their colleagues but also to others in search of a readable update on a small corner of their clinical practice. That the book does not encompass recent advances in imaging, telemetry, or ambulatory monitoring realistically reflects the sad state of funding of the departments from which most of the contributors come. In contrast, *Epileptic Syndromes in Infancy, Childhood and Adolescence* (J. Roger *et al*, 1985, John Libbey Eurotext) deals uniquely with the nosological insights and obfuscations provided by the Marseilles School of Gastaut and its European disciples and contempories. Here the emphasis is on extended EEG recordings, fine-grain analysis of seizure types, and sub-division into new syndromes. This volume records a 1983 conference. It is a larger, better produced and more expensive book.

No symposium ever resulted in a coherent textbook, but there was no need, for 1985 also saw the rebirth of O'Donohoe's masterwork, *The Epilepsies of Childhood* (2nd edition, 1985, Butterworths). If I could only have one of these three books it would be this one. *Paediatric Perspectives* covers less ground but it is quicker to read. Neither book overlaps with the French one.

MICHAEL PRENDERGAST, *Clinical Lecturer in Child and Adolescent Psychiatry, The Bethlem Royal Hospital, Beckenham*

Psychological Therapies for the Elderly. Edited by IAN HANLEY and MARY GILHOOLY. Beckenham: Croom Helm. 1986. Pp 200. £17.95.

This collection of ten papers by different authors has been compiled by the editors to reflect the usefulness of applied psychology in the field of the elderly. It should be of interest to psychologists and others working with the elderly, and to those involved in the training of such workers. The chapters vary greatly in quality and relevance. The first chapter is a useful review of some of the issues involved, but psychiatrists and geriatricians will not be endeared by comments such as, "Psychiatric and geriatric services are often organised without rhyme or reason and remain almost totally lacking in accountability for the quality of service given." The author describes a typical long-stay ward as having 35 people with severe dementia and four nurses. Those of us whose teams, without the help of psychologists, have managed to reduce the numbers of residents on long-stay wards to under 20 may be forgiven for thinking that the author is out of touch. The second chapter, on dynamic psychotherapy with the elderly, provides interesting reading. The relevance of the three case histories described must be judged by the reader; the first is a bereaved man of around 60 who is still at work, the second a lady in her early sixties in a responsible executive position, and the third a truly elderly lady of 84 with a 33-year-old lover.

There follow two excellent papers on the usefulness of reminiscence therapy and reality orientation therapy. The next two papers, on day care and self-help groups, review provision predominantly in America. A helpful paper on the difficult topic of introducing change and improvement in the care provided by institutions is followed by a straightforward and readable account of the development of a video-assisted teaching package. There is then a down-to-earth account by a residential social worker on life in a home for the elderly, run in a dignified and homelike manner. The final chapter, on legal and ethical issues, is useful but fails to deal with such important topics as informed consent from patients with organic brain syndromes, or patients' access to information.

In summary, this is a short and readable book, more than half of which is of interest and value to those working with the mentally ill elderly. It is of doubtful value for money in hardback, but certainly a useful addition to the library shelf.

CAROL TROTTER, *Consultant Psychiatrist for the Elderly, St James's Hospital, Portsmouth*

Practical Psychiatry of Old Age. By JOHN WATTIS and MICHAEL CHURCH. Beckenham: Croom Helm. 1986. Pp 195. £19.95(hb), £8.95 (pb).

The stated aim of the authors, to provide a practical reference book on the psychiatry of old age directed primarily at community health care teams, junior hospital doctors, and nurses, is more than adequately achieved. The combination of a psychiatrist and a clinical psychologist produces a refreshing 'middle of the road' view and the clear literary style, easy-to-understand diagrams and liberal use of case histories results in a volume which should be comprehensible to professional and layman alike.

The book adopts a problem-solving approach rather than one based solely on diagnosis, but still manages to emphasise the importance of thorough physical and psychiatric assessment and the need for accurate diagnosis and classification of mental illness in the elderly in order to produce effective management strategies. The chapter on depression offers sound practical advice, but it was disappointing that the management of the suicidal elderly patient, a common and difficult clinical situation, was not considered in greater detail. Confusion and hypochondriasis, two of the more frequent presenting symptoms in the primary care setting, are analysed in depth with suitable emphasis placed on the importance of complementary medical, psychological, and social approaches.

Two chapters shine out in particular. Firstly, the place of individual and family therapy, often overlooked in more 'organically orientated' textbooks, is discussed in depth, and the importance of practical psychotherapeutic skills in both patient management and relatives' support is underlined. Secondly, neuropsychological assessment in the elderly, so often a minefield of confusion, is presented in a detailed systematic way which must rate as one of the most easily understandable expositions available in the psychogeriatric literature.

This is an excellent book, highly recommended to all practising clinicians and a 'snip' at £8.95.

MIKE NOWERS, *Lecturer in Mental Health, University of Bristol*

Practical Psychotherapy. By MYRON F. WEINER. New York: Brunner/Mazel. 1986. Pp 322. $30.00.

I warmly welcome this admirable guide to pragmatic psychotherapy. Psychoanalytic psychotherapy has long suffered as the poor relation of psychoanalysis, while finding it difficult to establish a credible separate identity. Weiner starts from the premise that there is much to be learnt from behavioural, humanistic, and ego-supportive therapies which can be incorporated into everyday work with patients. He illustrates his approach with numerous clinical examples throughout the text.

There are excellent accounts of the life cycle, factors which induce change in psychotherapy, mechanisms of defence, therapist interventions, levels of therapy, and termination. Those countless practitioners who have found in Irvin Yalem's *Group Psychotherapy* a comprehensive and readable guide which is essentially practical rather than theoretical may feel that this book fills a similar need in the field of individual psychotherapy.

My only reservations concern the extent to which formulations are couched in Freudian drive and structural theory while failing to sufficiently reflect the contribution of object relation theory or self-psychology. It should be remembered that it is written for a North American audience, where these ideas still form the bedrock of psychoanalytic theory.

I would like to see this readable guide made widely available to trainees, who become easily disillusioned with over esoteric texts whose content is apparently divorced from their experience with their patients.

I. F. MACILWAIN, *Consultant Psychiatrist/ Psychotherapist, Netherne Hospital, Surrey*

Psychotherapist's Casebook. Edited by IRWIN L. KUTASH and ALEXANDER WOLF. London: Jossey-Bass. 1986. Pp 552. £49.50.

The aim of this admirable book is to present the reader with brief descriptions of a wide range of psychotherapeutic styles. The range is quite broad, including individual, group, and family therapy and both the traditional, orthodox methods and more innovative and controversial ones. Each of the 30 chapters is written by an acknowledged expert – sometimes by the orginator of the particular approach described, e.g. Carl Rogers wrote the chapter on client-centred therapy and Albert Ellis the one on rational emotive therapy. The title derives from the fact that each contributor has been required to provide some illustrative clinical material. Some have rather overdone this, leaving themselves insufficient space to present an adequate account of the psychodynamic theory on which the therapy is based and to give the reader a reasonable idea of what the therapeutic procedure amounts to.

This is an all-American book, and perhaps reflects the present American scene. I would like to have seen a chapter on the English object-relations school and also on the cognitive therapy of depression. To my mind there was no justification for a chapter on psychopharmacological therapy. The chapters on psychoanalysis and psychoanalytic therapy should have been fused into one. Also, two chapters on the existential approach seems excessive. The humanistic therapies, on the other hand, could have been better represented by including one chapter on bioenergetics and the body-centred therapies and another on the cathartic therapies.

In the main, the book is lucidly written and is a pleasure to read. It is, however, a sad reminder that psychotherapy is still appallingly compartmentalised. Hopefully the day will dawn when all competent therapists will have a knowledge of and expertise in the whole spectrum of psychotherapeutic strategies. Perhaps the publication of books such as this will help to bring that day a little closer.

JOHN BIRTCHNELL, *Scientific Officer and Senior Lecturer, Institute of Psychiatry, London*

Schizophrenia: New Pharmacological and Clinical Developments. Edited by A. A. SCHIFF, SIR MARTIN ROTH and H. L. FREEMAN. London: Royal Society of Medicine. 1985. Pp 121. £12.00.

Although it is perhaps astonishing to find a drug with novel actions on the mind, available for 15 years, whose clinical application is still unclear, it is not surprising that examination of this drug, sulpiride, is but one of the topics in this deceptively slim volume covering several new developments in understanding and treating schizophrenia. The actions of the drug are one of the absorbing themes presented at a symposium.

The scientific articles cover the 'negative' symptoms of schizophrenia, the nature of depression which can occur in schizophrenia, rapid stabilisation of acute schizophrenia with fluphenazine decanoate, and the result of a 14-year follow-up study using this depot preparation. The second session focused on sulpiride, dopamine and tardive dyskinesia, combining chemical and clinical considerations in a stimulating proportion. Taken as a whole, these papers examine well-known modern treatment, the problems remaining in its wake, and changing theoretical considerations, as a background to viewing the future prospect of the available and anticipated members of the substituted benzamide group.

Each paper is summarised and followed by brief discussion. Several psychiatrists present cases, and the whole work is brought together in Sir Martin Roth's succinct concluding overview. The book is well produced, containing much of clinical significance in this chemically and symptomatically enigmatic area.

JOHN POLLITT, *Medical Director, Hayes Grove Priory Hospital, Kent*

Hypnosis and Hypnotherapy. By DAVID T. ROWLEY. Beckenham: Croom Helm. 1986. Pp 192. £19.95 (hb), £8.95 (pb).

There is a mounting deluge of books on hypnosis and its applications. There are those which are based on the scientific foundations of hypnosis and its established areas of application; there are those covering the work and ideas of Milton Erickson and his followers, most of which are of dubious quality; and there are a few contributions by lay practitioners which cannot be taken seriously. David Rowley's book belongs to the first category.

The book is an introductory account of the nature of hypnosis and associated phenomena, its history, theories, measurement, some basic procedures, and therapeutic applications. It is general and comprehensive, and written in a non-technical and readable style. The author does not present any new material or formal theorising of his own, but he includes occasional personal reflections which are interesting, particularly concerning the nature of altered states of consciousness. There is only one chapter on clinical applications and, as the author covers a wide variety of problems, many of the discussions are too brief and superficial. This is a shortcoming of many introductory texts on hypnosis.

The book provides a very useful overview of hypnosis for medical and psychological practitioners, health workers, researchers and students in the biological and social sciences, and the educated layman. It is not a manual, and does not aim to teach the reader hypnotic procedures. Those who are already familiar with hypnosis and its applications may give the book a miss, unless they wish to refresh themselves quickly on such matters as history, theories, and measurements of susceptibility, for which purposes they should find the book admirably suited.

MICHAEL HEAP, *Principal Clinical Psychologist, Middlewood Hospital, Sheffield*

Volume 144, Number 3 March 1987

Special Articles

267 Intensive Psychodynamic Therapy With Borderline Patients: An Overview. *Robert J. Waldinger*

275 Control Groups for Psychosocial Intervention Outcome Studies. *Joseph M. Strayhorn, Jr*

Regular Articles

283 Use of Outpatient Mental Health Services Over Time in a Health Maintenance Organization and Fee-for-Service Plans. *Willard G. Manning, Jr, Kenneth B. Wells and Bernadette Benjamin*

288 Pregnancy-Related Affective Episodes Among Women With Recurrent Depression. *Ellen Frank, David J. Kupfer, Miriam Jacob, Susan J. Blumenthal and David B. Jarrett*

293 First-Rank Symptoms as a Diagnostic Clue to Multiple Personality Disorder. *Richard P. Kluft*

299 Auditory Hallucinations in Combat-Related Chronic Post-traumatic Stress Disorder. *Kim T. Mueser and Robert W. Butler*

303 Discontinuation of Alprazolam Treatment in Panic Patients. *Abby J. Fyer, Michael R. Liebowitz, Jack M. Gorman, Raphael Campeas, Andrew Levin, Sharon O. Davies, Deborah Goetz and Donald F. Klein*

309 The Significance of Past Mania or Hypomania in the Course and Outcome of Major Depression. *William Coryell, Nancy C. Andreasen, Jean Endicott and Martin Keller*

316 Ratings of Videotaped Simulated Patient Interviews and Four Other Methods of Evaluating a Psychiatry Clerkship. *Emily Mumford, Herbert Schlesinger, Timothy Cuerdon and James Scully*

Brief Communications

323 Dependent Personality Disorder Associated With Phobic Avoidance in Patients With Panic Disorder. *James Reich, Russell Noyes, Jr and Ed Troughton*

327 ECT-Induced EEG Asymmetry and Therapeutic Response in Melancholia: Relation to Treatment Electrode Placement. *Richard Abrams, Michael Alan Taylor and Jan Volavka*

330 High Rate of Affective Disorders in Probands With Attention Deficit Disorder and in Their Relatives: A Controlled Family Study. *Joseph Biederman, Kerim Munir, Debra Knee, Marie Armentano, Sherry Autor, Christine Waternaux and Ming Tsuang*

334 5-Hydroxytryptophan-Induced Cortisol Response and CSF 5-HIAA in Depressed Patients. *Tsukasa Koyama, Martin T. Lowy and Herbert Y. Meltzer*

338 Prediction of Response to Nortriptyline and Phenelzine by Platelet MAO Activity. *Anastasios Georgotas, Robert E. McCue, Eitan Friedman and Thomas Cooper*

341 A Biopsychosocial Approach to Treating Patients With Affective Disorders. *Russell G. Vasile, Jacqueline A. Samson, Jules Bemporad, Kerry L. Bloomingdale, David Creasey, Brenda T. Fenton, Jon E. Gudeman and Joseph J. Schildkraut*

344 Long-Term Effects of Extreme Situational Stress on Sleep and Dreaming. *Albert Hefez, Lily Metz and Peretz Lavie*

348 Seriously Depressed Preschoolers. *Javad H. Kashani and Gabrielle A. Carlson*

351 A Field Trial of *DSM-III-R* Psychoactive Substance Dependence Disorders. *Bruce J. Rounsaville, Thomas R. Kosten, Janet B. W. Williams and Robert L. Spitzer*

355 Current Need Versus Treatment History as Predictors of Use of Outpatient Psychiatric Care. *Matthew J. Friedman and Alan N. West*

358 Male and Female Psychiatrists and Their Patients. *Wayne S. Fenton, Carolyn B. Robinowitz and Phillip J. Leaf*

Clinical and Research Reports

362 Short-Term Course of Depressive Symptoms in Patients With Eating Disorders. *Frederick S. Wamboldt, Nadine J. Kaslow, William J. Swift and Marilyn Ritholz*

365 Prevention of Episodic Water Intoxication With Target Weight Procedure. *Morris Benjamin Goldman and Daniel Jonathan Luchins*

367 Predictors of Interepisode Symptoms and Relapse in Affective Disorder Patients Treated With Lithium Carbonate. *Paul J. Goodnick, Ronald R. Fieve, Ann Schlegel and Ngaere Baxter*

Contents of The Journal of Nervous and Mental Disease

Published by
The Royal College of Psychiatrists

ISSN 0007-1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary.*

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al, British Medical Journal,* 7 May 1983, **286,** 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translated (1952) as Suicide: A Study in Sociology, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. British Journal of Psychiatry, **124,** 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In Pathology and Treatment of Sexual Deviation (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal,* should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

SCHOOL OF HYPNOSIS AND ADVANCED PSYCHOTHERAPY

Since 1980, SHAP has been conducting comprehensive, professional HYPNOSIS/PSYCHOTHERAPY diploma courses based on modern (Ericksonian) methods and NLP.

The courses are in 3 Parts and applications are now being considered for the next Part I Course which spans 5 weekends in Autumn 1987.

For 24-page prospectus and details please send large stamped addressed envelope to Registrar, SHAP, 28 Finsbury Park Road, London N4 2JX.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

SYMPOSIUM
ON
AFFECTIVE DISORDERS
AN UPDATE

Affective disorders form an important part of psychiatric practice. In recent years a multitude of new findings of relevance for our understanding of these conditions have come to light and new treatments have become available.

This Symposium will focus on several key areas of recent research and the speakers will include:-

Biochemical Theories of Affective Disorders
Professor Brian Leonnard

Affective Disorders – Clinical Profiles
Professor Max Hamilton

Genetics of Affective Disorders
Professor Peter McGuffin

Mania
Professor Trevor Silverstone

This one-day Symposium will be held on:
Friday 26 June 1987
at
The Royal Society
6 Carlton House Terrace
London, SW1Y 5AG

The cost of registration will be £20 (£10 for junior medical staff.)
For further details of the Symposium and for registration forms, please contact:
Diane Carter, Charter Clinic, 1/5 Radnor Walk, London SW3 4PB. Tel: 01-351 1272

Charter Clinics

Call for research papers

Readers are invited to submit detailed research papers resulting from their work with people who are mentally and/or multiply handicapped for consideration for inclusion in *Mental Handicap Research* which is to begin publication in 1987/88.

It is intended that the new publication, which will accept contributions from workers in many different specialties, will have a multidisciplinary appeal, so authors will be asked to avoid technical jargon in the text wherever possible.

Full details of the required format, length and presentation of papers, and the editorial review procedure are now available on request from:

The Editor, Mental Handicap Research,
BIMH Publications, Foley Industrial Park,
Stourport Road, Kidderminster, Worcs.,
DY11 7QG.

Institute of Family Therapy
(London)

DIRECTOR
5 sessions equivalent or
17 hours a week.

Applications are invited for this expanding post which falls vacant from September 1987.

This appointment marks a critical stage in the Institute's development and the successful applicant will have the opportunity to lead a highly skilled team of Family Therapy Clinicians, Teachers and Researchers in the setting up of new premises and a range of innovative projects.

The post is open to suitably qualified professional staff from the fields of psychiatry, psychology and social work.

Further information and applications to:
The Administrator
Institute of Family Therapy (London)
43 New Cavendish Street
London W1M 7RG
01-935-1651

CONTEMPORARY ISSUES IN SCHIZOPHRENIA

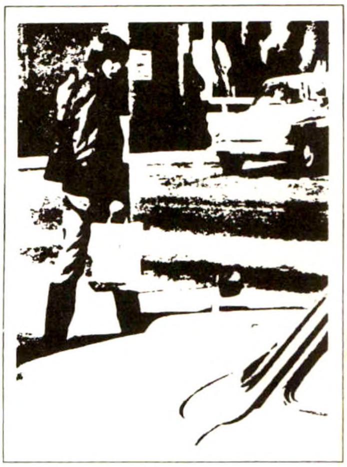
Edited by Alan Kerr and Philip Snaith

ISBN 0 902241 14 1 Pp 480 £17.50

This book presents a comprehensive selection of re-edited papers published in the British Journal of Psychiatry during the last ten years, together with a number of specially commissioned reviews of current knowledge in schizophrenia. The subject is considered under seven sections: general and historical concepts; classification and phenomenology; organic aspects; genetic aspects; social aspects; treatment; and outcome.

Contemporary Issues in Schizophrenia, published February 1986, at £17.50 postage free. Orders with cheques should be sent to: Editorial Office, Royal College of Psychiatrists, 17 Belgrave Square, London SW1X 8PG.

TOMMY'S STORY



Little is known of Tommy's earliest years but from the start of his school career he was reported as persistently misbehaving. When thwarted in any way he would become extremely violent. At the age of 16 he was placed in a Community Home. While there, his violence was a considerable problem and on one occasion he took an overdose of drugs.

A year later he came before the courts on a number of charges of theft and criminal damage.

It was decided that treatment might be beneficial and he was subsequently admitted to the **John Clare Unit** at **St. Andrew's Hospital.** This Unit offers behavioural treatment for young people of normal intelligence whether or not they have other psychiatric illnesses. After an initial three month assessment period Tommy spent a year in the hospital gradually achieving greater levels of independence and self control. He then moved to a hostel in his home town and has successfully completed a Youth Training Scheme.

(Tommy's story is a composite of several patients treated in the **John Clare Unit**).

For further details write or telephone

Kathy Perkins, Admissions Officer,
St. Andrew's Hospital,
Billing Road, Northampton NN1 5DG

Telephone 0604-29696

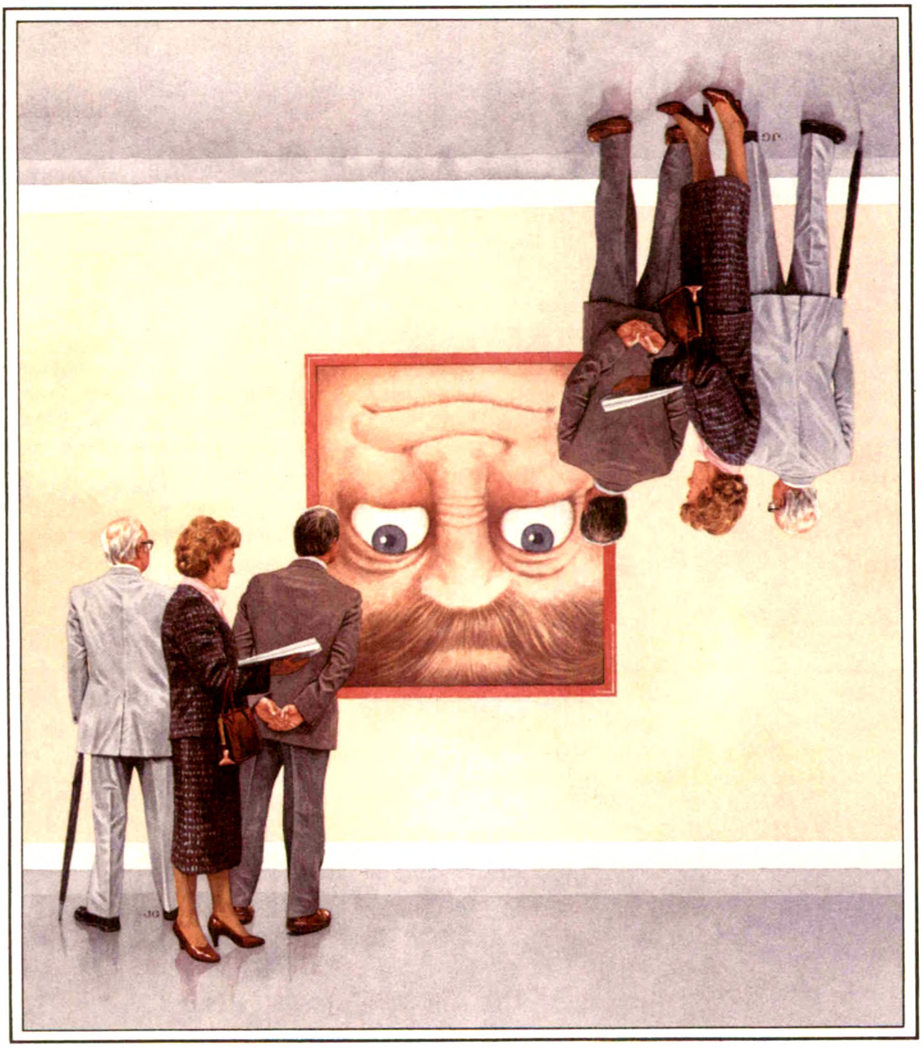
BOWDEN HOUSE CLINIC

London Road, Harrow on the Hill, Middlesex HA1 3JL

Conveniently situated for central London, the Clinic specialises in the private treatment of psychiatric disorders. Medical, nursing and therapeutic care of the highest standard is given in an understanding and sympathetic environment. All forms of acute psychiatric illness are treated in the clinic either on an inpatient or day patient basis.

For further information write to the Medical Director or phone 01 864 0221

Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices. Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 5 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.



TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept.
Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.
Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®

25 mg/ml

100 mg/ml

FLUPHENAZINE DECANOATE

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes.
Most patients can be controlled with an injection at intervals of 3 weeks or more.[1]
Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

Is There Really A Split In Schizophrenia?

The Genetic Evidence

P. McGUFFIN, A. FARMER and I. I. GOTTESMAN

Although the clinical presentation and course of schizophrenia is highly variable, it is unclear whether this reflects heterogeneity at an aetiological level. The genetic evidence is reviewed concerning 'traditional' clinical subtypes as well as more novel categories derived from multivariate statistical methods and Crow's type I–type II classification. Recent data based on a twin series and re-analysis of older published family material suggest that attempts to divide up schizophrenia have resulted in splits between two or more categories of disorder which occupy different positions on the same continuum of liability. Thus, apparent heterogeneity is more likely to be due to quantitative difference in familial-genetic loading rather than qualitative differences. Similarly, the hypothesis that schizophrenia can be broadly divided into two groups, one genetic and the other non-genetic has little to support it. It seems improbable that any further useful and genetically relevant subdivision of schizophrenia can be effected on purely clinical grounds. Further progress awaits developments in the discovery of endophenotypes and the application of molecular genetic marker strategies.

Current concern with categories such as 'type I' and 'type II' (Crow, 1980), positive-symptom versus negative-symptom (Andreasen, 1985; Pogue-Geile & Harrow, 1985) and 'sporadic' versus familial schizophrenia (Murray *et al*, 1985) represents a new and interesting phase in an old and unresolved debate over the unity and diversity of the disorder (*British Medical Journal*, 1969; Farmer *et al*, 1984). E. Bleuler (1911) introduced the term 'schizophrenia' to cover *a group* of disorders which Kraepelin (1896) had implied could be comfortably subsumed under a single category. Many researchers since, impressed by the clinical variety of patients described as 'schizophrenic', have taken a Bleulerian stance and have aimed to be splitters rather than Kraepelinian lumpers of the syndrome.

Psychiatric geneticists and biological psychiatrists, in particular, have been on the side of the splitters. The case was put authoritatively and succinctly by Eliot Slater in a paper written nearly 40 years ago (Slater, 1947). He wrote: "In view of the fact that schizophrenia is a good deal more common than any single genetically determined disorder is otherwise known to be, heterogeneity is inherently probable".

Our purpose, therefore, in this article is to review both the older and more recent genetic evidence concerning heterogeneity in schizophrenia and to decide whether it supports the widely held point of view that we are dealing with several, perhaps many conditions.

On lumping and splitting

In his encyclopaedic catalogue of mendelising genetic disorders McKusick (1983) favours the view that what is called 'schizophrenia' is a mixture of different entities. However, elsewhere he points out (McKusick, 1969) that the leading principles of genetic nosology include not only the idea of heterogeneity, but also of pleiotropism. Pleiotropism is the phenomenon of a single aetiological factor (for example a single gene) having multiple effects. A nice example with psychiatric relevance is the demonstration by Penrose (1952) of the various (biochemical, morphological and behavioural) phenotypic manifestations of the phenylketonuria gene. However, we can broaden the notion of pleiotropism to include non-genetic medical conditions and here syphilis and systemic lupus erythematosis provide excellent examples of how a specific pathogenic process can have clinical manifestations which are many and various, often leading to diagnostic error and perplexity.

In cases of late syphilis the contrasts in presentation between one patient and another may be quite

---

Based on a lecture given at the Royal College of Psychiatrists Annual Meeting on 9th July 1985

disparate, whereas in psychiatry classification and differentiation of syndromes is based on comparatively subtle differences, and moreover on differences which are liable to change over time. We therefore ignore at our peril McKusick's (1969) warning that when dealing with heterogeneity, purely phenotypic differences may provide "the most treacherous basis for decision". Against this, it must be allowed that progress in medicine has depended to a large extent on teasing apart broad clinical syndromes and on the delineation of specific, narrower disease entities. Little more than a century ago conditions such as 'dropsy' and anaemia were considered adequate diagnostic entities which were only subsequently separated by a combined process of refining clinical descriptions and pursuing all available clues concerning aetiologies and pathogeneses. In schizophrenia the pathogenesis remains obscure but there is compelling evidence of an important genetic contribution to the aetiology (Gottesman & Shields, 1982). Indeed if we are to start by lumping all of the conservatively diagnosed Western European studies of schizophrenia together, genes probably account for about two-thirds of the variation in liability to the disorder (Gottesman & Shields, 1967; McGuffin, 1984; McGue *et al*, 1985). Clinical heterogeneity in schizophrenia undoubtedly exists but it is only of limited interest if this does not reflect *aetiological* heterogeneity. Therefore whether there is a genetic split (or set of splits) in schizophrenia might be viewed as the most important current issue in the nosology of the syndrome.

Clinical and 'traditional' subtypes

Family data

Leonhard (1959) has provided probably the most elaborate and extensive scheme for splitting schizophrenia on the basis of descriptive psychopathology. Other workers, particularly those in the Soviet Union, have devised different schemes largely based on course and outcome (Snezhevnevsky, 1968). However, such complicated approaches have not won widespread acceptance and most twin and family researchers have adopted more time-honoured subtypologies largely based on Kraepelinian-Bleulerian categories. Particular attention has been focused on a paranoid versus hebephrenic (or paranoid versus non-paranoid) classification. The largest single dataset concerned with schizophrenic probands and their families is that of Kallmann (1938). By modern standards there are a number of methodological deficits. These include diagnoses in relatives which were mainly not made blind to proband information, an absence of explicit diagnostic criteria, and a lack of a suitable control group.

Nevertheless, the sample size and the wealth of detail provided encourages our close attention. Kallmann (1938) was himself unimpressed by the degree of familial homotypia in his material, i.e. the tendency for affected pairs of first-degree relatives to belong to the same subtype of schizophrenia. He pointed out that only in about 70% of affected relative pairs was the subtype identical. However, Slater (1947) subsequently retabulated Kallmann's data and performed a χ^2 analysis which showed that the tendency for like to go with like in parent-offspring pairs classified as hebephrenic, catatonic and paranoid, occurred at the 0.01 level of significance. There have been at least eight other studies (reviewed by Kendler & Davis, 1981) which have addressed much the same question. Most have shown a tendency for paranoid versus non-paranoid schizophrenia to 'breed true'. Only three comparatively recent studies (Tsuang *et al*, 1974, 1980; Scharfetter & Nusperli, 1980) carried out diagnosis of relatives blind to the proband subtype. Two of these studies (Tsuang *et al*, 1974; Scharfetter & Nusperli, 1980) found a tendency towards homotypia which in the latter study (1980) occurred at a better than chance level. However, the more recent study of Tsuang *et al* (1980) used narrow operational criteria (Tsuang & Winokur, 1974) to define a paranoid subtype and not only found absence of homotypia but also a tendency at long-term (30-40 years) follow-up for paranoid schizophrenia to progress to a hebephrenic or 'undifferentiated' picture.

A rather different way of examining family data is to concentrate on quantitative rather than qualitative differences between subtypes. Thus if we divide up probands according to subtype but simply examine the frequency of schizophrenia among relatives irrespective of subtype there is a fairly consistent pattern in nearly all studies in that the relatives of patients with paranoid schizophrenia tend to show a lower morbid risk for all types of schizophrenia than do the relatives of patients with non-paranoid or hebephrenic disorders. Kendler & Davies (1981) have suggested that this is sometimes an artefact of the method of age correction. The simplest and commonest method of age correction is the shorter (or abridged) Weinberg method (Slater & Cowie, 1971; McGuffin, 1984a). Here it is assumed that there is a (more or less) well-defined period of risk for acquiring a disorder and by a simple method of weighting of those relatives who have not lived through this period an adjusted denominator is calculated to estimate the life time expectancy (or morbid risk) of disorder. Kendler & Davies argue that if the period of risk is assumed to be the same for all subtypes of disorder then the rates in relatives of older, later onset cases such as paranoid schizophrenics will tend to be underestimated. However, this bias cannot account for all the differences in the literature. For example, in Kallmann's (1938) study the differences in the frequency of schizophrenia in relatives of index cases which 'nuclear' (hebephrenic and catatonic) versus 'peripheral' (paranoid and simple) disorders are apparent even in the non-age corrected data.

Twin studies

The available twin data is mainly in keeping with the family findings. Kringlen (1967) and Fischer (1973) showed that in monozygotic twins, there was virtually complete homotypia for subtype in twin pairs concordant for schizophrenia. However, co-twin assessment was not, however, performed blind to that in the proband. This was rectified in the study of Gottesman (1968) where there was again a marked tendency toward subtype concordance even though diagnosis was here made blindly. One of the drawbacks of these earlier studies, as with the earlier family data is that they were carried out without using explicit operational criteria. We have therefore reexamined the Maudsley twin series originally studied by Gottesman & Shields (1972) and have applied the subtyping criteria of Tsuang & Winokur (1974) to the detailed case abstracts. In our hands these criteria have been found to provide very good inter-rater reliability (Farmer *et al*, 1983; McGuffin *et al*, 1984). The results of the subtyping of the twin material are shown in Table I. In common with previous investigators we find a marked tendency toward subtype concordance. However, this is not complete in the monozygotic (MZ) sample and it is apparent that when the proband has a non-paranoid form of disorder we obtain higher concordance rates for schizophrenia as a whole than when the proband has a paranoid condition. This is therefore in good agreement with the results reported by Gottesman (1968) and by Kringlen (1967) both of whom found a similar pattern and hints that the distinction between paranoid and other forms of schizophrenia is quantitative rather than qualitative.

TABLE I
Probandwise concordance in the Maudsley (1948–1964) Schizophrenic Twin Series

Subtypes of Tsuang & Winokur (1974) Concordance for	*MZ*	*%*	*DZ*	*%*
Schizophrenia, where proband is:				
Paranoid	2/5	40	1/14	7
Non-paranoid (hebephrenic and 'undifferentiated')	13/21	62	3/20	15
Subtype, where both twins are diagnosed schizophrenic	13/15	87	3/3	100

MZ = monozygotic, DZ = dizygotic.

Explanatory models

The transmission of schizophrenia is best considered in terms of liability/threshold models (Falconer 1965; Gottesman & Shields, 1967; Reich *et al*, 1972). Clearly schizophrenia does not show a typical Mendelian pattern of segregation and *discordance* of over 50% in pooled data from recent series of identical twins (Gottesman & Shields 1972) is sufficient evidence that environmental as well as genetic factors are involved. 'Liability' is considered to be a continuously distributed variable in the general population which is determined by both genes and environment (acting in a predominantly additive fashion) such that only those individuals whose liability exceeds a certain threshold value at some point in time, manifest the disorder. Single major locus models, where a single gene is the sole source of familial liability have been shown to be inadequate in explaining the familial aggregation of schizophrenia as a whole (O'Rourke *et al*, 1982). It seems more likely that in schizophrenia we are dealing with many genes at different loci acting in a mainly additive way (Gottesman & Shields, 1967) or possibly a major gene against a polygenic background (McGue *et al*, 1985). Reich and his colleagues (1972, 1979) have extended Falconer's (1965) original single threshold model to include disorders which occur in two or more forms. It is assumed that liability is normally distributed (or could be transformed to normality) and that those individuals who lie beyond a first threshold will show a 'broad', milder form of the disorder while those beyond a second, more extreme, threshold will show a 'narrow', more severe form. Relatives of affected individuals will show a mean liability which is greater than that of the general population and thus more will lie beyond the threshold for being affected. The 'isocorrelational' version of the model (Reich *et al*, 1979) predicts that the mean liability of relatives of 'narrow' cases will be greater than that of 'broad' cases. The model is illustrated in a somewhat simplified form in Fig. 1. Thus in schizophrenia we might consider schizophrenia-as-a-whole as a 'broad' form, with non-paranoid (or hebephrenic or 'nuclear') categories as a narrow form, and paranoid schizophrenia as 'broad-but-not-narrow' category.

TABLE II

A reanalysis of Kallmann's (1938) family study of schizophrenia

			Relatives		
Proband subtype	*Class of relative*	*Total at risk (BZ)*	*% Affected*	*Observed n affected*	**Expected n*
Peripheral (paranoid or simple)	Children	307	9.1	28	32.5
Nuclear (hebephrenic or catatonic)	Children	373	17.7	66	63.9
Peripheral (paranoid or simple)	Siblings	739	6.2	46	39.6
Nuclear (hebephrenic or catatonic)	Siblings	1257	8.2	103	106.1

*Expected *n* affected under two threshold 'isocorrelational' models (Reich *et al*, 1979) where nuclear schizophrenia = 'narrow' from disorder and peripheral schizophrenia = 'broad-but-not-narrow' form assuming population morbid risk of broad form (K_pB) = 1%, $\chi^2 = 0.332$, 1d.f. (NS), parameter estimates: $r_c = 0.524$, $r_s = 0.361$, $K_pN = 0.54\%$.

Less common, more severe (narrow form) disorders
Common, milder (broad form) disorders

FIG. 1 Two-threshold multifactorial model.

As an illustrative example we have attempted to fit a model of this type using Kallmann's (1938) data (Table II). This was carried out using a FORTRAN computer program, TETCOR, where the best fit is found iteratively by minimising a χ^2 function using the MINUIT optimisation routine (CERN, 1974). We have assumed that population morbid risk of the broad form (K_pB) is 1% and we have employed the program to calculate the best fit values of the remaining parameters, comprising the population morbid risk of the narrow form (K_pN) and the correlations in liability. As we can see from Table II, if we allow different correlations in liability for parent–offsprint (r_c) and sibling–sibling (r_s) pairs we obtain an excellent fit (cf. Barn, 1982). We have not attempted a similar model-fitting procedure on the other smaller datasets but as we have already commented the overall pattern in most of these is similar. We therefore consider that most of the family and twin evidence on the transmission of 'traditional' subtypes of schizophrenia is in keeping with the notion of differing thresholds on a single continuum of liability rather than of the existence of qualitatively distinct subentities.

Statistically derived subtypes

As instruments with which to 'carve nature at the joints' multivariate statistical methods have found favour in studies of affective disorder (Kendell, 1975; Paykel, 1981) but have been much less popular in schizophrenia research. Some investigators have attempted to use cluster analytic methods for defining subtypes within the schizophrenia syndrome (e.g. Strauss *et al*, 1973; Bartko *et al*, 1981) but only one group (Farmer *et al*, 1983, 1984) have viewed their results from a specifically genetic perspective. Farmer *et al* (1983) applied two mathematically different methods of cluster analysis to data on chronic schizophrenics. The variables used were from a comprehensive checklist of symptoms derived from commonly used operational diagnostic criteria. Two fairly distinct clusters were derived and there was surprisingly good agreement between the two clustering programmes. Simulation studies indicated that the level of agreement would occur by chance less than once in a hundred. The clusters remained stable when extra cases were added. Furthermore, where index cases and their schizophrenic relatives were assigned to subgroups the level of homotypia was significantly better than chance expectation.

Subsequently the characteristics of the groups were further explored using discriminant analysis (Farmer

TABLE III

Subtype, where both twins are diagnosed schizophrenic	11/15	73	4/4	100

MZ = monozygotic; DZ = dizygotic.

et al, 1984). Because of their resemblance to some descriptions of more 'traditional' subtypes the group with onset before 25 years, poor premorbid work adjustment and such clinical features as blunting of affect, thought insertion and third-person auditory hallucinations was named hebephrenic-like or 'H-type', while the group with later onset, poor premorbid *social* adjustment and well organised delusions was named paranoid-like or 'P-type'. Using discriminant function scores the twins from the Gottesman & Shields (1972) study were assigned to H- and P-subtypes and the concordance examined (Table III), a pattern very similar to that for the Tsuang & Winokur (1974) criteria emerged. That is, there is a tendency towards homotypia, which is nevertheless incomplete in genetically identical twins. But when subtype in co-twins is ignored and only concordance rates for schizophrenia as a whole considered according to whether the proband is H- or P-type, and the co-twins of H-type probands have higher rates of schizophrenia than do the co-twins of P-type probands. The findings are therefore suggestive once more of a quantitative rather than a qualitative distinction. Although no formal model fitting has been attempted it might be again postulated that H-type schizophrenia is but another narrow-form disorder with P-type schizophrenia a broad-but-not-narrow form.

Type I, type II and negative symptom schizophrenia

A finding which has achieved a high level of consistency across different centres is of enlarged lateral cerebral ventricles on the computerised tomographic (CT) brain scans of a proportion of schizophrenics. This was first reported by Johnstone and colleagues (1976) and has been replicated in nearly all subsequent studies (Reveley, 1985) (however, the recent criticisms of Smith & Iacono (1986) regarding schizophrenia/control comparisons must be noted). The finding of ventricular enlargement has caused renewed interest in what Johnstone *et al* (1976) have termed the 'dementia of dementia praecox'. Crow (1980) has proposed that there may exist two syndromes, a type I disorder, characterised by positive symptoms and responsiveness to neuroleptics, while a type II syndrome is more closely associated with negative symptoms, poor response to treatment and perhaps with cognitive impairment and morphological changes reflected in CT brain scans. Crow suggested (1980) that although the syndromes overlap to a considerable extent, the type I disorder is likely to be associated with abnormal dopaminergic mechanisms while the type II disorder would have some other (perhaps viral-infective) pathology. We have attempted with author's guidance to cast Crow's (1980) clinical criteria in an operational format to facilitate investigation of genetic aspects of this subtypology and have been able to demonstrate good inter-rater reliability using this approach (Farmer *et al*, 1987).

As with other subtyping systems described above we have reexamined the clinical abstracts for the Gottesman & Shields (1972) schizophrenic twin series and have reclassified affected individuals (Table IV). Pure type II cases are rare in this series but once again we see a tendency towards homotypia which is incomplete. Furthermore, there is some suggestion that the mixed form is a 'more genetic' condition than is type I schizophrenia in that there is a very marked difference between MZ and DZ concordance rates where the proband has a mixed type disorder.

Unfortunately such a small amount of data does not permit any definite conclusions about the Crow subtypology and we are unaware of any other familial

TABLE IV
Probandwise concordance in the Maudsley (1948–1964) Schizophrenic Twin Series

Subtypes of Crow (1980) *Concordance for*	*MZ*	*%*	*DZ*	*%*
Schizophrenia, where proband is:

Subtype, where both twins are diagnosed schizophrenic	11/15	73	3/4	75

MZ = monozygotic, DZ = dizygotic.

data which might help clarify the issue. Furthermore, as a result of the CT scan studies of the Northwick Park group, Crow's own views on what forms the most useful clinical basis for a type I–type II separation are evolving and changing (Crow, 1985).

There is, however, some evidence which has a bearing on a related concept, that of a separation of schizophrenia into two groups on the basis of whether negative or positive symptoms predominate. Dworkin & Lenzenweger (1984) have examined the available published extracts from systematic twin studies. Using their own unpublished system, which they find to be reliable in rating the presence of negative symptoms, they were able to divide up probands from monozygotic pairs into 'high negative' and 'low negative' categories. A fairly consistent picture emerged, with all twin studies, except for that of Kringlen (1967) showing higher concordance where the proband exhibited a high rate of negative symptoms. This approach is rather different from and considerably simpler than the Crow subtypology. Nevertheless, there is clearly a resemblance between these results and those of our own efforts to apply the operationalised Crow criteria to the Maudsley schizophrenic twin series.

It is therefore tempting to speculate that in separating off a group of patients with type II mixed, or predominantly negative symptoms, we are simply selecting a more severely affected group which, as with non-paranoid, hebephrenic or 'H-type' cases tend to occupy a more extreme position on a continuum of liability. It might be argued therefore that all of these findings are reminiscent of the earlier work of Gottesman & Shields (1968, 1972) who took a more straightforward approach to the question of severity. The probands from identical twin pairs were divided according to time spent in hospital. Where the proband had spent less than 2 years in hospital there was a concordance of only 27% as against a rate of 77% where a proband had spent more than 2 years in hospital since the onset of his/her illness. Similarly, where the proband had shown an inability to stay out of hospital for at least 6 months since the onset of their disorder, the rate of schizophrenia in the co-twins was 75%.

Non-genetic schizophrenia?

The evidence considered thus far would seem to favour the existence of 'more genetic' and 'less genetic' varieties of schizophrenia lying on the same continuum with cut-off points dependent on chosen clinical criteria. A more radical suggestion has recently been put forward by Murray *et al* (1985), that 'sporadic' or non-genetic forms of schizophrenia may be quite common and that presence or absence of a family history of the disorder provides a useful starting point for such a classification scheme. There are undoubtedly many organic conditions which can present with a schizophrenic like disorder (Davison & Bagley, 1969; Propping, 1983) but well-established cases of 'symptomatic' schizophrenia which, from a genetic viewpoint, might be considered as 'phenocopies' are uncommon in clinical practice. Murray and his colleagues (1985) suggest that sporadic cases of schizophrenia may be commoner than are generally supposed and that the environmental causes most often go undetected. They point out that identical twins discordant for schizophrenia show marked differences in cerebral ventricular size measured on CT brain scans. Although the numbers involved were small Reveley *et al* (1982) found significant tendency for the affected proband to have larger ventricles than the non-schizophrenia co-twin. It was postulated that this might reflect early trauma such as birth injury, and a subsequent study (Reveley *et al*, 1984) found a relationship between enlarged cerebral ventricles, negative-family history of psychiatric illness and positive history of early cerebral insults in schizophrenic twins. However, it should be noted that 'family-history negative' here meant absence of illness in relatives other than the co-twin so that the sample of 'family history negative' probands appears to have included some individuals with affected co-twins. Thus the apparent elegance and simplicity of a family-history positive/family-history negative division may be dangerously deceptive.

There are a number of general objections to a family-history positive/family-history negative split. First, any plausible model of transmission (McGue *et al*, 1985) would predict that those patients without a family history of schizophrenia would comprise a high proportion of genetic cases who are 'chance isolates' (Elandt-Johnson, 1971) as well as those who are true non-genetic cases. However, there would be no straightforward way of differentiating between the two. Second, the chances of obtaining a positive family history of psychiatric disorder are closely related to the quality of information available. Thorough family interview studies inevitably uncover more secondary cases among relatives than do studies based on history alone. Third, the proportion of family-history positive cases must also depend on family size and on the proportion of relatives who have passed through the age of risk. Most authors agree that there is an increased rate of schizophrenia and of 'spectrum' disorders among the relatives of schizophrenia rather than an increase in psychopathology generally (Gottesman & Shields, 1982). Nevertheless, Reveley *et al* (1984) have taken a broad perspective on what constitutes a 'family-history positive' case and include a family history of *any* major psychiatric disorder is about 10% (and recent studies suggest that this is a conservative estimate (Sturt *et al*, 1984; Helzer *et al*, 1985)) then we would obtain a distribution of family-history positive cases by chance alone like that shown in Table V. Obviously this is not entirely realistic since it does not take into account the tendency of most psychiatric disorders to aggregate in families (McGuffin, 1984). However, the table serves to illustrate that family size cannot be ignored as a potential confounding variable in studies of this type.

TABLE V

Proportion of a population expected to be family-history positive for a 10% trait by chance

*Proportion (%)**	*Number of relatives*
10	1
19	2
27	3
34	4
41	5
47	6
52	7

*proportion, p, calculated as $p = 1-(1-\pi)^n$ *where* π = population frequency and n = number of relatives

A more direct criticism of the hypothesis of Murray *et al* (1985) is that we might expect to see a consistent relationship between presence or absence of family history and cerebral ventricular size in other studies of schizophrenics. However, as Table VI shows, there is a disappointing lack of agreement between studies carried out in different centres. Some (e.g. Turner *et al* 1986) support Murray's hypothesis; one (Nasrallah *et al*, 1982) produced findings in the opposite direction of that predicted, while most others actually find no significant differences between the family-history positive and family-history negative groups. This is perhaps not surprising in the light of the recent analysis presented by Eaves *et al* (1986) which demonstrated that the discriminatory power of a familial/non-familial distinction is actually very low.

TABLE VI

CT brain scan studies VBR in family-history positive (FHP) vs family-history negative (FHN) schizophrenics

Authors	*Summary of finding*
Reveley *et al* (1984)	Mean VBR in FHN twins significantly *greater* than in FHP twins
Nasrallah *et al* (1982)	Mean VBR in FHN patients significantly *less* than in FHP patients.
Owen *et al* (1985)	More FHP than FHN patients with VBR greater than control mean.
Farmer *et al* (1985)	No significant difference between FHP and FHN patients.
Williams *et al* (1985)	
Reveley & Chitkara (1985)¹	
Turner *et al* (1986)	Mean VBR in FHN patients significantly *greater* than in FHP patients.

1. One-way anova showed significant differences with VBR in FHN patients >VBR in FHP patients >VBR in controls.

Do earlier twin or family studies provide any clarification? Only a minority of even the most thoroughly investigated schizophrenics have secondary cases in their first- or second-degree relatives and over 60% must be classified as 'family-history negative' (Bleuler, 1978). Given that this is so, it could be asked whether discordance in identical twins might be due to an admixture of genetic and non-genetic cases. The question was first investigated by Luxenburger (1928). He found that discordant pairs had other affected family members as often did concordant pairs, results which were subsequently replicated by other investigators (Kringlen, 1967). Furthermore, a study of the adult offspring of MZ twins discordant for schizophrenia revealed a similar morbid risk for the disorder in both the children of the schizophrenic probands and the children of the non-schizophrenic co-twins (Fischer, 1971). (The latter finding has been confirmed and extended in the offspring of MZ and DZ twins by Gottesman & Bertelsen (in preparation)). Both findings strongly suggest that a genetic/sporadic admixture hypothesis to explain discordance for schizophrenia in identical twins is incorrect but supports the idea that 'sporadic' or non-genetic forms of schizophrenia are uncommon. This being so, the studies of discordant twins should provide an ideal means of pinpointing specific environmental stressors which may precipitate the disorder in the genetically susceptible as well as indicating possible protection factors. Unfortunately, results from older studies are disappointingly inconsistent. Pollin & Stabenau (1968) are often quoted as finding that in discordant MZ pairs the schizophrenic index case was more likely to have had a history of birth trauma and low birth weight and to have had a submissive dependent premorbid personality than his unaffected co-twin. Other studies provide some support regarding premorbid personality factors but despite evidence of the general role of birth trauma (McNeill & Kaij, 1978) there has been no convincing replication of the *specific* birth history findings (Gottesman & Shields, 1982).

Biological and genetic markers

Thus far, we have mainly discussed subcategories based upon clinical signs and symptoms, or what Gottesman & Shields (1972) have called 'exophenotypes'. It might be hoped that the discovery of biological markers or 'endophenotypes' for schizophrenia might take us a step nearer toward primary gene products and facilitate less ambiguous methods of classification (McGuffin, 1984*b*). Attempts to subclassify schizophrenics according to biological criteria have been reviewed by Meltzer (1979) but there is, for the most part, a disappointing inconsistency in results. The biochemical marker which has perhaps excited the most attention and which may be of genetic relevance is platelet monoamine oxidase (MAO). Potkin *et al* (1978) reported that platelet MAO activity was significantly lower in paranoid than in non-paranoid schizophrenic patients. Unfortunately, other groups, (e.g. Meltzer *et al*, 1980) have been unable to replicate this finding and the weight of evidence from other studies (reviewed by Kendler & Davis, 1981) does not favour a clear separation of groups of schizophrenics on the basis of platelet MAO activity. Further doubt concerning the usefulness of MAO as a marker derives from the studies of Rice *et al* (1982, 1984) which suggest that platelet MAO is controlled by a single major locus but that the less common of its two alleles is the one coding for *high* MAO activity and that the vast majority of the population, over 90%, carry at least one 'low MAO' gene. Clearly there is some difficulty in reconciling this finding with suggestions that platelet MAO may be a marker for schizophrenia, a disorder where the lifetime incidence in the population is 1% or less.

Genetic markers are a special category of biological marker. Although still often used in a rather broad sense in the psychiatric literature (e.g. Shuckitt, 1986) the term genetic marker is probably best restricted to cover traits which have a simple mode of inheritance and which are demonstrably polymorphic (i.e. where there are two or more alleles with a gene frequency of at least 1%) (Giblett, 1969). The better known genetic markers include red cell groups such as ABO, rhesus, MN and soon as well as major histocompatibility (HLA) antigens, various blood protein polymorphisms and red cell enzymes. In addition to these 'conventional' markers the advent of 'the new genetics' of recombinant DNA (Emery, 1984) has meant that many more genetic markers are now available and that the day is not far off when the human genome (i.e. the set of 22 pairs of autosomes and two sex chromosomes) will be extensively mapped. So far over 900 genes have been assigned to chromosomal locations (De La Chapelle, 1985), but only about 25% of genes so far mapped are detectably polymorphic (*American Journal of Human Genetics*, 1983) and only a proportion of these have been investigated in relation to schizophrenia (see recent review by McGuffin & Sturt, 1986).

Possible associations discovered by recent population studies involving blood complement factors (Rudduck, 1985) merit further investigation, but most genetic marker findings in schizophrenia to date have been disappointingly inconsistent and convincing replications of positive findings have been rare. A notable exception is the evidence concerning the HLA system and subtypes of schizophrenia.

Associations between certain specificities of the HLA system and a number of common diseases are now well established (Thomson, 1981). Such disorders include juvenile diabetes, multiple sclerosis and ankylosing spondylitis. Most HLA associated diseases are not rare have a tendency to run in families, but show complex patterns of inheritance which are not classically Mendelian. Not surprisingly, therefore, schizophrenia came under scrutiny not long after the first HLA-disease reports (Cazzulo *et al*, 1974; Eberhard *et al*, 1975). However, studies of schizophrenia as a whole provided no clear pattern of association across different centres (McGuffin, 1979). It was only when schizophrenia was broken down into possible subtypes that a more consistent set of results emerged. In particular there was evidence of an association between paranoid schizophrenia and HLA A9, while the hebephrenic subtype showed a less consistent association with HLA A1 (McGuffin *et al*, 1981). There have now been a total of nine published studies which provide data on an A9-paranoid schizophrenia association (reviewed by McGuffin & Sturt, 1986). Seven of these are consistent with the presence of an association and when the data are pooled it seems highly unlikely that the association has arisen by chance ($\chi^2 = 19.378$, calculated by Woolf's (1955) method, P corrected for number of comparisons $= 0.0003$). There are, however, a number of difficulties. First, it is not clear whether the diagnosis of a paranoid subtype is comparable in the different centres. Second, A9 is a composite antigen consisting of two subspecificities, AW23 and AW24 (Festenstein & Demant, 1978), and it is uncertain which of these is more important in the paranoid schizophrenia association. Third, and perhaps most importantly, despite its high statistical significance the strength of the association is low. The estimated relative risk of developing paranoid schizophrenia for an A9 positive individual compared with an A9 negative individual is 1.6. If we assume, as we have done earlier, a liability/threshold model for the transmission of schizophrenia, then using the method given by Edwards (1965) we calculate that the contribution of the HLA locus to variation in liability to paranoid schizophrenia is only about 1.1%. It therefore appears that the HLA studies may indicate a minor susceptibility locus rather than an important major gene effect in paranoid schizophrenia. The results would therefore require only some slight modification of our earlier speculations that the separation between paranoid and other types of schizophrenia is entirely quantitative and based purely on different thresholds on a liability continuum. Instead we would have to allow that there may also be overlapping sets of polygenes each of which modify the clinical picture in subtly different ways.

By contrast with the association studies, linkage studies which seek to detect a marker gene in close proximity to a major disease gene have been predominantly negative with respect to HLA. Turner (1979) reported that there was suggestive, but inconclusive, evidence of linkage between HLA and 'schizotaxia' in 'typical' families multiply affected by schizophrenia but not in 'atypical' families in which multiple family members were affected not just by schizophrenia but by other conditions such as affective disorder. McGuffin *et al* (1983) failed to replicate this finding and subsequent investigations (Chadda *et al*, 1986; Goldin *et al*, 1987; Andrews *et al*, 1987) are also negative.

So far, there are no published results of studies of schizophrenia and the new genetic markers of recombinant DNA technology, so called restriction fragment length polymorphisms (Botstein *et al*, 1980). But there is considerable optimism about the future usefulness of such markers in detecting major gene effects and resolving problems of heterogeneity in schizophrenia and other common diseases (White *et al*, 1985). Unfortunately the statistical analysis of linkage studies involving conditions with complex and non-Mendelian patterns of inheritance, presents formidable problems which will need to be solved before the 'new genetics' can yield tangible benefits for schizophrenia research (Sturt & McGuffin, 1985).

Conclusions

Although Eugen Bleuler is often regarded as the original instigator of the search for separate subforms of schizophrenia, his son Manfred Bleuler (1978) has more recently concluded that there is little compelling evidence of their existence. This accords well with our own assessment that despite considerable efforts to define subtypes and despite the conviction of many research workers that natural lines of cleavage might exist, no convincing split extending back to a genotypic level has yet been demonstrated in schizophrenia. Time honoured clinical separations of schizophrenia into paranoid and hebephrenic or other non-paranoid subtypes produce a tendency toward homotypia in family and twin studies as do some more recently derived statistically based categories (Farmer *et al*, 1984). However, neither approach produces a clear qualitative separation and the available data can best be explained using liability threshold models in which the subtypes of disorders lie on the same continuum. Although theoretically attractive, subtypologies based on the presence or absence of negative symptoms or on a Crow type I–type II pattern of symptoms do not appear to provide separate, genetically distinct subentities. Similarly a separation of schizophrenia into a distinct familial and sporadic categories is difficult to justify on the basis of current evidence. Rather than providing a means of 'carving nature at the joints', the systems of classifying subtypes which are so far available appear to offer different ways of slicing up the salami. Undoubtedly the salami has more genetic content at one end than at the other, but as yet there is no convincing evidence that we are dealing with two or more completely different varieties of sausage.

Nearly all of the debate on the unity or diversity of schizophrenia has so far been based upon recurring clusters of clinical features. We have been dealing with what Gottesman & Shields (1972) have called 'exophenotypes' which are distantly removed from what must be occurring at a genotypic level. Future prospects for a better understanding of subtle morphological or pathophysiological change which may occur in the living brain of the schizophrenic have been greatly enhanced by recent developments in brain imaging (Buchsbaum *et al*, 1982; Herold & Frackowiak, 1986) and refinements of regional blood flow techniques (Weinberger *et al*, 1986). However, for the present perhaps the most consistent pointer toward a qualitative distinction between subtypes of schizophrenia has so far come from genetic marker studies involving the HLA system. The size of the HLA-paranoid schizophrenia association is small and would be quite in keeping with a multifactorial view of the aetiology of the condition. However, this represents a starting point for future genetic marker studies and signals the passage of psychiatric genetics into a new phase in which the molecular biological aspects of mental disorders must inevitably merit more detailed attention.

Acknowledgements

We are grateful to Dr Tim Crow for helping us devise the operational version of his (1980) criteria and to Dr Michael Neale for computer programming advice. This research was in part supported by an MRC senior fellowship (P. McGuffin) and travel funds from the John D. and Catherine T. McArthur Foundation (I. Gottesman).

Lecture

Behavioural Psychotherapy in General Psychiatry
Helping Patients to Help Themselves*

I. MARKS

It is widely believed by psychiatrists that patients who require behavioural psychotherapy need to be referred for such treatment to a specialist in the subject. Two assumptions underlie this idea. One is that behavioural treatment requires a detailed knowledge of learning theory which is possessed by few psychiatrists. The other assumption is that behavioural methods are too time-consuming for a busy psychiatrist in a routine outpatient or primary care clinic.

Neither of these assumptions is borne out by the evidence. Hundreds of general psychiatrists and nurses in the UK have in the last few years learned to give behavioural psychotherapy successfully to a wide variety of problems without formal training in learning theory and after very brief instruction in the treatment methods themselves. Moreover, these effective behavioural applications often required the clinician to devote no more time to the patient than is customary with pharmacological and other forms of psychiatric treatment in routine use. The evidence for these statements comes from extensive experience of tutors running courses in behavioural psychotherapy for senior psychiatrists, and from the teachers of nurses. Within days of instruction many clinicians become able to find ways of helping patients in routine psychiatric and general practice clinics by behavioural means.

This encouraging development arises partly from the recent move away from the idea of behavioural treatment as something done to patients towards a realisation that behavioural methods form a system of self-help that the patient learns from a clinician who largely acts as coach and monitor. In most cases there is no need to practise behavioural manoeuvres with the patient in the natural situation, only to guide them on what to do there.

The more usual pattern of a behavioural session in the clinic takes a different form, the practice part of the treatment now being mainly carried out by the patient without a clinician being present (steps 3 & 4 in Table I). Once the detailed nature of the patient's problem has been carefully unravelled in the course of an interview, the therapist explains to the patient (and a relative too if one is available as a co-therapist) how he can overcome the problem; he asks him to use a suitable manual, if one is available, to assist him in the self-help programme and to record every day in a structured but simple diary the tasks carried out and their outcome. The patient then leaves the clinic to practise the suggested procedures as homework between sessions while keeping a daily record of this homework and its results. He brings this homework diary back to the therapist in the next session for discussion and suggestions how to proceed further. Sometimes it is also helpful for patients to phone the therapist once or twice between sessions to make an interim report on progress and setbacks and to get ideas on how to deal with these. The patient is taught to anticipate setbacks and how to manage them.

In fact this model has been the norm in treating sexual problems for many years. The clinician never stands in the patient's bedroom telling him how to improve his lovemaking. Rather, the therapist, after taking a careful history from the patient and partner, works out suitable exercises for the couple to follow in the bedroom; these bedroom exercises constitute homework sessions outside the clinic. We can see this in an actual case that improved after a total of only 3½ hours of nurse-therapist time with the couple, including initial assessment.

A man of 36 complained of premature ejaculation for 3 years. Coitus took place once a week, with ejaculation within 45 seconds of penetration, though ejaculation could be delayed up to 3 minutes if his wife was in the female superior position. He refused to let her touch his genitals lest that precipitate ejaculation. The marriage was otherwise satisfying.

TABLE I
Process of behavioural treatment

1. Assess in clinic
2. Suggest behavioural methods to produce improvement
3. Practise these methods in the natural situation[1]
4. Record outcome in daily diary[1]
5. Monitor results
6. Repeat points 3–5 until adequate improvement obtained
7. Follow-up

[1] Used to be carried out with a clinician; now usually done by patient alone

*Maudsley Bequest Lecture given at the Winter Quarterly Meeting of the Royal College of Psychiatrists, 22 January 1986

TABLE II

Diary of self-exposure homework: example from an agoraphobic. From Marks (1978)

	Session						
Day	Date	Began	Ended	The exposure task I performed was:	(0 = complete calm, 8 = absolute panic) My anxiety during the task was:	Comments, including coping tactics I used:	Co-therapist, if any: *J. Smith* (Co-therapist's signature that task was completed)
Wednesday		2:30 p.m.	4:30 p.m.	Walked to local supermarket and surrounding shops, bought food and presents for family, had coffee in restaurant	7	Felt worse when shops were crowded, practised deep-breathing exercises	J. Smith (husband)
Thursday		10 a.m.	11:30 a.m.	Walked to local park, sat there for ½ hour till I felt better, then caught a bus to town and back home	6	Felt giddy and faint, practised imagining myself dropping dead	J. Smith
Friday		2 p.m.	4 p.m.	Rode a bus to town and back 3 times till I felt better about it	5	Worse when bus was crowded – did deep-breathing exercises	J. Smith

Plan for next week: Repeat exposure exercises in bus, park and shops every day until my anxiety is no higher than 3. Thereafter start visits to my hairdresser, and short surface train journeys.

The couple was instructed in mutual caressing that gradually included the genitals for lengthening periods, and how to use the squeeze technique to delay ejaculation. Coitus was first banned and then gradually reintroduced as the couple became skilled with the squeeze method. Within weeks, coital time was prolonged to 30 minutes in varying positions of intercourse, and when last seen at 1 month follow-up, progress was maintained.

Even severe agoraphobia can respond with very little therapist investment, merely appropriate advice.

A woman of 40 was enduringly helped by only 1½ hours of my time. She had been almost housebound for 5 years, from classic agoraphobia. First, with her and her husband we mapped her *avoidance profile* – which phobic situations she needed to enter in her everyday life yet avoided regularly because they evoked panic, so leading to handicap. This discussion yielded a profile of the public places she avoided, such as walking outside her home and going alone on a bus or train.

From the avoidance profile we devised a systematic *exposure-homework* programme that she could embark on. Starting with those avoided situations which she especially wanted to be able to re-enter in everyday life (e.g. walking outside her home alone, going alone on a bus), she was asked to daily go into at least one such situation for an hour or more until the ensuing panic had subsided somewhat. This exposure had to be carried out with*out* taking sedative drugs or alcohol. Every day she had to repeat the self-exposure exercise until she felt comfortable in the formerly panic-evoking situation. As continuing exposure produced habituation to particular places, she was to slowly extend self-exposure to further avoided places. I explained how she should keep a daily diary of her exposure-homework exercises, and asked her to post them to me (Table II). This she did, weekly at first and then at lengthening intervals. Her diligent self-exposure programme led her within weeks to become mobile for the first time in years. She kept up her progress without seeing me again but relapsed 4 years later, feeling low from some family problems. Seeing her once more for another hour prompted her to revive her original exposure homework programme. On doing this she recovered her gains. At 9 years follow-up she had residual fears but remained much improved and mobile.

That is a gratifying result for 2½ hours of time from a clinician. Even less therapist time – merely 1 hour – was needed to reduce a variety of troublesome compulsive rituals in an 11-year old girl (Zikis, 1983).

Her rituals had been troublesome for 6 years. The therapist began the exposure and response prevention with Jane and her mother together, after which mother continued this programme for 2 hours daily with Jane for a week, by when the rituals disappeared, then for an hour daily for 3 weeks, after which Jane did the homework on her own. Tics that had been associated with the rituals also disappeared, and Jane remained well to 1-year follow-up.

The single 45-minute session with the therapist had been carried out in the mother's presence. Jane was instructed to throw her glove down on the floor and to pick it up with her hand once only, and was told she was not allowed to throw it down again and pick it up with the other hand in the usual manner of one of her rituals. She was also asked to touch the handle of a door with her hand once only without repetition. These two tasks initially evoked anxiety and tics which gradually faded away as Jane performed the tasks several times without the ritual. Homework prescriptions for Jane to carry out included: (a) while pouring milk into her tea, to deliberately spill some drops of milk on the floor or table once only, (b) after telephoning from home, to put down the receiver once only, (c) on going to bed to close her eyes and avoid opening them again while saying 'I am not going cross-eyed – I do not see double'.

The point of these vignettes is not to show what wonderful things clinicians can do. Rather, they illustrate what might be achieved by means of minimal interventions of the right kind for the right types of problem. We are not talking about a general placebo effect in which saying almost anything soothing might help. Advice to relax, for example, will not improve phobics or obsessive-compulsives; nor will anti-exposure instructions. When such patients were given advice to take a holiday from anxiety and systematically avoid whatever was upsetting them they did not improve, though these same patients did improve on being asked to embark on an exposure programme (Greist *et al*, 1980; Marks *et al*, 1987). Nor is persuasion of a premature ejaculator to talk about childhood problems likely to prolong his ejaculatory time, whereas giving him some basic sexual skills training has a fair chance of doing so. Nor can a child with enuresis or encopresis be expected to become drier and cleaner if parents systematically reward him for being wet and dirty rather than for being dry and clean; the shaping has to be appropriate.

Though we are talking of a touch of the rudder, the touch must be in the right direction. Even simple procedures have to be executed properly; psychological interventions can be as specific in their effects as are drugs.

Cases responding to brief behavioural guidance of the above kind are not rare. General psychiatrists who are alert to the possibilities of behavioural treatment might find patients every week who could benefit from suitable detailed advice which is tailored to the patient's particular problem.

Some people can in fact treat themselves without ever even needing advice from a clinician, devising and completing a methodical self-help programme without instruction, once they know what principle to apply systematically. Take for example an autobiographical note in 1770, from Wolfgang von Goethe, who as a 20-year-old law student at Strasbourg University decided to apply the exposure principle to remedy his phobias of heights, diseased bodies, loud noises, and dark, lonely places.

> I ascended quite alone the highest pinnacle of the cathedral spire, and sat in the so-called neck under the knob or crown, as it is called, for a quarter of an hour, before I ventured to step out again into the open air, where, on standing on a platform scarcely an ell square, without anything particular to hold on to, one sees before one the boundless land, while the nearest objects and ornaments conceal the church and everything on which and above which one stands. It is exactly as if one saw oneself carried up into the air in a balloon. Such anxiety and pain I repeated so often until the impression became quite different to me, and I have therefore derived great advantage from these practices in mountain travels and on geological studies, and on great buildings, where I have vied with the carpenters in running over the freelying beams and the cornices of the building, and even in Rome, where one must run similar risks in order to obtain a nearer view of important works of art.

Goethe went on to treat his other fears similarly.

The amount of behavioural help that sufferers need from a clinician varies enormously. Many sufferers merely lack the knowledge of what principle to apply, and on learning what to do from the clinician or on reading a suitable self-help manual, can then go off and apply it on their own without further help. Detailed manuals and diaries to record homework help sufferers to execute their programme properly. In planning a self-exposure programme phobics and compulsive ritualisers have to remember that long exposure periods reduce fear more than do shorter ones. Some cases need prompting to get started and can then take off on their own; others require more help from the clinician in monitoring their progress at intervals. Clinicians need to teach patients to expect setbacks and to rehearse dealing with them alone, but be available for occasional booster sessions that some people require. All these cases can be treated fairly easily by a general psychiatrist.

When patients need additional help (e.g. certain phobics and obsessive-compulsives require some therapist-aided exposure), then at that point the average general psychiatrist might wish to call in specialist help. A few such cases want therapists to continue helping them indefinitely with exposure, despite having repeatedly improved during sessions; the long-term outcome in such cases is dubious, as the therapist must eventually fade out of the scene.

The best controlled evidence for the value of self-treatment in the behavioural area is in phobics and obsessive-compulsives. At least 20 controlled studies have found self-exposure to be helpful for such problems, most of these studies being in agora-, social, and specific phobics, while only one controlled trial found no benefit from self-exposure (reviewed by Marks, 1987). In the largest controlled study (Ghosh *et al*, 1987; Ghosh & Marks, 1986) marked gains from self-exposure occurred despite there being no interaction with a clinician beyond initial screening. Over 10 weeks 71 phobic patients were randomised to get self-exposure instructions from a self-help book (Marks, 1978), a psychiatrist, or a computer. Apart from a 1½-hour initial assessment, mean clinician time per patient in the three groups was respectively only 0, 1.6, and 1.5 hours. All three groups improved markedly and equally up to 6 months follow-up, in both the agoraphobic ($n = 40$, Ghosh & Marks, 1986) and social/specific phobic subgroups. Neither the clinician nor the computer conferred any advantage over the manual.

An obvious question is whether all three treatment conditions in the above study were doing anything more than placebo. In other controlled studies patients who expected to improve with another procedure – anti-exposure – failed to get better (Greist *et al*, 1980) and while anti-exposure almost abolished gains from anti-depressants – imipramine in the case of agoraphobics (Telch *et al*, 1985) and clomipramine in the case of ritualisers (Marks *et al*, 1987). Improvement from self-exposure thus has little to do with the mere expectation of improvement, but a great deal to do with the component of exposure that causes anxiety to subside.

The study of Marks *et al* (1987) also found that adding therapist-aided exposure after 8 weeks of a self-exposure programme conferred surprisingly few advantages in ritualisers, the long-term gains in both groups being similar. On the face of it, compulsive ritualisers seem to need to do more complicated things by way of treatment than, say, agoraphobics. However, our results are in line with Dutch findings that self-exposure helped obsessive-compulsives (Boersma *et al*, 1976 and Emmelkamp & Kraanen in controlled studies, and Hoogduin, 1985 in uncontrolled work).

Self-exposure seems to have better results when patients use an appropriate manual and diary, recording homework tasks for regular review. Still to be tested is the value of reading a manual without any prompting from a clinician. Two patients in the book-instructed condition of Ghosh *et al* (1987) had in fact previously bought the book on their own initiative but failed to follow its directions until they were asked to do so by the psychiatrist in the trial; initial contact with a clinician is thus an important motivator for some people. This raises critical theoretical issues. Why should certain people who know exactly what to do need to have a guru before they can do it? Some can learn a language, tennis or carpentry by self-practice with the aid of books and tapes without any coaching, while others, even if highly intelligent, find such tasks a losing battle despite intensive skilled teaching. Many ill-understood variables affect this process.

The need for therapist-aided exposure for phobics and obsessive-compulsives has diminished as self-exposure manuals have been refined. This is welcome as therapist-aided exposure is time-consuming and thus expensive. Patients on the author's waiting list are asked to first try treating themselves, using *Living With Fear* as a manual, and not infrequently improve enough therewith to obviate the need for a therapist. For most of the remaining cases the clinician's role is to assess the problem and to teach people to help themselves better.

Clinicians on the lookout for behavioural applications might find quite straightforward ways of helping certain problems.

In shy students, simple practice at dating helped them become more sociable (Arkowitz *et al*, 1975). They had a programme of 6-weekly practice-dates, each with a different matched opposite-sex partner who had similar anxiety. Subjects were told that the aim was not to find an ideal partner but to increase dating comfort and frequency. Each week the student was sent the name and phone number of the partner to be dated that week. Practice-dating increased the frequency of dates with partners outside the study until 3 months follow-up, and this continued in the 60% who could be followed up for 15 months; practice-dating also reduced social avoidance and distress and enhanced social skill. Improvement was greater after practice-dating than after a waiting list control (Christensen *et al*, 1975; Kramer, 1975) or reading and discussing a manual (Royce, 1975).

Of course great caution is needed before extrapolating from such students to cases with severe social deficits, but the principle of self-treatment is worth trying to adapt for them. In patients with social skills deficits, Stravynski (personal communication) found that to the end of treatment a similar social-homework approach helped as much as did social skills training; follow-up is now in progress.

General psychiatrists can give effective behavioural guidance not only to many phobics and obsessive-compulsives but also to some patients with sexual problems, e.g. premature ejaculation. Simple advice has even helped paedophiliacs with erectile dysfunction.

A clergyman came to me because he had not consummated his marriage of 3 years' duration: he had regularly masturbated little boys and lacked interest in women. It transpired that he had been impotent twice on his honeymoon and that he and his wife had not tried to have intercourse in the 3 years thereafter. I gave him the advice given by John Hunter to an impotent man two centuries ago, i.e. to lie naked with his wife and engage in mutual caressing but on no account to have intercourse with her. Soon he was achieving erections during caressing and gradually became able to sustain them. At that point he was asked to start partial and later complete coitus. This was successful, and his paedophiliac urges disappeared.

Obviously this is hardly a cure for all paedophiliacs; the point is that behavioural measures that take little therapist time can be of great help, provided the clinician is aware of such possibilities. Most behavioural psychotherapy can probably be given by non-specialists, with specialists only being needed for complex cases whose management might be especially difficult and time-consuming.

With little expenditure of time, general psychiatrists could help many patients by giving appropriate brief behavioural guidance and intermittent monitoring of the patients' homework.

Review Article

Prevalence Studies in Schizophrenia

E. FULLER TORREY

Over 70 prevalence studies of schizophrenia published since 1948 are reviewed. Despite problems of method, the studies suggest that there may be significant differences in prevalence among different populations and that prevalence may change over time. Further research is needed on how much differences in diagnosis or the course of schizophrenia contribute to the variable prevalence rates. The paper suggests the following as areas for additional enquiry: a possible north-south gradient, special populations (e.g. American Hutterites, northern Swedes, western Irish, castes in India) and ongoing case registers in areas of suspected high and low prevalence.

> Warm climates are not those which produce the greatest amount of insanity, but rather temperate climates, subject to great atmospheric vicissitudes, and especially those whose temperature is alternately cold and humid, damp and warm.
> Jean E. Esquirol (1845)

Geographical comparisons of the prevalence of schizophrenia have been of interest to mental health specialists for well over a century. When Emil Kraepelin voyaged to Singapore and Java in 1904 he specifically looked for cases of dementia praecox, and concluded that "in all civilized nations" the disease "comes under observation in approximately the same forms and everywhere accounts for the greatest number of the permanent inhabitants of institutions" (Kraepelin, 1919).

In recent years there has been a resurgence of interest in prevalence as epidemiological studies have multiplied. No longer can the field be characterised, as it was in 1963, as composed of "a small amount of inadequate research combined with a large amount of adequate criticism" (Mishler & Scotch, 1963). Since 1948 over 70 prevalence studies of schizophrenia have been published in which many used sophisticated techniques equivalent to epidemiological studies in other areas of medicine.

The interpretation of these studies, however, has varied widely. Jablensky & Sartorius (1975) reviewed 23 prevalence studies with an almost ten-fold difference from the lowest to the highest rate and concluded that "with few exceptions . . . the data on the prevalence of schizophrenia appear to be very similar in different cultures." More recently, in summarising the World Health Organisation (WHO) study of the incidence of schizophrenia in which a two-fold difference was found using a narrow definition and an almost three-fold difference using a broad definition, Sartorius *et al* (1986) concluded that "the results provide strong support to the notion that schizophrenic illness occurs with comparable frequency in different populations." Similarly Leff (1981) reviewed 11 prevalence studies of schizophrenia with an almost five-fold difference and concluded that "we can state on the basis of the studies reviewed that there is no evidence suggesting that schizophrenia is much more frequent in one part of the world than in another." On the other hand, Torrey (1980) reviewed a large number of studies and concluded that "the difference is greater than ten-fold and cannot be ignored," while Eaton (1985) also noted "roughly a ten-fold variation in the rates" and asserted that the differences were highly significant.

One reason for the differing interpretations of the data is problems of method inherent in prevalence studies of schizophrenia. Differences in diagnostic standards have varied widely around the world and certainly account for some of the different rates. Differing life expectancies will also affect rates, as will the age distribution of the population (e.g. large numbers of young children will lower the rate). For this reason some researchers have calculated the schizophrenia prevalence rate for a given age cohort (e.g. 18–65) or applied an age correction factor (e.g. the Weinberg abridged method). Another factor to be considered is the course of the illness; there is evidence from several studies that schizophrenia has a more benign course in developing countries which would produce lower prevalence rates.

Incidence studies of schizophrenia have the advantage of counting cases at their inception so the rates are not as affected by course and outcome; their big disadvantage, however, is that a significant subgroup of persons develop schizophrenia insidiously over months or years and it is virtually impossible to date the onset. Some studies of incidence have defined it as when the person was first referred for psychiatric care but this measure is affected by cultural factors and the availability of care. For these reasons incidence studies have been less used than prevalence studies and will not be included in this review. As Cooper (1978) summarised: "Reported incidence rates for schizophrenia tend to vary more widely than reported prevalence rates, and on the whole are probably less reliable."

It should be noted that all major diseases in which both genetic and non-genetic factors are thought to be important have significant prevalence differences. Heart disease varies approximately six-fold (Thom *et al*, 1985), rheumatoid arthritis ten-fold (Utsinger *et al*, 1985), type I diabetes 30-fold (Marble *et al*, 1975) and multiple sclerosis at least 50-fold (Kurtzke, 1975). In all these diseases there have been problems of method of narrow versus broad diagnostic definitions and differing mortality rates, similar to problems faced with schizophrenia. In addition, all current aetiological hypotheses of schizophrenia (genetic, diathesis-stress, biochemical, nutritional, infectious, psychosocial) would logically predict significant differences in the prevalence of the disease. If schizophrenia has no such differences it would be a unique disease and that fact alone would be one of its most significant aspects. In looking at the prevalence studies of schizophrenia it would be surprising if differences were not found.

Range of prevalence

Table I summarises schizophrenia prevalence studies with approximately 1000 or more subjects which have been published (or summarised) in English since 1948. According to Dr Assen Jablensky of WHO several additional studies have been published in the Russian literature (pers. comm.) The studies are arranged from the lowest prevalence to the highest. Prevalence rates are given per total population but the rates are not necessarily comparable because of the problems with method previously noted. In some studies prevalence rates were calculated only for age-corrected cohorts but, since different cohorts were used in different studies, these rates are also not comparable. Countries with large numbers of young children have a greater difference between the prevalence rate per total population and age-corrected rate.

The prevalence period used in the studies varies from cases symptomatic at the time of the survey (point prevalence) to cases which have occurred at any time during the person's life (lifetime prevalence). Cases of schizophrenia in which the person has recovered will be excluded from the shorter prevalence periods, while the longer periods must rely on recall of past clinical states. Case finding is done by using key informants to identify suspected cases who are then interviewed, doing house-to-house surveys (census method), or utilising ongoing case registers. For schizophrenia there is evidence that using key informants in rural areas produces results very similar to those obtained by house-to-house surveys (Nielsen & Nielsen, 1977).

The range of prevalence from the lowest reported rate (0.3 per 1000 among the ultraconservative agrarian Amish sect in the USA) to the highest reported rate (17.0 per 1000 in a restudy of an isolated population in northern Sweden) is over 50-fold. The Amish findings must be qualified, however; only four cases of schizophrenia were diagnosed among 12 500 Amish but 22 cases diagnosed with bipolar disorder had initially been called schizophrenia on hospital records. One can argue, therefore, that some of the bipolar patients would have been diagnosed with schizphrenia by other investigators and the schizophrenia rate is artificially low.

The three studies with the next lowest prevalence rates – in Ghana, among Taiwanese Aborigines, and among the Hutterites in the USA – cannot be as easily dismissed. Rin & Lin's (1962) study of the Aborigines, for example, was cited by Mishler & Scotch (1963) as having the best methods for case finding of any study done to that time. Leff (1981) criticised the study because cases of 'malarial psychosis' were not counted as schizophrenia, but in fact acute psychosis secondary to malaria is relatively common in tropical countries and should not be confused with schizophrenia. Among the 10 cases of schizophrenia diagnosed by Rin & Lin two had lasted less than 3 months and another four had recovered in less than 2 years. Despite a life expectancy of only 40–45 years among this population (which would reduce the number of older schizophrenics), the disease appears to have been genuinely uncommon in this group at the time of the study.

High prevalence was reported in Book's two studies of northern Sweden done 25 years apart (Book, 1953; Book *et al*, 1978), Vaisanen's study of communities in both northern and southern Finland (1975), and the study by Torrey *et al* (1984) of an area in western Ireland. It should be noted that both Book and Torrey *et al* selected areas for study which were reputed to have a high prevalence rate for psychosis, but this was not true for the Finnish study. The comparatively high schizophrenia prevalence rates found by Vaisanen *et al* (1975) were confirmed by a restudy of the same communities 5 years later in

TABLE I *(continued)*

Country	*First author*	*Year published*	*Type of study*[1]	*Total population*	*Prevalence period*	*Total population*	*Schizophrenia Prevalence/1000 Age corrected*[2]
Ireland (suspected high prevalence area)	Torrey	1984	R, K	2 848	6 months	12.6	17.4 (15+)
Sweden (restudy of high prevalence area)	Book	1978	R, K	5 748	point	17.0	?

R: Rural; U: Urban; K: Key; CR: Case register; C: Census

1. Type of census is characterised as either the key informant type (key) in which official and hospital records are examined, key persons are asked to name all mentally ill persons, and all suspected cases are then interviewed; or the census type (census) in which a house-to-house survey is conducted in addition to the above. For schizophrenia there is evidence that the key method over a long prevalence period identifies all cases of schizophrenia in the community and thus is equal to rates obtained by the census method (Nielsen & Nielsen, 1977). However, the key method for a point prevalence would presumably not detect all cases extant and thus would not be directly comparable to rates obtained by the census method.
2. Age-corrected schizophrenia rates are calculated by number of cases per population in the susceptible age group. Since these differ the rates in this column are not strictly comparable one to another. Many of them are calculated using the Weinberg abridged method (indicated by W) which is a measure of the expectancy of developing schizophrenia if a person lives through the 16–40 age-susceptible group. It is computed by the number of schizophrenic patients divided by (a) the total number of people who have reached age 40 plus (b) one-half the population in the 16–40 group; this product is multiplied by 100. W figures are comparable with one another in the chart (see Lin, 1953).
3. The Sri Lanka rate of 3.8 is based on the findings of the first two studies which the researchers claimed were considerably more reliable than the last two studies. If all four studies are used the rate becomes 3.2 per 1000.

which the number of persons found with psychoses was 50% higher than the original study (Lehtinen & Vaisanen, 1981); unfortunately the authors do not provide a diagnostic breakdown of the psychoses so the restudy is not included in Table I.

There are other suggestions that schizophrenia prevalence rates in northern Scandinavia are high. Bremer (1951) reported a rate of 5.3 per 1000 for a northern Norwegian village; the village was restudied 30 years later and the number of persons with 'functional psychosis' (no diagnostic breakdown given) had increased (Bjarnar *et al*, 1975). Fugelli (1975) surveyed two northern Norwegian islands and found 10 cases of schizophrenia among 1726 residents (5.8 per 1000); in addition he diagnosed another 15 cases of 'organic and senile psychosis' and 17 cases of 'other psychosis' yielding a prevalence of all psychoses of 24.3 per 1000. Anderson (1975) studied another area of northern Norway and found a prevalence rate for all psychoses (no diagnostic breakdown given) of 24 per 1000 for the Norwegian inhabitants and 54 per 1000 for the Lapps.

The area in western Ireland in which Torrey *et al* (1984) found a schizophrenia prevalence rate of 12.6 per 1000 (included 21 with DSM-III schizophrenia, 11 with schizoaffective disorder, and four with atypical psychosis) has not yet been restudied. The authors reported widespread belief among mental health professionals in the western counties that some areas have much more schizophrenia than others. The prevalence rate of the area studied in County Roscommon is more than twice the 5.9 per 1000 rate found by case register for the county as a whole and more than seven times the rate found for the St Loman's case register in Dublin for 1982 (Walsh, pers. comm., 1986). Emigration from western Ireland has been high for over a century but the authors claim this would account for only a small portion of the high prevalence observed. Schizophrenia has also been noted to be common among Irish immigrants to the USA so the high Irish rate cannot be explained simply by saying that the healthier individuals left and the pre-schizophrenic individuals remained at home.

High and low prevalence pockets

A further perusal of schizophrenia prevalence studies, worldwide, suggests an uneven distribution between some population groups which are geographically contiguous. The Amish and Hutterite prevalence rates in the USA, for example, are less than 25% of the rates reported for rural (North Carolina) or urban (New Haven, Rochester, Baltimore, Durham, St Louis) areas in recent studies. Differences in the prevalence of schizophrenia in the USA are also suggested by studies of hospitalisation rates although it must be recognised that these are determined by availability of beds and other factors in addition to true prevalence. A 1903 study of hospital admission rates for schizophrenia in the USA noted that "the greatest proportion of insanity is in the northeast . . . If from this center of greatest prevalence of insanity we draw a line in any direction — west, south, or southwest — we see that no matter which way we go we find a steady decrease until we strike the Pacific slope" (White, 1903). First admission figures for schizophrenia in various states for subsequent years have confirmed White's conclusion (Torrey, 1980).

As previously noted the Taiwanese Aborigines have a schizophrenia rate less than half that of the Taiwanese Chinese, the northern Swedes studied by Book have a rate twice that of southern Swedes, and the western Irish studied by Torrey *et al* have a rate twice that of their neighbours a few kilometres away. The most intensive study of intrapopulation differences, however, was the research done in Yugoslavia by Kulcar *et al* (1971). It had long been rumoured that the Istrian peninsula had an unusually large number of people with psychosis, and this was subjected to sophisticated study over 10 years. It was found that both schizophrenia and bipolar disorder were higher in the study areas compared to other parts of Croatia; the schizophrenia prevalence rate (for people ages 20–64) was 7.4 per 1000 in villages and 7.3 per 1000 in an urban area on the Istrian peninsula compared with 2.9 per 1000 (villages) and 4.2 per 1000 (urban) elsewhere in Croatia.

The existence of high and low prevalence pockets has been observed elsewhere. Researchers in Japan did two studies of Hachijo Island and reported the prevalence of schizophrenia to be 3.9 and 4.7 per 1000; surveys done elsewhere in Japan at the time consistently found a prevalence rate of 2.1–2.3 per 1000 (Kato, 1969). Murphy & Vega (1982) found that "first admissions for schizophrenia in Northern Ireland are significantly higher for the Roman Catholics than for the rest of the population." Murphy (1968) also reported that Catholics in Canada had significantly higher hospitalisation rates for schizophrenia compared with non-Catholics. In a study in Singapore, Murphy (1968) reported that Indian (mostly Tamil-speaking) students at the University of Singapore had twice as high a schizophrenic prevalence rate as the Malay students; Chinese students had an intermediate rate. Differential prevalence rates for schizophrenia have also been observed in the Soviet Union with its many ethnic groups; it was recently reported, for example, that schizophrenia is significantly less common among Uzbeks in the Samarkand region compared with Russians in the Moscow region (Yursinova, 1982).

India is another country which has provided intriguing findings on the prevalence of schizophrenia. In a series of studies in villages in West Bengal, Nandi and his colleagues (1975, 1979, 1980) found the prevalence rate for schizophrenia to vary from 2.2 to 5.6 per 1000. The highest schizophrenia rates were found among Indians of the highest castes. This is the ninth group of researchers over the past 50 years to find that schizophrenia occurs more commonly in India in individuals of higher castes (Dhunjibhoy, 1930; Shaw, 1930; Rao, 1966; Dube, 1970; Elnager *et al*, 1971; Dube & Kumar, 1972; Saxena *et al*, 1972; Kapur, 1975; Carstairs & Kapur, 1976; Varma *et al*, 1980). This observation contrasts with claims in the USA and Western Europe that schizophrenia occurs more commonly in lower socioeconomic groups. At least a partial explanation for the latter is 'downward drift' of individuals prone to schizophrenia; it is difficult to imagine how 'upward drift' could account for the Indian findings however.

Reports that there are large areas of the world in which schizophrenia is uncommon must be viewed with caution since many such reports are based on impressions only. Where schizophrenia is in excess it can be counted, but where there is a deficit it can always be said that the cases were missed or died off. In sub-Saharan African countries there have been such reports over many years. The surveys by Giel & Van Luijk (1969*a*,*b*) in Ethiopia and Ahmed's work in the Sudan (1979) (0.4 per 1000) are two more recent examples of such impressions. The best study methodologically from Africa was that of Ben-Tovim & Cushine (1986) of rural Botswana; omitting the patient with an onset at age 60 they reported a prevalence rate of 2.0 (total population) or 4.4 (15+) per 1000 which are higher rates than previous African studies.

The South Pacific is the other area of the world from which there have been reports of schizophrenia being uncommon. Torrey *et al* (1984) studied hospitalisation records for psychiatric disorders in Papua New Guinea and concluded that there was a 20-fold difference between some highland districts (very low prevalence) and some coastal districts (comparatively higher prevalence). Zigas & Rodrigue (Dohan *et al*, 1983) also had the impression that schizophrenia was rare in some highland areas. Murphy (1984), however, stated that "I myself could find only a two- to three-fold difference when I conducted a key-informant village survey in various highland and coastal districts.'

Elsewhere in Melanasia, in the Solomon Islands Clark (Dohan *et al*, 1983) found no schizophrenia among 3000 Kwaio adults living in remote villages but a prevalence rate of 2.2 per 1000 among 32 000 adults in the coastal region. In Polynesia, Murphy &

Taumoepeau (1980) reported a low prevalence of schizophrenia (and also organic and affective psychosis) on Tonga. Dale (1981) did an extensive survey of Micronesian islands and reported a point prevalence for schizophrenia of 1.5 per 1000 (age 15 and over). Among the various islands, however, there was an east-to-west gradient with rates of 0.8 per 1000 in the Marshall Islands to 9.7 per 1000 on Yap. Three decades earlier a survey had found no individuals with schizophrenia on Yap (Dohan *et al*, 1983).

Given the lack of methodological rigour in most of these surveys it is not possible to draw any firm conclusions. The impression remains, however, that there are some areas in the world where schizophrenia is uncommon. These areas are tropical, and when compared with the higher schizophrenia prevalence rates reported for western Ireland and northern Scandinavia there is the suggestion of a possible north–south gradient in the disease's distribution similar to the gradient reported for heart disease (Thom *et al*, 1985) and multiple sclerosis (Kurtzke, 1975).

Changes in prevalence over time

Research on prevalence rates of schizophrenia is complicated by the fact that the rates may change over time. Suggestions that the prevalence of schizophrenia may have increased sharply in the nineteenth century have elicited much controversy (Torrey, 1980; Hare, 1983). In Books studies of northern Sweden the schizophrenia prevalence rate increased from 9.4 to 17.0 per 1000 over 25 years, while in Finland the prevalence of schizophrenia apparently increased less dramatically over 5 years (Lehtinen & Vaisanen, 1981). In the USA there are also suggestions that the schizophrenia rate may have increased in recent years; 1984 studies in Baltimore and New Haven using a narrow definition of schizophrenia report schizophrenia prevalence rates (Myers *et al*, 1984) which appears to be twice as high as earlier studies which used a broader definition in Baltimore (Lemkau *et al*, 1942, 1943) and New Haven (Hollingshead & Redlich, 1958).

Schizophrenia prevalence rates may also decrease. The rural areas in southern Sweden studied by Essen-Moller (1956) was restudied 10 years later by Hagnell (1966) who found a substantial decrease in the number of individuals with schizophrenia. Shepherd (1957) claimed that England's Buckinghamshire County experienced a major decrease in first admissions for schizophrenia between 1931–1933 and 1945–1947. In Scotland, Eagles & Whalley (1985) claimed that schizophrenia had decreased in that country between 1969 and 1978. It is also interesting to speculate whether the difference in Scotland between Mayer-Gross' 1948 study (4.2 per 1000) and the 1981 Aberdeen case register (1.4 per 1000) is a result of a decrease in schizophrenia or because the two studies covered different geographical regions (southern and northeastern regions respectively). In Ireland, data from the three county case register for 1973 (Walsh *et al*, 1980) compared with 1982 (Walsh, pers. comm., 1986) suggests that a decrease in schizophrenia prevalence may be taking place in that country as well. Finally, a recent New Zealand study suggests that schizophrenia may also be decreasing there (Joyce, 1987). Some of these apparent changes may of course also be due to changing diagnostic practices as in recent decreases in first admissions for schizophrenia in Denmark (Munk-Jorgensen, 1986; Munk-Jorgensen & Jorgensen, 1986).

There are also examples of schizophrenia prevalence rates remaining relatively constant over time. Odegard (1971) reported that in Norway between 1926 and 1965 the number of individuals in hospital with 'functional psychoses' increased very little, while case registers in Denmark and Iceland also showed no substantial change (Hafner & Heiden, 1986). Dilling & Weyerer (1984) studied villages in Southern Germany and found an age-corected schizophrenia prevalence rate of 3.9 per 1000. Brugger had carried out two research studies in the same region 40 years earlier and found virtually identical age-corrected rates (3.8 and 3.9 per 1000) (Torrey, 1980). In both sets of studies the institutionalised schizophrenics were not included.

Perhaps the most intriguing report of a changing schizophrenia prevalence rate came from studies in Northern Ghana. From 1934 to 1937 Fortes, trained in both psychology and anthropology, studied Tallensi villages there; among approximately 5000 people he found only one who was psychotic, a 22-year-old man who had become ill in adolescence. In 1963 Fortes returned to the village accompanied by his wife, Dr Mayer, a psychiatrist. In the same population where 27 years earlier there had been a single psychotic individual there were now 17; of these, 13 were diagnosed with schizophrenia and one each with manic-depressive psychosis, acute reactive psychosis, postpartum psychosis, and involuntional depression. Fortes & Mayer (1969) noted that Tallensi elders were themselves alarmed over the rise in psychosis; organic factors (such as trypanosomiasis) or immigration were rejected as being causal factors. Fortes was also certain that he had not missed the cases in his earlier study: "What was quite startling . . . is that several of these cases occurred in families which were specially well known to me in 1934–1937 . . . These were the families of my best friends and informants, some of whom are still living. Had such cases occurred among them in 1934–1937 I could not have missed them'' (Fortes & Mayer, 1969).

Prognosis and seasonality

As mentioned previously, the course and prognosis of schizophrenia will affect prevalence rates if they differ among different groups. If, for example, a much higher percentage of patients fully recover in country A versus country B, then the prevalence rate in the country A will be lower even if the incidence rates in the two countries are equal.

There is evidence that prognosis and outcome do vary considerably, with schizophrenic patients in developing countries having a higher percentage of very good outcomes. Murphy & Raman (1971) brought attention to this fact in their study of Mauritius in which, 12 years after hospital admission, 59% of individuals with schizophrenia were completely recovered; a comparison with British figures showed that, 5 years after admission, only 34% of individuals with schizophrenia had completely recovered. Waxler (1979) did a similar 5-year follow-up in Sri Lanka and found that 40% of the patients had recovered completely. The most definitive study of this problem to date was the multi-nation WHO study of schizophrenia. At 2-year follow-up in this study the percentage of patients with a 'very favourable' outcome ranged from 57% (Nigeria) and 49% (India) to 24% (England), 23% (USA), 21% (Columbia), 14% (Czechoslovakia), 9% (USSR) and 6% (Denmark). In all of these studies it is important to note that the percentage of schizophrenic patients having a 'very unfavourable' outcome is relatively comparable; the difference is that more patients in developing countries recover completely while more patients in developed countries have intermediate outcomes.

Seasonality of schizophrenic births is another interesting aspect of the disease which may have a bearing on prevalence differences. It has now been shown in every northern hemisphere country which has been studied with an adequate number of subjects that a disproportionate number of individuals, who later in life develop schizophrenia, were born in the late winter and early spring months. The studies to date include England and Wales, Ireland, Denmark, Norway, Sweden, the USA, Japan, and the Phillipines and are extensively reviewed in several recent publications (Bradbury & Miller, 1985; Torrey & Kaufmann, 1986; Boyd *et al*, 1986). The excess schizophrenic births vary between 7 and 20% in these studies and the phenomenon is not necessarily constant within a single country (e.g. northern Sweden shows more seasonality than southern Sweden, the northern states in the USA more than the southern states). Nor is the seasonality fixed over time with evidence from Japan, England and Wales, and the USA suggesting shifts. Although the number of countries studied is still too few to make firm generalisations, there does not appear to be a relationship between the percentage of excess schizophrenic births and the countries with higher or lower prevalence rates for schizophrenia. In view of the firmly established seasonality of schizophrenic births, however, it would be surprising to find that the prevalence of schizophrenia did not vary around the world since seasons do vary from region to region.

Discussion

Despite methodological limitations, prevalence studies of schizophrenia published since 1948 suggest that there may be significant differences among population groups. Although the magnitude of these differences is debatable, I believe that a ten-fold range of prevalence for schizophrenia is supported by the data; this would be approximately comparable to the prevalence range reported for rheumatoid arthritis.

Since all hypotheses regarding the aetiology of schizophrenia would logically predict prevalence differences, it is not surprising that advocates of these hypotheses have utilised prevalence data to support their positions. Book (1953, 1978) explained his findings in northern Sweden by genetic mechanisms of inbreeding among the isolated population. Dohan *et al* (1983) claimed that the distribution of schizophrenia best fit nutritional theories of neuroactive peptides from grain glutens. Torrey (1980) put forth neuroviruses as the most logical explanation for the prevalence differences, and Murphy (1975) invoked psychosocial mechanisms such as the mother–son relationship in Ireland and the stress of acculturation in Ghana (Murphy, 1972) to explain the findings in those countries. The fact is that the studies on the geographical distribution of schizophrenia done to date do not point in any single aetiological direction.

The prevalence studies of schizophrenia do suggest important questions which need to be pursued. What portion of the lower rates reported from developing countries can be accounted for by the more benign course of schizophrenia in those countries? Is there a north–south gradient as has been shown for heart disease and multiple sclerosis? How much of the prevalence differences or changes over time are due to diagnostic differences? Groups such as the American Hutterites, northern Swedes, western Irish, and castes in India should be studied in detail with the collection of genetic, biochemical, nutritional, virological, immunological, and psychosocial data. Migrants from suspected high prevalence or low prevalence areas need to be followed to see whether their prevalence rate changes in their new home, similar to the work done in multiple sclerosis. Data on the seasonality of schizophrenic births should be collected in many more countries to ascertain its possible relationship to the prevalence of the disease. Ongoing case registers should be set up in areas thought to have a very high or very low prevalence.

There is one important advantage in studying the prevalence of schizophrenia—it does not require sophisticated and expensive laboratory equipment. We have grown accustomed in the waning years of the twentieth century to equating research with labora-tories. This is unfortunate, for some of the potentially most promising research on schizophrenia can be pursued with a diagnostic manual, pocket computer, and clinical acumen. There are methodological problems to be certain, but they are not any more formidable than those in laboratory research. As tragic a disease as schizophrenia is, it is also one of the greatest intellectual challenges of contemporary medicine.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941. PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available on request.

Review Article

Hostility and Deliberate Self-Poisoning: The Role of Depression

R. FARMER

The evidence for an association between hostility and deliberate self-poisoning is reviewed. Although the concept of hostility is poorly defined and different measuring instruments may not measure the same entity, self-poisoning subjects as a group appear to have very high levels of hostility. However, depression is also associated with hostility and when studies have taken into account the psychiatric diagnosis of overdose patients it is outwardly-directed hostility which distinguishes these individuals from other psychiatric patients or normals. A model is proposed to show the inter-relationships of hostility, depression and self-poisoning.

Following an epidemic rise in incidence in the 1960s and early 1970s deliberate self-poisoning became the most common reason for acute admission of women to hospital, and second only to ischaemic heart disease as the most common reason for men (Farmer, 1986). Its aetiology remains unclear. The motivation to take an overdose is often complex, with frequently a simultaneous interplay of different psychological motives in any individual.

Kreitman (1978) has reviewed some of the possible themes: (1) seeking an interruption from unendurable tension (Shneidman, 1964); (2) attempting to secure the attention of others as in the 'cry for help' (Stengel & Cook, 1958); (3) self-poisoning as a means of inducing guilt in others; (4) testing the benevolence of fate; and (5) true suicidal intention, the intention of actually ending one's life. Notable in two of these, (2) and (3), is the implication that negative, hostile feelings towards other persons may play a major role in self-poisoning. If so, this would have important consequences for the management of these patients, and for the prevention of further attempts and completed suicide. Also, the presence of true suicidal intent, motivation (5), is consistent with the psychodynamic view that hostility may also be directed inwards on the self.

But, what is the empirical evidence for a link between hostility and self-poisoning? When the literature is reviewed it becomes clear that the concept of hostility has several different meanings (Gottschalk *et al*, 1963) and the different instruments which have been developed to measure it do not necessarily measure the same thing (Edmunds & Kendrick, 1980). Hostility directed outwards includes at least four inter-related factors, any one of which may be erroneously equated by an investigator with the global construct of hostility. The factors are (1) an act, either physical or verbal, sometimes called 'aggression' which is interpreted as having a destructive function by an outside observer; (2) a self-reported attitude of dislike, resentment, suspicion towards other persons or objects sometimes called 'hostility'; (3) a subjective experience of an affect called 'anger'; (4) a predisposition of character to become hostile or aggressive. Any particular measuring instrument may focus on one or more aspects of this aggression-hostility-anger complex without indicating explicitly the meaning intended. Likewise the concept of hostility directed towards the self is frequently ill-defined and sometimes it is not differentiated from outwardly directed hostility.

The various kinds of measuring instrument have different theoretical bases, aims and characteristics (Edmunds & Kendrick, 1980). Projective tests aim to evaluate deeper, even unconscious hostility traits, but have been unwieldy to manipulate, difficult to quantify and unreliable. Questionnaires, scales and inventories, while relatively straightforward to administer and score, may suffer from response bias and ambiguity of meaning of specific items. Two scales which are commonly used and whose items were selected as being logically related to particular psychological theories are the Hostility and Direction of Hostility Questionnaire, HDHQ (Caine *et al*, 1967) and the Buss–Durkee Inventory (Buss & Durkee, 1957). These theoretically developed scales, like intuitively derived instruments, depend for their usefulness on the subject's self-knowledge and truthfulness and the perspicuity of the test items. Because of their theoretical orientation, however, their content validity is more clearly defined and it is easier to determine what the devices are supposed to measure. Studies using this kind of measure have been considered particularly important in this review.

The way the HDHQ was designed is congruent with a psychodynamic approach to hostility as Foulds (1965) assumed that hostility was a unitary entity which could, however, be directed inwards on the self or outward against others. Validation studies have offered support for this notion. Foulds *et al* (1960) found that while the correlations between the subscales were positive, suggesting a factor of general hostility, the patterns of correlations indicated that the extrapunitive subscales were measuring something different from the intropunitive ones. Hope (1963) and Philip (1968) tested the assumptions regarding the unitary nature of hostility and its direction inward or outward by principal component analysis of scores on normal and neurotic subjects. A similar component structure was found for both kinds of subject, the first component being unipolar with all five subscales represented, while the second contrasted the intropunitive and extrapunitive measures. The Buss-Durkee Inventory aims to measure aggressiveness and hostility as separate entities. Attempts to assess the empirical validity of the instrument have generally yielded negative results but a number of studies indicate that the subscales possess construct validity (Edmunds & Kendrick, 1980).

Given the conceptual and semantic problems which make comparison between studies using different measures difficult, the evidence for a link between hostility and self-poisoning is reviewed below. Also examined is the evidence for an association between depression and hostility. As many individuals who take an overdose have an identifiable depressive syndrome, if depression is independently related to hostility this would have to be considered in any close examination of hostility in self-poisoning. Those studies which have taken psychiatric diagnosis into account would then be of particular importance. Firstly however, how hostile are overdose subjects generally?

Hostility in self-poisoning subjects considered collectively

In a study by Lester (1967) the resentment and irritability subscales of the Buss-Durkee Inventory differentiated psychology undergraduates who had attempted or threatened suicide ('suicidal') from those who had at the most only considered suicide ('non-suicidal'), scores being higher in the former group. In this study the validity of data on past 'suicidal' behaviour and thoughts depended totally on subjects' recall and self-disclosure, and the theoretical grounds for including subjects who only threatened suicide alongside suicide attempters are uncertain. In a subsequent study (Lester, 1968), when neuroticism was controlled for, the apparent association between resentment and attempted or threatened suicide disappeared. Conte & Plutchik (1974) found that parasuicide patients scored significantly higher than 'non-suicidal' psychiatric patients on various measures of hostility, but the diagnostic profiles of the two groups were quite different and the status of the 'suicide attempters' is ambiguous as several subjects made what are described only as 'gestures'.

Several studies have used the Hostility and Direction of Hostility Questionnaire, HDHQ. Vinoda (1966) compared female parasuicides admitted to hospital, matched psychiatric controls and normal subjects. The parasuicide patients showed a similar pattern of diagnoses to the psychiatric patients who had no record of attempted or threatened suicide. There were significant differences in general hostility among the three groups with highest levels in the parasuicides and lowest in the normal controls. Similar results were obtained by Philip (1970) who assessed 100 admitted parasuicide subjects and drew comparisons with previous data concerning normal persons and neurotic patients (Philip, 1968). Again in a study by Eastwood *et al* (1972) 92 subjects admitted to hospital after parasuicide were found to be relatively hostile with a mean general hostility score almost two standard deviations above that of Philip's normals (1968).

These studies suggest therefore that self-poisoning subjects have relatively high levels of hostility, certainly that they are more generally hostile than normal or neurotically depressed patients. In terms of inwardly-directed hostility, the HDHQ studies suggest that overdose patients may be intermediate between normal and neurotic depressives who tend to have the highest levels.

These studies have looked at overdose subjects as a group and have not considered what effect the presence or absence of psychiatric illness, particularly depression, might have on hostility scores. There is good agreement that depression is the most commonly identified disorder in self-poisoning subjects and personality disorder the second (Vinoda, 1966; Morgan *et al*, 1975; Newson-Smith & Hirsch, 1979; Urwin & Gibbons, 1979), although estimates of the prevalence of depression have varied between 35 and 79% (Weissman, 1974).

In looking at the role of hostility in self-poisoning more closely, if an independent association were to exist between hostility and depression this would have to be taken into account. So what is the evidence for this?

Hostility and depression

Abraham (1911) was one of the first to draw attention to the relationship between depressive illness and hostility. The classical psychoanalytical view (Freud 1917; Abraham, 1924) is that hostility held against a loved 'object' becomes turned against the self when that object is lost, by a process of introjection.

Empirical studies have since confirmed a relationship between hostility and depression but there has been disagreement over the nature of this association.

Certain studies using the HDHQ have suggested that hostility is directed *inwards* predominantly in depression thereby lending support to psychoanalytical theory (Mayo, 1967; Philip 1971; Blackburn, 1974; Blackburn *et al*, 1979). On the other hand, consistent with Rado's observation (1928) of the depressive as 'irritable and brittle, easily taking offence' other studies have emphasised the *extrapunitiveness* of depressed subjects (Wessman *et al*, 1960. Weissman *et al*, 1971). Others again have suggested that hostility may be directed both *inward and outward* in depression (Gershon *et al*, 1968; Klerman & Gershon, 1970; Friedman, 1970).

Multivariate analysis studies of depressed persons represent a different way of looking at hostility and depression. In a study by Schless *et al* (1974) four questionnaires including the Buss–Durkee Inventory were administered to 37 depressed patients and four patterns of hostility expression emerged from factor analysis of the data. These were (1) anxious, guilt-ridden, inward turning of hostility with resentment; (2) verbal hostility with negativatism; (3) anxious, suspicious, resentful, control of hostile feelings; (4) assaultive, verbally abusive, outward expression of hostility. The overall group was dichotomous with regard to the direction of hostility expression, equal numbers showing a predominance of hostility inward or outward. However, sample size was small and it is difficult to exclude both type 1 and type 2 errors, particularly in the absence of any estimates of error.

Paykel (1971) applied a cluster analysis technique to data on 165 depressed patients in a variety of treatment settings although a specific measure of hostility was not used. At the first level of analysis two groups were obtained: one older and more severely ill, the other younger and more mildly ill. Further division produced four groups: (1) psychotic; (2) anxious; (3) hostile; and (4) young depressives with personality disorder. The group 3 subjects had particularly high hostility and self-pity scores. The 'psychotic' group had similar scores on these variables but in the 'hostile' depressives the hostility and self-pity were striking in comparison with the otherwise mild symptomatology. A factor analysis study by Overall *et al* (1966) on only in-patients delineated three groups corresponding to Paykel's first three categories.

From the above it can be seen there is a lack of consensus regarding the predominant direction of hostility in depression. Possible reasons for this include:

Methodological shortcomings

The conclusions that can be drawn from some studies are limited by (1) small sample size (e.g. Gershon *et al*, 1968; Schless *et al*, 1974; Blackburn *et al*, 1979); (2) a failure to use standardised diagnostic criteria for depression (Wessman *et al*, 1960; Friedman, 1970); (3) failure to check inter-rater reliability (e.g. Mayo, 1967; Weissman *et al*, 1971); (4) failure to use validated reliable measures of hostility (Weissman *et al*, 1971; Paykel, 1971). Projective tests have been used in certain studies (e.g. Wessman *et al*, 1960; Gershon *et al*, 1968; Klerman & Gershon, 1970) and may lack the reliability of more structured instruments.

The heterogeneity of the depressed subjects studied

The studies using multivariate analysis suggest that the expression of hostility may differ among different subtypes of patient.

The complex nature of hostility

It is likely that different instruments measure different aspects of hostility. Inwardly- and outwardly-directed hostility may be different phenomena and in certain studies the direction of hostility has not been clearly specified.

It is, however, possible to draw some conclusions. It appears inwardly-directed hostility rises sharply with severe depression. However, certain individuals may be predominantly extrapunitive when depressed. Philip (1969) has suggested that extrapunitiveness as measured by the HDHQ is a personality trait. This view is supported by its relative stability over time (Mayo, 1967; Philip, 1971; Blackburn *et al*, 1979) and also by the high levels of extrapunitiveness in overdose 'repeaters' and self-poisoning subjects who have received treatment for alcohol or drug misuse (Farmer, 1985; Farmer & Creed, 1986). If this is true, depression may act as a releaser for the expression of this personality characteristic. On the other hand, of course, personality difficulties may lead to adverse situations such as relationship or work problems, or alcohol and other drug misuse with consequent emotional distress and even an identifiable depressive syndrome in some cases.

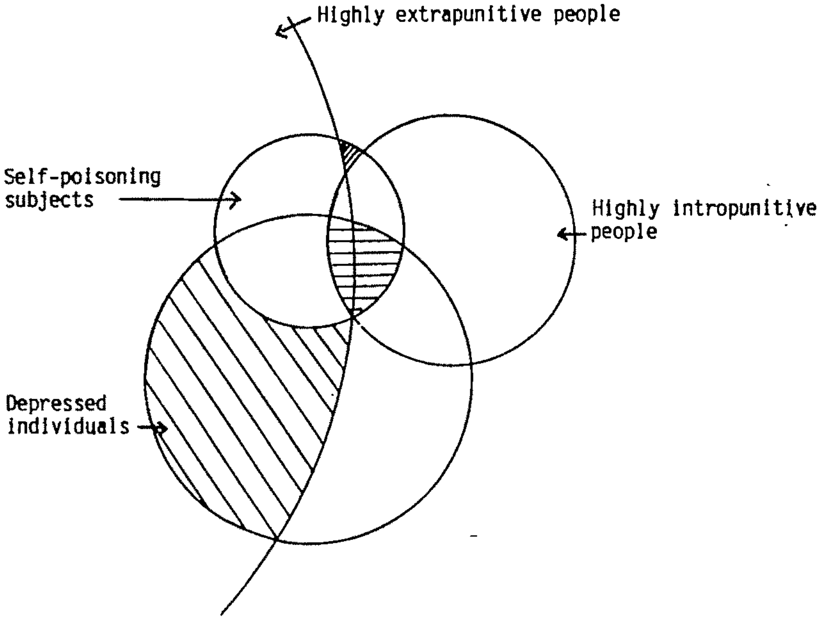
Given the association between hostility and depression, those studies which have taken account of the presence of depression in self-poisoning subjects become particularly important.

Hostility and self-poisoning, the role of depression considered

Certain studies have contributed to an understanding of the relative aetiological roles of hostility and depression in self-poisoning. In a study by Paykel & Dienelt (1971), 189 depressed patients were followed up 10 months after the initial contact and those subjects who had made 'suicide attempts' during that time were compared retrospectively with those who had not. Hostility was assessed from two self-report scales administered at initial interview and by a psychiatrist at initial and follow-up interviews. A distinguishing characteristic of the suicide attempters was their outwardly directed hostility. Guilt which would reflect inwardly directed hostility was not scored higher by the parasuicide group.

Crook *et al* (1975) divided 308 depressed in-patients into 'suicide attempters' and 'non-attempters', although 'attempts' included merely threats of self-harm. The attempters displayed more hostility including irritability towards others on a variety of measures including the Buss–Durkee Inventory, but their younger age compared to the non-attempters is a possible confounding factor.

While these two studies did not ensure that levels of depression were similar in the parasuicide and non-parasuicide groups this was attempted by Weissman *et al* (1973) and Yesavage (1983). In the first study, although an instrument designed specifically to measure hostility was not used, the parasuicides were judged to be more hostile and demanding during interview with evidence of more hostile interpersonal relations outside the clinical setting. Yesavage (1983) found that 'indirect hostility' and irritability as measured by the Buss–Durkee Inventory correlated



The circles represent four overlapping populations: self-poisoning subjects, depressed individuals, people with high levels of intropunitive hostility and people who are highly extrapunitive. The shaded areas represent three subgroups to illustrate use of the model.

▤ 1. Highly intropunitive and depressed self-poisoning subjects.

▨ 2. Self-poisoning subjects with low hostility levels.

▧ 3. Highly extrapunitive and depressed people who do not deliberately poison themselves.

FIG. 1 Hostility and depression in deliberate self-poisoning.

positively with self-destructive acts in depressed in-patients. 'Indirect hostility' referred to damage to property, gossip or practical jokes. Because levels of depression were not associated with self-harm it was suggested this kind of hostility might be a better predictor of parasuicide than the degree of depression.

A different approach involves dividing self-poisoning subjects into depressed and non-depressed. Farmer & Creed (1986) compared HDHQ scores in patients divided according to Present State Examination ratings. While the depressed subjects were more intropunitive, comparison with previous data on psychiatric patients and normals suggested that extrapunitive hostility might characterise self-poisoning subjects as a group.

Therefore, these studies suggest that among depressed patients those who have attempted to harm themselves, usually by taking an overdose, are more outwardly hostile than those who have not. When non-depressed self-poisoning subjects have been compared to normals their high extrapunitive scores have again been a distinguishing factor.

Summary

Self-poisoning patients appear to have very high levels of hostility, both inwardly- and outwardly-directed.

Studies using the HDHQ have found overdose patients to be more generally hostile than normal individuals or psychiatric patients and probably intermediate in intropunitiveness between these two groups.

Not all studies of hostility and self-poisoning have taken account of psychiatric diagnosis. This is important because depression, the most frequently occurring psychiatric disorder in overdose subjects, is independently associated with hostility. Inwardly-directed hostility seems to be related to severe depression but extrapunitive hostility, thought to be a personality trait, may also be associated with depressive symptoms.

Levels of extrapunitive hostility discriminate between non-depressed self-poisoning subjects and normals, and also between those depressed subjects who have deliberately taken an overdose and those who have not. Thus extrapunitiveness appears to characterise self-poisoning subjects.

The figure shows a tentative model of hostility as measured by the HDHQ and depression in self-poisoning in the form of a Venn diagram. Four overlapping populations are represented: self-poisoning subjects, individuals with a depressive syndrome, persons with high levels of inwardly directed hostility, and those who are highly extrapunitive. Any such model must be a oversimplification and the relative sizes of the groups are not claimed to be accurate; they would depend anyway on the thresholds used for depression and high or low hostility scores. Also it is important to distinguish between 'trait' and 'state' measures (Fava, 1986). While extrapunitiveness appears to be a 'trait' (a long-standing, enduring disposition), intropunitiveness seems to be mainly a 'state' which is temporary and changeable. As shown most self-poisoning subjects have high extrapunitive scores. A minority of depressives (mostly severely depressed) and also a minority of overdose patients have high levels of inwardly-directed hostility. Three groups are shown to illustrate the use of this model: (1) those highly intropunitive and depressed subjects (mostly severely depressed) who deliberately take an overdose; (2) the small number of overdose subjects who have low hostility levels including perhaps some of those with altruistic motives (Durkeim, 1951); (3) those highly extrapunitive people (many with personality difficulties) who develop an identifiable depressive syndrome without, however, taking an overdose. Personality-related problems may then be expressed in other ways such as an unstable work record or substance abuse.

The association between extrapunitive hostility, which seems related to personality, and self-poisoning has been stressed and may partly explain why some individuals deliberately take overdoses at times of stress while others do not. A prospective study of depressed subjects, with and without a history of self-poisoning would not only clarify the status of extrapunitiveness as a personality trait but also whether it has any predictive value for self-poisoning. Intropunitive hostility has been found to be associated not only with depression but also with high suicidal intent in self-poisoning subjects (Farmer & Creed, 1986). Again a longitudinal study would determine whether its measurement would assist in the assessment of patients who have taken overdoses.

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.
Children Not recommended.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusion states; serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.
CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia.
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Children Not recommended.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.
Package quantities & NHS price (correct a of printing) 10 x 200mg (1ml) ampoules £30.1 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7

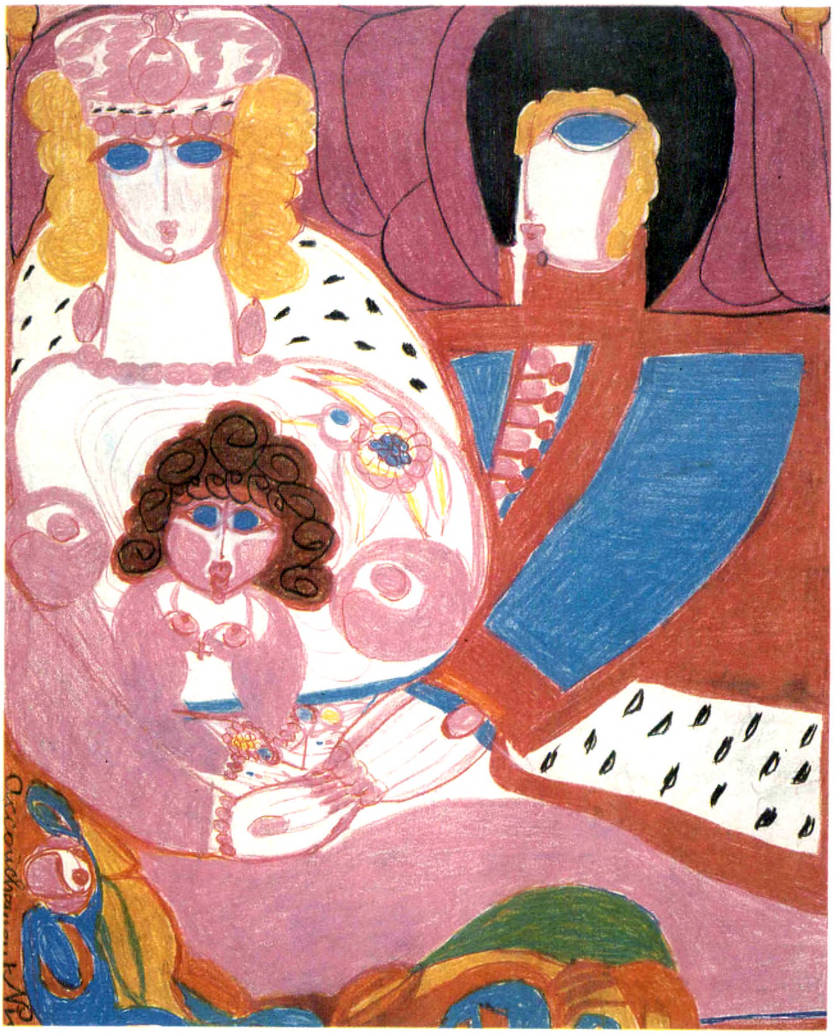
AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone halopheridol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication[2] leaving him/her better able to participate in other forms of therapy.

Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

Female Sex Offenders

ART A. O'CONNOR

Information on 19 women convicted of indecency and 62 women convicted of other sex offences was examined. Those convicted of indecency offences often had poor social skills and had a high incidence of mental illness, mental handicap and alcoholism. Two were convicted of indecent exposure, a rare offence in women. In 39 (63%) of the sex offences with individual victims, the victims were children and in 9 cases the offender was the mother or step-mother. In 25 cases the women were convicted of aiding and abetting a male offender. Of those convicted of indecent assault on persons under 16 and of gross indecency with children, 48% had a previous history of psychiatric disorder.

Sex offences are generally thought of as being committed by men against women or children. However, although rare, sex offences can also be committed by women. According to Home Office Criminal Statistics (Home Office, 1975-1984) 0.95% of all sex offences were committed by women. Table I shows a comparison of male and female sex offences over the 10-year period.

Literature on this topic is very sparse. There are a few case reports of female exhibitionists (Zavitzianos, 1971; Hollender *et al*, 1977; Grob, 1985) but there are no previous systematic studies of female sex offenders. Sarrel & Masters (1982) in their paper concerning 11 male *victims* of female sexual molestation suggest a classification of assaults into: (1) forced assault; (2) baby-sitter abuse; (3) incestuous abuse; and (4) dominant woman abuse. Their paper was mainly concerned with the victims and their subsequent problems.

TABLE I

Convictions for sex offences (excluding bigamy, abduction and prostitution) for the years 1975-1984 in England and Wales. (Source: Home Office Criminal Statistics 1975 to 1984).

	Males	*Females*	*Females as percentage of totals*
Buggery	2067	4	0.19
Attempted buggery[1] and indecent assault on males	6740	112	1.6
Indecent assault on females	23,640	113	0.48
Rape	3462	9	0.26
USI on girl under 13 years	978	6	0.61
USI on girl under 16 years	5223	13	0.25
Incest	1286	40	3.0
Procuration	2217	124	5.6
Indecency with children	2621	41	1.5
Totals	48,234	462	0.95

USI = unlawful sexual intercourse.

1. Offences in this section were classified as 'attempted buggery etc.' until 1977 and then as 'indecent assault on a male'.

Sexual offences against children are causing increasing concern to many agencies. Up to 80% of the victims are female and the commonest offence is unlawful sexual intercourse (Davidson, 1983). The victims are most commonly in the 11-15 year age group (Mzarek *et al*, 1981).

The offenders are often from within the family: 34% are parents or surrogate parents, 2% being mothers (Mzarek *et al*, 1981). The mother may be involved by giving active or passive permission either because it relieves her of sexual activity or because of fear of her husband (Davidson, 1983). The literature on incest is well reviewed by Batten (1983) and aspects of management are reviewed by various authors (Ciba Foundation, 1984).

This paper describes aspects of a group of imprisoned women convicted of sex offences.

Legal background

Crimes of indecency are offences such as indecent behaviour, outraging public decency and indecent exposure. They are dealt with at common law. The act in general has to be lewd, grossly scandalous, outraging public decency or offensive and disgusting. The punishment is a fine or imprisonment or both. There is no limit to the sentence but it must not be inordinate.

Indecent assault is dealt with under the Sexual Offences Act 1956 (Section 14 and 15). An example could be kissing a girl without her consent and suggesting that sexual intercourse take place. Consent to the act is no excuse if the victim, boy or girl, is under the age of 16. The maximum penalty on indictment for indecent assault on a man is 10 years imprisonment. The maximum penalty, if the victim is female and under 13 years of age, is 5 years imprisonment and if she is over 13 years of age the maximum penalty is 2 years imprisonment.

The Indecency with Children Act 1960 is concerned with acts of gross indecency with or towards children under 14 years of age. An example of gross indecency with a child is when a man allows a child to hold his penis and masturbate him. An example of gross indecency towards a child is when a person masturbates in front of a child. The maximum sentence on indictment is 2 years imprisonment.

Rape (Section 1 of the Sexual Offences Act 1956) can only be committed by a man but a woman can be found guilty of aiding and abetting rape or any other sexual offence. By the Accessories and Abettors Act 1861 a person who aids, abets, counsels or procures for the commission of an offence is liable to be tried and punished as the principal offender. The maximum sentence for rape is life imprisonment. Unlawful sexual intercourse with a girl under 13 years and incest with a girl under 13 years also have a maximum sentence of life imprisonment. Unlawful sexual intercourse with a girl under 16 years (S6), sexual intercourse with a defective (S7) and procurement of a defective (S9) (male as principal) all have a maximum sentence of 2 years (Cross & Jones, 1980; The Howard League for Penal Reform, 1985).

Method

Holloway Prison is the main female remand prison for London and South East England. Information was collected on all women committed to Holloway Prison from January 1974 to October 1985, who were convicted of sex offences. They numbered 81 in all. Prison records were examined in all cases and prison medical records in 64 cases. In 17 cases the medical records were missing. Eleven cases were examined personally by the author.

Information was obtained about basic socio-demographic items and also details of the offences and outcome in court. Where possible, information concerning past psychiatric and criminal history was obtained. Psychiatric reports, hospital and probation reports were all consulted where available.

One of the problems of a retrospective study such as this is the incompleteness of case notes. However, it would seem reasonable to document the information available as there is no substantial descriptive study of female sex offenders in the psychiatric literature.

Results

The offenders were divided into three groups according to the legal definition of the offence:

(1) Indecency (19 cases)
(2) Indecent Assault and Indecency with Children (39 cases) and
(3) Unlawful Sexual Intercourse (23 cases).

There were no individual victims in the indecency group but there were in the other two groups.

Indecency

There were 19 cases of indecency: indecent behaviour (14 cases), outraging public decency (three cases) and indecent exposure (two cases). Their average age was 35.9 years. Thirteen were single and six were divorced or separated; nine were of no fixed abode. Five had concurrent convictions for prostitution and four for being drunk and disorderly.

Eight had previous committals to Holloway Prison for similar minor offences such as being drunk and disorderly. Psychiatric diagnoses were made in eight of the group of 19. One had chronic schizophrenia, one had recurrent hypomania, two were mentally handicapped, two were alcoholic and two were dependent on drugs. The remaining 11 had no formal psychiatric diagnosis recorded.

As would be expected, the sentences were very light. Five were sentenced to imprisonment for periods ranging from 5 to 21 days. Five received 1-year conditional discharges, one received a Probation Order, seven were fined sums under £15.00 and one was put on a Hospital Order.

Case 1

M. was a 46-year-old single woman. She was mentally handicapped with an IQ in the range of 46–52. She was an illegitimate child and her mother was a long-term patient in a psychiatric hospital suffering from schizophrenia. M. spent periods in hospitals for the mentally handicapped and also sleeping rough. She had previous convictions for being drunk and disorderly and one conviction for actual bodily harm. The index offence was of outraging public decency by urinating in public. She had taken some alcohol and urinated in the street. She was given a conditional discharge for 1 year. At a later date she was charged with assaulting a policewoman and urinating in public. She was dealt with under Section 37 of the Mental Health Act 1983, and admitted to a hospital for the mentally handicapped.

Case 2

F. was a 25-year-old single chambermaid. She had a history of recurrent hypomanic episodes. She had several hospital admissions for this but also several criminal convictions for offences such as theft (4) and breach of the peace (1). The index offence (outraging public decency) involved exposing her genitals in public and inviting passers by to commit acts of indecency with her. All the offences occurred during hypomanic episodes. These rapidly resolved with treatment while on remand and a Hospital Order was never required. She was fined £5.00 for the index offence.

Case 3

H. was a 21-year-old single woman. She was second in a family of five. All her family were hard working and achieving people and there was no family history of psychiatric illness or criminal behaviour. She was borderline mentally handicapped but was able to read and write adequately and take care of herself. She had few friends but when aged 18 she got to know a group of similar unemployed people. Partly to impress them and gain their admiration she started episodes of stripping in public places. This behaviour continued until it became a frequent occurrence. It was often accompanied by masturbating in public, and occurred particularly when she was under stress. Self-exposure and masturbation often occurred when she had taken some alcohol because, while she enjoyed the activity, she found it embarrassing to start. She had several admissions to a psychiatric hospital for overdoses and short-lived depressions. She served four short prison sentences for theft and threatening behaviour. Although she was brought before the courts on many occasions for her indecent exposure she was never imprisoned for these.

Indecent assault and indecency with children

There were 39 cases in this group and details of the offences are given in Table II. Their average age was 28 years. Eleven of the 39 were married at the time of the offence, nine separated or divorced, two widowed, 15 were single and the marital status of two was unknown. There were only two people of no fixed abode.

There was little information available about the past histories of the 14 in the indecent assault group. However, in the next two categories 48% of the women had a psychiatric diagnosis and a history of previous treatment. Nineteen cases involved indecent assault on persons under 16. Eight of these had previous psychiatric treatment, five for depression, one for schizophrenia and one for personality disorder. The remaining one had been taking flupenthixol for 3 years but the diagnosis is unclear. Of the six in the indecency-with-children group, four had a history of inpatient psychiatric treatment: one for schizophrenia, one for schizo-affective psychosis and two for personality disorder.

The outcome of the court cases is shown in Table III. The more severe sentences were given for offences involving victims under 16 years. Hospital Orders were used in three of the six cases of indecency with children (two schizophrenia, one subnormality) and in only one case of indecent assault on a person under 16 (schizophrenia and subnormality).

TABLE II
Offences of indecent assault and indecency with children

Indecent assault	
indecent assault	9
aiding and abetting indecent assault	1
indecent assault and actual bodily harm	4
	14
Indecent assault on a person under 16 years	
indecent assault on a person under 16 years	12
indecent assault on a person under 16 years and indecency with a child	6
encouraging indecent assault on a person under 16	1
	19
Indecency with children	
indecency with a child	5
attempted gross indecency with a child	1
	6

Information about victims in the 14 indecent assault cases was sparse. One was a 17-year-old girl and the defendant aided and abetted her boyfriend in the assault. One was a 16-year-old girl and the 15-year-old co-defendant claimed it was a joke. Three of the offenders were jointly charged with two boys of offences against a 16-year-old girl (Cases 8, 9 and 10).

Of the 19 cases involving indecent assault on persons under 16 years of age information about the victims was obtained for 14 cases. In all there were eight female and eight male victims. (In one case there were two female victims and in another a male and a female victim.) Some of the motives given for the behaviour were: boredom after a broken marriage complicated by sedative and alcohol abuse (two cases); sex with a 13-year-old boy as revenge against her husband for being unfaithful; punishment of a 13-year-old boy for breaking into her house by taking his trousers off and interfering with him, (aided and abetted by her husband); fear of being beaten by her boyfriend if she did not aid and abet him in indecently assaulting a 9-year-old boy. In one case the mother of the victim was involved, and in one, the step-mother.

In the six cases involving indecency with children two involved boy victims and four involved girls. In two cases the perpetrator was the mother of the children.

TABLE III
Outcome of offences of indecent assault and indecency with children

Indecent assault on person under 16	8	2	1	1	4	2	1	19
Indecency with children	1	1				1	3	6
								39

Case 4

L. was a 36-year-old woman of West Indian origin. She was separated from her husband and her four children. The index offence was of attempted gross indecency with a child under 14 years of age. She made improper suggestions to a four-year-old boy within earshot of his parents. She had a past history of schizophrenia for which she had several admissions to hospital. At the time of the index offence she had several bizarre delusions and one of them was that the child was her own. She had a previous charge of child stealing and at the time of that offence she also thought the child was her own. She was dealt with under Section 37 of the Mental Health Act.

Case 5

J. was a 40-year-old separated woman of West Indian origin. On three consecutive days she was arrested for outraging public decency. She called at peoples' houses and asked to use the telephone. When admitted to the house she took all her clothes off and asked to have sex with the man of the house. On the fourth day she exposed her breasts in public and held them close to a young boy who was passing with his mother. She was charged with outraging public decency and indecency to a child. She had a long history of recurrent hypomanic episodes and seemed obviously mentally ill to all concerned. However, she was committed to Crown Court for trial but was regarded as unfit to plead. The charges were withdrawn because the court was reassured that she would get psychiatric treatment under Section 3 of the Mental Health Act 1983. This was achieved by the co-operation of the Crown Court and the area psychiatrist.

Case 6

C. was a 23-year-old woman separated from her husband. Her marriage had been a very unhappy one because of her husband's alcoholism and his violence, including sexual violence, towards her. There was one child, a 3-year-old girl, from the marriage who lived with C. and her common-law husband. This relationship was a loving and caring one and they intended getting married. They had sex on several occasions while the 3-year-old was present and once the man allowed the child to hold his penis. He was convicted of gross indecency towards the child and she of aiding and abetting him. She was sentenced to 2 years imprisonment and he to 3 years imprisonment. She naively felt that she was educating the child by exposing her to loving sex rather than the violent variety she had experienced before. No psychiatric abnormality was found in this woman by the doctors who saw her initially nor by the author who interviewed her while she was serving her sentence.

Case 7

M. was a 23-year-old divorced woman. Her marriage had been very unhappy because of her husband's drinking, beatings and sexual violence towards her. She drank heavily and abused sedatives towards the end of her marriage. They had three children and they lived with her ex-husband. She never knew her real father and there was a history of sexual abuse by her step-father over several years in her early teens. She had several previous convictions for theft. For approximately 1 year before the index offence she had been living with a man and he was planning to end the relationship. He had an 8-year-old daughter who lived with them. M. did housework for a 60-year-old man whose wife was an invalid. She had an affair with him and says that he threatened to tell her common-law husband about it if she did not agree to the sexual assaults on the 8-year-old step-daughter. The offence involved M., the 60-year-old man and the child engaging in various sexual acts and taking photographs. They were both convicted of gross indecency with the child. He was sentenced to 6 months imprisonment and she to 2 years 6 months as it was thought she was the instigator.

Cases 8, 9 and 10

In this case there were three female and two male co-defendants. The first two girls were aged 16 and 17 years and had a history of being in care and previous minor convictions. Both had a disrupted background with paternal alcoholism. The third girl was aged 17 and had no previous criminal background. The boys were aged 14 and 15 years and had known the girls for several months. The first two girls had been in a hostel but moved into a flat with the third girl some months previously. The victim was 16 and was known to the three girls as she stayed in the hostel. She absconded from the hostel several days prior to the offence and the girls were hiding her in their flat. On the afternoon in question the three girls, the victim and the two boys were in the flat. An argument broke out and the victim started teasing the boys, daring them to have sex with her. Everyone became angry towards the victim and took her clothes off. She was held down by the girls while the boys repeatedly rammed a candlestick up her vagina. She subsequently needed treatment for vaginal injuries. The five were convicted of causing actual bodily harm and indecent assault. They were each sentenced to four months Youth Custody. No psychiatric diagnosis was made on any of these three young women by the doctors who saw them initially nor by the author who interviewed them during the course of their sentences.

Unlawful sexual intercourse

There were 23 cases in this group and some details, including the outcomes, are given in Table IV. In all but two of the 23 cases the woman acted as aider and abettor of a man committing a sexual offence. The average age of the offenders was 33 years. Thirteen were married, six were divorced or separated, three single and the marital status of one was unknown. Fourteen had no previous psychiatric contact but there was no information concerning past history on seven. One woman was treated as an out-patient for depression and one had several admissions for immature personality disorder.

In 14 of the 23 cases the victims were under 16 years of age. In four cases the mother was involved in the crime, and in one, the step-mother. In one case both parents were involved and the boy and girl victims were both under 13

TABLE IV
Details of cases in the unlawful sexual intercourse (USI) group

Offences	*No. of cases*	*Age*	*Outcome*
USI	2	19, 19	3 months, Probation × 3 years
AA USI	2	42, 35	3 months, 9 months
AA rape	1	20	1 year
AA USI – victim under 16 years	8	Average 34 years	5 years, 4½ years, 2 years, 1 year (2) 3 months, suspended sentence (2)
AA USI – victim under 13 years	2	59, 29	1 year, 4 years
AA rape – victim under 16 years	2	32, 32	5 years, 4 years
AA buggery and abduction	1	21	6 months
AA incest	2	43, 36	4 years, 18 months
Unlawful administering of drug to AA USI victim under 16 years	1	39	18 months
Procure defective and AA USI	2	31, 25	9 months, 15 months
	23		

AA = aid and abet. Periods of time in the outcome column refer to sentences of imprisonment.

years of age. Some example of reasons given for the behaviour were: prostitution of a child; another woman claimed she was persuaded by her 14-year-old daughter to allow her to have sex to get money; another aided and abetted rape to punish her 14-year-old daughter for being naughty and disobedient.

Case 11

P. was a 51-year-old separated woman. She had a very unhappy marriage because of frequent violent attacks on her by her husband. They separated 10 years prior to the offence and he subsequently became a chronic psychiatric patient. She had six grown-up children and a 13-year-old daughter. For several years prior to the offence she was living with a 65-year-old man. Her 14-year-old daughter knew the man wanted to have sex with her and tried to persuade her mother to agree to this over several weeks. She said they could get money for a holiday that way. P. claimed that she agreed one evening when she was intoxicated. The girl told a visiting social worker and they were arrested. He was convicted of unlawful sexual intercourse and she of aiding and abetting him. She was sentenced to 12 months imprisonment and he to 6 months because of his age.

Discussion

Of those convicted of gross indecency with children and indecent assault on persons under 16, 48% had a psychiatric diagnosis and a history of psychiatric treatment. Little information was available on those convicted of indecent assault and one wonders if these also had a similar high incidence of psychiatric disorder. In the unlawful sexual intercourse group only two were recorded as having had previous psychiatric contact. Only one of this group was examined by the author and she was alcoholic. It is difficult to accept the low rate of psychiatric contact that the case notes suggest in this group.

The first group of offences described were those of indecency. They were minor offences, there was no individual victim and the offences were against accepted standards of social behaviour. Most of the offenders were women with poor coping skills, often of low intelligence and frequently having associated alcohol or psychiatric problems. A large proportion were homeless people.

Two women were convicted of indecent exposure. Of the 21 215 cases of indecent exposure recorded in Home Office Criminal Statistics between 1975 and 1984 all were male. The two women in this study were charged under Section 28 Town Police Clauses Act 1847 and Section 5 Public Order Act 1936 respectively, offences which may not be recorded centrally by the Criminal Records Office. Exhibitionism has generally been thought of as an exclusively male perversion. In men psychodynamic formulations suggest that castration anxiety is relieved by exposing the penis and eliciting a response from a female victim. It is suggested that because females have no penis to lose they have no significant castration anxiety and so have no need to expose their sex organs. Hollender *et al* (1977) describe a case of female genital exhibitionism and they suggest that while male exhibitionism results from castration anxiety, in the female exhibitionism usually stops short of genital exposure and results from the need for attention. Rarely, as in their case, genital exposure may occur in women as a pregenital attention seeking manoeuvre. They comment that males usually desire an aversive response and that the activity is genital (phallic) in psychoanalytic terms.

Zavitzianos (1971) describes a case of female fetishism and exhibitionism and suggests that there is a close relationship between perversion and some psychopathic personalities. Grob (1985) describes a case of a woman whose emotional deprivation led to feelings of rejection and the inability to develop empathic relationships. Her self-esteem relied on success in her profession, and when she lost her position she sought validation through exposing her genitalia while driving alongside large trucks on the highway. The intense need for attention in this case was stressed. Case 3 in the present study has many features of exhibitionism and the need for attention, especially when under stress, was prominent. The other case of indecent exposure was a woman with a history of many convictions for minor crimes and also alcohol abuse. Her offences could not be regarded as sexually motivated.

In this study 39 (63%) of the sex offences with victims involved children and in nine of these the woman was the mother or step-mother. Of interest also is the fact that in all but two of the 23 cases in the unlawful sexual intercourse group the women were convicted of aiding and abetting a male committing the offence. Sexual gratification was never noted as a motivation for the women involved in sex offences with a victim.

Conclusions

Sex offences are rare in females. Offences of indecency are relatively minor offences committed by women of poor social skills and with a high incidence of mental illness, mental handicap and alcoholism. While indecent exposure is a relatively common offence in men, only two women were convicted of this offence in the present study. Women who commit sex offences that have individual victims are a more heterogeneous group and of interest is the number of offences that involve children (63%) and also mothers or step-mothers (nine cases). Of those women convicted of indecent assault on persons under 16 and gross indecency with children, 48% had a past history of psychiatric disorder. Nearly all the women in the unlawful sexual intercourse group were convicted of aiding and abetting a male rather than being the instigator themselves.

Acknowledgements

I would like to thank Dr Paul d'Orban for advice and encouragement in the preparation of this paper and Anna Stafford BA for secretarial assistance. The views expressed in this paper are my own and do not necessarily reflect those of the Home Office.

No Fixed Abode

A Comparison of Men and Women Admitted to an East London Psychiatric Hospital

J. L. HERZBERG

There is little information available on psychiatric disorder in homeless women. This study compares clinical casenote information of all homeless women admitted to an East London psychiatric hospital from 1971–1980 inclusive, with information on a cohort of homeless men admitted during the same period. The results show that the women appear to have been socially more stable than the men prior to admission and yet they have less satisfactory admissions to hospital. Possible reasons for these apparent inconsistencies are discussed.

The relationship between homelessness and psychiatric morbidity has been studied by many people. Although there have always been people who have adopted a wandering lifestyle by choice, some of whom have written about their experiences (Davies, 1908; Orwell, 1933), others, less fortunate, have adopted a nomadic lifestyle as a result of illness. Ødegard (1932) studied the link between emigration and insanity and found that Norwegians in Minnesota were more likely to be suffering from schizophrenia than those in Norway and some of those who had emigrated were ill before they did so. The relationship between high admission rates for schizophrenia and populations living in impoverished inner city areas has been elucidated by Faris & Dunham (1939) in Chicago, Gerard & Houston (1953) in Worcester, Hare (1956*a*,*b*) in Bristol and Dunham (1965) in Detroit.

Research in the UK has been mainly centred on people living in common lodging houses or hostels, people living rough or using soup kitchens and people with no permanent address who are in prison or hospital. This last group are often referred to as of 'no fixed abode' (NFA) for the purposes of record-keeping. Operational definitions of homelessness are often of limited value as the boundaries are unclear. A survey carried out in 1965 of 'homeless single persons' (National Assistance Board, 1966) demonstrated the overlap between the populations of various establishments with those who slept rough. In general, the lower the standard of accommodation, from lodging house, to hostel, to reception centre, to the street, the greater is the proportion of physically and mentally disabled people found.

Surveys carried out in Salvation Army hostels (e.g. Crossley & Denmark, 1969; Lodge Patch, 1970) have generally concentrated on the assessment of men. However, Priest (1971) interviewed men and women in common lodging houses in Edinburgh and found that the residents were typically men in their 50s or 60s, who had resided in lodging houses for several years. There was a preponderance of Catholics from Scotland and Ireland and half the residents were unemployed at the time of interview. Psychiatric morbidity was diagnosed in 58 (78%) of the residents and the most common diagnosis was schizophrenia, in 25 residents (32%). Alcoholism was diagnosed in 14 residents (18%) and personality disorders in a further 14 (18%). Priest (1976) then compared the characteristics of men and women in Edinburgh lodging houses with patients from similar accommodation who were referred to a psychiatric hospital. Both populations were predominantly male, with approximately 18% of women. He showed that the patients presenting to hospital were likely to be younger and have a history of law-breaking, and were more likely to be diagnosed as alcoholic or personality-disordered. The lodging house residents not presenting to hospital were more likely to be older and suffering from schizophrenia. However, these studies did not attempt to compare diagnostic and social data of men and women.

A retrospective survey of patients admitted from NFA to a Birmingham mental hospital from 1961–1965 was made by Berry & Orwin (1966). The figures for 105 men and 40 women were combined and, in all, 49% of patients were diagnosed as suffering from schizophrenia and 28% were diagnosed as having a personality disorder. Some 90% of the patients were unemployed, 75% had been homeless for one year and 37% had a criminal record; 74% of patients had been previously admitted to a psychiatric hospital.

Reception centres were set up by the National Assistance Board after its inception in 1948 and were designed to give temporary shelter to 'persons without a settled way of living'. Surveys by Edwards *et al* (1968) and Tidmarsh and Wood (1972) demonstrated the high degree of social and psychiatric morbidity among the residents of the Camberwell Reception Centre. However, the demand on services there were such that nearly two-thirds of the mentally ill, three-quarters of the alcoholics and half of the physically handicapped new cases did not receive medical treatment at the centre and most were not referred elsewhere (Wood, 1976).

The studies dealing specifically with homeless or destitute women are few, and to date there has been little work delineating the characteristics of destitute women who are admitted to psychiatric hospitals. Higgs & Hayward (1910) described the generally poor working conditions and low wages which employed women endured. Low wages or an unwanted pregnancy could force women into common lodging houses or workhouses, where they lived with prostitutes and the mentally ill. In 'casual wards' for vagrants they were subjected to a dehumanizing regime, and in 1905, 9% of vagrants thus 'relieved' were women. Between the wars there were adequate numbers of lodging house places for women (Menzies, 1927), in which charges were higher than in similar institutions for men and the institutions were generally dreary. It was said that the women were more destructive than the men, were likely to steal the sheets and spent longer indoors, thereby increasing staffing and heating costs. Laidlaw (1956) surveyed women and men in Glasgow lodging houses and found that the women residents were more likely than the men to be or have been married and fewer of the women had been in prison. Few residents of either sex were employed and about 25% of all residents were mentally ill or mentally handicapped.

Digby (1976) in a nation-wide survey of hostels and lodging houses estimated that approximately 2200 women were living in such settings compared with 23 300 men. He found that the women were socially more stable than the men on several criteria including maintaining contact with relatives and holding a job. In contrast, a study of the residents of a hostel for homeless women (Brandon, 1973) describes markedly disturbed behaviour by the residents when the community opened, with violent acting out, overdoses and slashed wrists. Some social and psychiatric characteristics of destitute men and women in Dublin have been delineated by Fernandez (1984) in a survey designed to assess the needs of the homeless mentally ill, but there is a general lack of information about NFA women (Herzberg, 1984).

It is apparent that people of no fixed abode do not form a homogeneous group and rehabilitation strategies will depend on the availability of resources allocated to medical and social services. The situation is further complicated by a general lack of low-cost accommodation. Digby (1976) showed that there was a 17% loss of beds in hostels and lodging houses between 1965 and 1972. Furthermore, the number of reception centres throughout the UK had fallen from 270 in 1948 to 17 in 1970. However, moves have been made to establish smaller reception centres with the aim of providing a better assessment of the needs of referred clients. Leach & Wing (1980) found that these smaller centres were considered more acceptable by both staff and clients. Although the Housing (Homeless Persons) Act 1977 does state that priority for rehousing should be given to the mentally ill, homeless families generally take precedence over the single homeless.

There is evidence that destitute alcoholics can be helped by hospital rehabilitation programmes (Myerson & Mayer, 1966) or through contact made in 'shop fronts' leading on to placement in long term hostel accommodation (Cook, 1975). A flexible attitude to service provision is necessary when dealing with the needs of the destitute. Leach & Wing (1978) and Leach (1979) found that the effectiveness of the St Mungo's service for helping destitute men was improved by the use of 'action research' techniques where research findings were used to modify the original project. They found that the men who were suitable for placement in a rehabilitation scheme were assessed more effectively from a night shelter than a soup run. Similar flexibility in approach was shown to be helpful by Brandon (1973), who found that violence in a hostel for destitute women was reduced by the introduction of encounter groups and relaxation therapy.

The provision of rehabilitation facilities for mentally ill patients in the community is often inadequate, and official estimates of the number of hostel places required have been too low (Christie Brown *et al*, 1977). There is currently much worry about the move of patients from long stay hospital care into a community with a widespread lack of after-care facilities. There is anecdotal evidence that in the USA, where a programme of 'deinstitutionalisation' is well under way, the night shelters are filling with the mentally ill homeless (Bassuk, 1984).

Leach & Wing (1978) describe an 'enabling model' of rehabilitation for the destitute, with contact services on the street, leading on to chains of housing and vocational opportunities at closely spaced levels, with the necessity to provide facilities for those who cannot move upwards from any one level. They state that this policy would require adequate assessment of the projected need for facilities, proper funding and close co-operation between government, local authority and voluntary agencies.

Method

The study was based at the London Hospital (St Clement's), the psychiatric unit of an East London teaching hospital, which offers a catchment area service to Whitechapel, Stepney, Bethnel Green, Poplar and the Isle of Dogs. This is an impoverished Inner London catchment area which at the time of the 1981 census had the highest proportion of unemployed men of any of the Inner London boroughs (Office of Population Censuses and Surveys, 1982). The area contains a large number of hostels and lodging houses for homeless people.

Various studies of the homeless have used different definitions of homelessness. For example, the National Assistance Board (1966) survey included persons sleeping rough, and those using reception centres, lodging houses, shelters and hostels, together with the people seeking financial aid from the Board's offices. The present survey took the form of a retrospective casenote study. The entry of a patient into this study was initially determined by the patient being recorded as homeless on admission and therefore noted as NFA in hospital admission books kept in the medical records department. Thus the type of accommodation previously used did not determine initial entry into this study and neither did the length of time for which the patient had been homeless. However, attempts were made to note the duration of homelessness and previous use of hostels and reception centres in the subjects who were finally included in the study.

When the casenotes were studied in detail it sometimes transpired that patients recorded as NFA in the admission books did in fact have an abode to which they could return on discharge, but this information had not been available at the time of admission. It was decided to study only those patients who were homeless at the time of admission and who had no home to return to on discharge. Furthermore, it was apparent when studying the casenotes that some NFA patients had been transferred to hospital from prison, but otherwise met the criteria for entry into the study (i.e. they were homeless offenders who subsequently were thought to require hospital treatment). These patients, 10 men and 3 women, were included in the study and allowance was made in the analysis of the results where their admission from prison was likely to have affected the data.

Inspection of the admission books showed that between 1971 and 1980 inclusive, 79 NFA women had been admitted. Exclusion of cases not meeting the above criteria gave a final sample of 50 women.

Inspection of the admission books showed that 272 NFA men had been admitted in the same period. A subsample of every third admission during this period was taken to provide a sample of men of approximately equal size to the sample of women. The subsample of men chosen (90) was similar to those not chosen (182) in respect of age ($P<0.4$), number of previous admissions to the index hospital ($P<0.95$) and whether the current admission was on section ($P<0.3$). Exclusion of cases from the subsample not meeting the entry criteria gave a final sample of 63 men.

A schedule was drawn up to record the wide range of information found in the medical and nursing notes. For convenience, information is presented on the whole group of 113 subjects where there is no appreciable difference between the sexes for a specific item. It is acknowledged that information obtained from casenotes retrospectively may be unreliable in detail and that prospective studies are likely to yield the most accurate results. However, retrospective casenote studies of the hospitalised homeless have yielded valuable information in this field (e.g. Whitely, 1955; Berry & Orwin 1966). Information about individual items was not obtained for every subject, and percentages, where stated, refer to the percentages of valid cases (i.e. those cases where the information was available for a given item). Where there are significant differences between the sexes these are delineated and have been subject to non-parametric statistical analysis using a χ^2 test. For items where two by two tables were obtained, a Yates correction was applied. Only one item on the schedule, namely, age of subjects, was analysed by parametric statistics using a *t*-test. Statistical computations were performed using the Statistical Package for the Social Sciences (Nie *et al*, 1973).

Results

Social data

The mean age of all subjects was 38.6 years (s.d. 12.2). The mean age of the women, 36.3 years, was less than that of the men, 40.5 years. This result tended towards, but did not reach, statistical significance ($P<0.07$).

Thirty-eight men (61.3%) were single, compared with 18 women (36.7%). Only 24 men (38.7%) were currently or previously married, compared with 31 (63.3%) of the women. The women were significantly more likely to be married than the men ($P=0.02$). Thirty-two women (72.7%) had one or more children compared with 19 men (34.5%); significantly more women than men had children ($P<0.005$).

Virtually half of all the subjects, 53 (48.6%) were born in England, 17 (15.6%) were born in Scotland and 13 (11.9%) in Eire. Five subjects (4.6%) came from other parts of Ireland. Only 22 subjects originated from London. There were as many subjects registered Catholic, 42 (44.7%) as Church of England, 42 (44.7%).

Forty-five subjects (49.5%) had experienced a separation of greater than 3 years from one or both parents before the age of 15, and further information was available in 41 cases. Of these, in 17 (41.5%) the separation was due to the death of a parent and in 18 (43.9%) it was due to the separation or divorce of the parents. Only in two cases did the separation appear to be attributable to delinquent behaviour by the child. In general, the subjects came from large families with a mean of 3.5 siblings (s.d. 3.1).

The subjects left school at an early mean age, 15.3 years (s.d. 1.9), and left home at a mean age of 18.1 years (s.d. 3.7). It was noted that 21 of the men left home to join the armed services or the merchant navy and the records suggest that four of these men were subsequently dishonourably discharged. Eight women left home to get married or live with a boyfriend and four left for residential jobs as cleaners or nannies. Five women left home to attempt training as student or pupil nurses and another two women subsequently attempted such training. Further information available on six of these trainee nurses suggested that only one actually completed her training.

Nearly two-thirds of all subjects, 60 (64.5%), had been in London for more than 1 year, and relatively few, 12 (12.9%), had arrived in London within a week of their admission to hospital. Twenty-eight subjects (45.2%) had been in accommodation within a week of their admission to hospital and a further 19 subjects (30.6%) had been in accommodation within a month of their admission. Fifty-six subjects had previously used hostels and four subjects, all men, had used facilities for destitute alcoholics. Only one subject was recorded as having used a reception centre, but the index hospital was situated relatively far from reception centres. Only 37 subjects (32.7%) had definitely been living rough prior to admission and 24 of these had lived rough for less than one week. Places used included streets, parks, under bridges, shop doorways and a bombed site.

Fourteen men (29.8%) were in contact with their families compared with 18 women (64.3%). Contact was loosely defined to include any known personal contact or contact by telephone or letter within the previous 12 months. Women were significantly more likely to be in contact with their families than men ($P<0.008$).

Only two subjects were currently in employment at the time of admission. The mean time of unemployment for subjects was 25.6 months (s.d. 41.0). It was noted that 22 men had done casual labouring or building site work and 5 had been kitchen porters. Three men had been barmen, all of whom were diagnosed as alcoholic at the time of admission. Only nine men held a skilled or semi-skilled job when they last worked. Few jobs were coded for women. Seven women had worked in factories, three had done domestic work and three had worked in laundries. The notes suggested that nine of the women had earned money by prostitution.

The mean number of known admissions to other psychiatric hospitals was 2.5 per subject (s.d. 2.9). One subject had at least 20 previous admissions and only in 19 subjects was there no history of previous admission. In addition, 28 subjects (24.8%) had previously been admitted to the hospital under study.

Forty-one subjects (53.9%) had a history of imprisonment and 13 of these subjects (ten men and three women) were transferred to hospital from prison on the index admission. When all 113 subjects were considered, the men had a higher mean number of terms of imprisonment (1.5) than the women (0.6), and women were significantly less likely to have a history of imprisonment than men ($P<0.04$). However, when the data were reanalysed excluding the subjects transferred from prison, this result tended towards, but failed to reach, statistical significance ($P<0.1$).

Referral to hospital

In the following section only data on those subjects admitted to hospital from the community (53 men and 47 women) will be considered. Forty subjects (40.0%) were referred by doctors, who were generally casualty staff, 25 (25.0%) were self referrals and 28 (28.0%) were referred by the police. Overall, seven men (13.2%) were referred by the police compared with 21 women (44.7%). The women were significantly more likely to be referred to hospital by the police than the men ($P<0.001$). It was also apparent that Section 136 was being used more frequently by the police for women than men, although this result could not be subject to statistical analysis due to low cell frequencies in the χ^2 table. However, 16 women (34.0%) were admitted under Section 136 compared with 6 men (11.3%). In addition, women admitted from the community were significantly more likely than men to present via the emergency clinic rather than organised channels of referral ($P<0.02$).

The reasons for admission under Section 136 are noteworthy. Six subjects were walking or running dangerously through traffic five women and one man) and four subjects (all women) were admitted following assaults on people or property. Three subjects (two women and one man) were admitted having been found in varying degrees of nudity in a public place and three other subjects (one woman and two men) had been talking to themselves. Two subjects (both women) had been found on a railway track and two others (one woman and one man) had been fire-setting. One subject (woman) told the police that she was in America and demanded that they take her to India, and another subject (man) was found cutting his wrist. Seven out of the 16 women admitted under Section 136 (43.8%) were subsequently diagnosed as schizophrenic and a similar proportion of the men, three out of six (50.0%) of those admitted under section 136, were also diagnosed as schizophrenic. Two thirds of the non-schizophrenic men and women admitted under Section 136 subsequently received a diagnosis of personality disorder. The patients' diagnoses did not correlate with the behaviour precipitating their referral by the police. Violent, potentially self-destructive and bizarre behaviours seemed equally prevalent among the schizophrenics as the personality-disordered.

Admissions

The mean length of admission for all subjects was 30.7 days, with a large standard deviation (s.d. 35.8). Seven subjects had a stay of 24 hours or less and the maximum length of stay was 170 days by one subject.

Symptom/sign combinations were coded for each subject but were not analysed due to low cell frequencies. A summary of these findings is given in Table I.

Seventeen subjects had physical illnesses needing treatment (Table II) but only two subjects, both women, were transferred to a general hospital. One subject had a previously undiagnosed carcinoma of the breast and the other had a pyrexia of unknown origin which did not require treatment. Four of the 63 men (6.4%) suffered from epilepsy, a condition with a high psychiatric morbidity.

TABLE I
Symptoms and signs by sex[1]

	Men	*Women*
Depression	29 (50.0%)	19 (41.3%)
Suicidal ideation	10 (17.2%)	9 (19.6%)
Delusions/hallucinations	16 (27.6%)	19 (41.3%)

1. Valid cases: 58 men, 46 women.

A diagnosis had been coded in the casenotes of 110 subjects and was recorded for this study, but the casenote diagnosis was not subject to formal validation by standardised measures. Where more than one diagnosis was coded, the primary diagnosis was used. Thirty-six subjects (32.7%) were diagnosed as schizophrenic, 26 (23.6%) as alcoholic and a further 32 subjects (29.1%) were diagnosed as personality-disordered. Relatively few subjects, nine (8.2%), received a primary diagnosis of depression. Of the 13 subjects transferred to hospital from prison, seven (53.9%) were schizophrenic. A breakdown of diagnostic data by sex is given in Table III.

TABLE II
Diagnosis by sex[1]

	Men	*Woman*
Schizophrenia	16 (25.8%)	20 (41.7%)
Depression	3 (4.8%)	6 (12.5%)
Mania	0 (0.0%)	1 (2.1%)
Alcoholism	22 (35.5%)	4 (8.4%)
Personality disorder	16 (25.8%)	16 (33.3%)
Organic	2 (3.2%)	0 (0.0%)
Other	3 (4.8%)	1 (2.1%)

1. Valid cases: 62 men, 48 women

Excluding the use of benzodiazepines for night sedation, 82 subjects (72.6%) were treated with drugs and eight (7.1%) received ECT. The rest received milieu therapy with or without a benzodiazepine night sedative. Of the eight subjects (four women and four men) who received ECT, five had a primary diagnosis of depression and two others (one alcoholic, one personality-disordered) had attempted suicide prior to admission and were suicidal on admission. The other subject had a paranoid psychosis which was not diagnosed as schizophrenia.

Nineteen women (54.3%) were noted in medical or nursing notes as co-operating poorly with treatment, compared with 19 men (31.7%). Women were significantly more likely to co-operate poorly with treatment than men ($P = 0.05$). Furthermore, 23 women (46.0%) took their own discharge, compared with 13 men (21.0%); women were significantly more likely to discharge themselves from hospital than men ($P < 0.02$).

Sixty-three subjects (36.8%) were considered to have an improved mental state on discharge, while 48 subjects (43.2%) had not shown improvement. Follow-up was arranged for 35 subjects, of whom 17 subsequently attended.

In general, the hospital-based social workers attached to each consultant firm were involved in facilitating the after-care arrangements for the subjects who had a planned discharge. During the period covered by this study there was only one small psychiatric after-care hostel in the vicinity of the hospital under study and there were no group homes nearby. Of necessity, most subjects would be referred to voluntary agencies such as the Salvation Army for accommodation after discharge.

TABLE III
Physical illnesses present in the subjects

Sex	*Illness*	*Number of subjects*
Male	Epilepsy	4
	Tuberculosis	2
	Ischaemic heart disease/ chronic bronchitis	1
	Alcoholic gastritis	1
	Deep vein thrombosis	1
	Hypertension	1
Female	Carcinoma breast	1
	Pyrexia of unknown origin	1
	Epilepsy	1
	Buttock abscess	1
	Vaginal discharge/pelvic inflammatory disease	1
	Oedematous legs (? cause)	1
	Diarrhoea	1

Discussion

Despite the limitations imposed by undertaking a retrospective survey from casenotes, the results of this study correlate well with other studies of the destitute. The typical male subject in this study is aged 40, and single with no children. A significant proportion of the subjects are of Irish or Scottish origin. The fact that just under a half of all subjects were separated from their parents in childhood is similar to findings by Edwards *et al* (1966) and Priest (1976). The finding that nearly half the subjects had been in accommodation within a week of admission and only a third had been living rough, substantiates the clinical impression that NFA subjects often present to emergency hospital services when their accommodation has been lost. This is not to say that all homeless people behave in this way, as there is little doubt that many, including those who are ill, avoid all helping agencies completely.

Edwards *et al* (1966) noted that skid row alcoholics have often been in the merchant services and in this study 21 men had been in the armed or merchant services, although the contribution of conscription to this figure cannot be evaluated from the data. Of more interest is the finding that seven women had attempted nurse training. It may be that this group, having experienced emotionally impoverished childhoods, sought a sheltered, hierarchically determined environment similar to that provided by the armed or merchant services for men. Presumably all but one of the women were unable to cope with the emotional and intellectual demands made on them during the training.

Many subjects in this study had a history of previous periods in hospital and/or prison; these findings were similar to those of Berry & Orwin (1966). The use of Section 136 to admit many of the subjects, particularly women, is noteworthy. Szmukler *et al* (1981) reviewed all compulsory admissions in a London borough and found that NFA patients were over-represented among those on sections. They found that Section 136 patients were younger than those on other sections, often male and with a short episode of disturbance prior to admission. These patients often had brief admissions, and presented a nursing problem. They were also likely to abscond, a finding previously described by Sims & Symonds (1975). There are suggestions in the literature that NFA personality-disordered patients often know how to secure an admission (Berry & Orwin, 1966), and this may be particularly true of Section 136 patients (Szmukler, 1981). The finding that most subjects in this study were admitted through the emergency clinic is not a surprising one. Lim (1983) notes in a survey of the Maudsley Hospital emergency clinic that use of emergency services are often the only way that NFA patients can get help.

The actual determinants of the admissions for all patients were not specifically elicited in this study, but a third of all subjects were psychotic (i.e. deluded or hallucinated) and by definition were suffering from severe mental illness. The patients who were admitted on Section 136 had generally shown marked behavioural disturbance prior to admission. Patients fell into three main diagnostic categories, namely, schizophrenia, personality disorder and alcoholism, a feature in common with all other studies in this field.

When comparing the NFA men and women, the findings of this study appear paradoxical. The women appeared socially more stable than the men prior to admission, a finding similar to that of Laidlaw (1956) and of Digby (1976). Women were more likely to have been married, to have had children and to have remained in contact with their families. Furthermore, proportionally fewer women had been in prison than men. However, at the time of admission, women were more likely than men to have been referred by the police on a Section 136, and they co-operated less well with treatment and were more likely to discharge themselves. The comparison of diagnoses of the men and women (Table III) shows that proportionally more women were schizophrenic than men, and that more men were alcoholic, but this does not appear to provide an answer for all these differences. Social and attitudinal explanations should also be considered.

It is possible that people dealing with destitute women are prepared to tolerate a greater degree of behavioural disturbance than they would from a similar group of men. This could explain why the women were more likely to have remained in contact with their families and were less likely to have been in prison. However, this does not explain why significantly more women were referred to hospital by the police and why more use was made of Section 136 in the case of the women, as the men and women admitted on this section seemed equally disturbed, and similar percentages of the men and women admitted on this section were schizophrenic.

It is interesting to question whether the police perceive similar disturbed behaviour by men and women differently, or indeed handle it differently. The study was not designed to answer this question and there certainly seems little difference between the men and women admitted under Section 136. It is possible, however, that the police are more likely to perceive a woman behaving strangely as 'sick' and initiate a hospital disposal in circumstances where a man is likely to be charged and remanded to prison. Indeed, 10 out of 63 men (15.9%) in this study were transferred to hospital from prison, whereas three out of 50 women (6.0%) were similarly transferred. It is therefore possible to suggest that the women who become NFA and get admitted to hospital are a more disturbed group than NFA men who get admitted to hospital, for two reasons. Firstly, in this study, proportionally more women than men were schizophrenic and secondly, many disturbed men may have ended up in prison. These suggestions could explain why the women's admissions appear to have been less satisfactory than those of the men.

The availability of money for rehabilitation facilities is obviously linked to the economic health of the country as well as to the prevailing political climate. The deteriorating economic climate of the 1970s seems not to have affected the numbers of NFA admissions to the index hospital during the period under study. NFA admissions were in double figures from 1971 to 1975 inclusive, but only reached double figures in one subsequent year under study. It is sad to note the dearth of group home and small hostel accommodation during the 1970s, in an Inner London teaching district which has been a traditional haven for many destitute men and women. Unfortunately this situation has not changed in the 1980s.

Acknowledgements

This work was submitted in partial fulfilment of the requirements of the MPhil degree of the University of London.

I am grateful to the consultants of the Department of Psychiatry at the London Hospital for allowing me access to the patients' casenotes. Dr J. R. W. Christie Brown provided invaluable help throughout the course of this study and Dr G. Dunn gave helpful statistical advice. I also thank Professor R. G. Priest for his comments on the study.

Tics and Heredity
A Study of the Relatives of Child Tiqueurs

D. M. ZAUSMER and M. E. DEWEY

The limited literature on the pedigrees of tiqueurs, including those with Gilles de la Tourette's syndrome, is reviewed. Most statistical analyses have been restricted to affected family members without specifying the unaffected ones. The present statistical analysis of a series of child tiqueurs, including 91 probands and 1293 first- and second-degree relatives, 46 of whom were tiqueurs, predicts the odds on being a tiqueur for individuals, and establishes how those odds are affected by certain explanatory variables using log-linear models. The data do not confirm a familial pattern beyond reasonable doubt, but if the suggested prevalence of tics in the population is 10% then the figure for parents is large enough to support a familial hypothesis. The pedigrees do not indicate a simple mode of genetic transmission. Further research is needed to confirm that there is a connection between childhood tics and Gilles de la Tourette's syndrome, to establish that the predisposition to tics is familial, and, if so, whether there is a complex genetic mechanism involved, or some other environmental aetiology so far undisclosed.

Throughout the literature on tics and Gilles de la Tourette's syndrome (henceforth referred to as Tourette's syndrome) there are innumerable case-reports containing family histories of members with tics, but few large-scale investigations of the pedigrees of child tiqueuers have been published (Mahler *et al*, 1945—34 cases; Zausmer, 1954—96 cases; Torup, 1962—220 cases; Corbett *et al*, 1969—180 cases). The modest literature on the familial nature of Tourette's syndrome and multiple tics is summarised by Kidd *et al* (1980). There are even fewer genetic studies and these relate to patients with Tourette's syndrome (Shapiro *et al*, 1978; Friedhoff & Chase, 1982). It is evident that the debate regarding the inheritance of tics continues. Shapiro *et al* (1972) investigated 34 patients with Tourette's syndrome and found no relationship between this disorder and a family history of tics; they concluded that genetic factors were not involved in the aetiology. This view was later modified (Shapiro *et al*, 1978) and they recorded that the syndrome occurs with increased frequency in relatives of the patients but that there is no discernible pattern of transmission. Moldofsky *et al* (1974) studied 15 patients with Tourette's syndrome and found nine who had at least one first-degree relative with tics; although no specific sex-linked dominant forms of inheritance were seen, a recessive mode of genetic influence was suggested.

A valuable contribution is that of Kidd *et al* (1980), who collected data on Tourette's syndrome and tics for relatives of 75 patients with the syndrome as part of a pilot questionnaire survey. The frequencies of Tourette's syndrome and/or tics among relatives were significantly heterogeneous in a familial pattern. This suggests (a) that the disorder is transmitted, with tics alone being a milder manifestation, and that this severity difference is a threshold phenomenon related to transmission, (b) that the sex difference in prevalence is real because it was found among relatives of both male and female probands, and (c) that the sex difference is related to transmission as a threshold effect since female probands, although less common than male probands, had a higher proportion of affected relatives. These pilot data provided evidence for the transmission of Tourette's syndrome and can be qualitatively explained by a genetic model of transmission. Kondo & Nomura (1982) agreed that these conclusions are fundamentally compatible with their own; however, in an investigation of 43 patients (41 Japanese and 2 Koreans) with Tourette's syndrome they found that among a total of 428 known relatives only nine (2%) showed evidence of Tourette's syndrome or chronic multiple tics. Kidd & Pauls (1982) discussed the genetic hypotheses for Tourette's syndrome and chronic multiple motor tics. They analysed a combined sample containing 421 first-degree relatives of 118 probands using three different models, and concluded that such models can explain the complex transmission pattern observed in families of patients with the syndrome, but that discrimination between the quite different models for the inheritance of a complex trait is extremely difficult if the only information available is the trait phenotype.

Other recent genetic research includes the study of HLA typing and red blood cell choline levels in Tourette's syndrome (Comings *et al*, 1982*a*,*b*). Reporting the former investigation, the authors state that the available data are compatible with a two-locus hypothesis, with a major gene for Tourette's syndrome and a modifying gene which decreases the threshold for penetrance. However, their findings from a preliminary study of HLA A and B antigens in 12 patients with Tourette's syndrome and their family members do not point to a predominant HLA A or B type associated with the disease. In the latter investigation, to determine whether red blood cell choline could be used as a marker for Tourette's syndrome, 16 patients and their relatives were studied. The findings confirmed an earlier observation of raised levels in Tourette's syndrome, which seem to be genetically controlled. The authors conclude that although the elevated levels do not appear to be a direct marker for Tourette's syndrome, they may be a marker for genetic or environmental influences that serve to enhance the expression of the major gene(s) for the syndrome.

There is therefore a diversity of hypotheses to explain the familial predisposition to these disorders and a paucity of data to support a genetic theory. In view of this we carried out further statistical analysis of the first author's research findings relating exclusively to child tiqueurs (Zausmer, 1954), both for its historical interest and because of the hypothesised connection between chronic multiple motor tics and Tourette's syndrome (Kidd & Pauls, 1982).

Historical background

During the period 1952–1954 the first author studied 96 child tiqueurs (63 boys and 33 girls) as a research project at the University of Liverpool. The sample is described elsewhere (Zausmer, 1954). In 32% of the families there were relatives who had had tics. There were no recorded members exhibiting features of Tourette's syndrome. The figure of 32% tallies with that of Torup (1962), who found a family history of tics in 30–40% of close relatives, but not with that of Corbett *et al* (1969) who noted it in only 10% of cases. Interestingly, Shapiro *et al* (1978) found that the percentage of family members with tics in their sample of Tourette patients was 34.5.

In 1965 the first author had the good fortune to interest Dr C. A. Clarke (at that time Reader in Medicine at the University of Liverpool) in the analysis of the pedigrees of the research sample of tiqueurs to determine if it was possible to explain the familial transmission of tics on a genetic basis. Clarke summarised his findings as follows (5 of the 96 pedigrees were omitted from the analysis because of insufficient background information). (a) There was a highly significant sex difference (87 males as against 50 females). (b) The impression of family size was that it did not differ significantly from that of the general Liverpool population. (c) Most of the tiqueurs were not the first or last born in the families (see also Table V). (d) The mean ages of the parents (where the ages of both were known) at the birth of the propositus were fathers 31.3 (s.d. 5.7) and mothers 28.3 (s.d. 5.1) years, which was probably typical for the population.

Clarke concluded that no simple genetic system could explain the pattern of cases, assuming they were a homogeneous group. (If they were clinically heterogeneous, the numbers in each class would be too small for statistical analysis). The nearest approach to simplicity would be to invoke a single dominant gene with incomplete penetrance, but the lack of penetrance would be so great as to make it valueless from a practical point of view (56 out of 91 tiqueurs had no family history of tics). Clarke then considered the possibility of a single dominant gene plus a multifactorial background. One might expect that where the sex of the tiqueur was the unusual one (that is, female) there would be more likelihood of her parents (mother) or offspring being affected than would be the case in a male tiqueur. There was no evidence that this was so. Thus, where the propositus was a female there was a positive family history in 11 cases and a negative one in 18 cases. Where the propositus was a male there was a positive family history in 24 cases and a negative one in 38 cases.

This was not statistically significant and our more recent analysis described below confirms this finding. (For this analysis illegitimate births, adoptions and incomplete family histories were omitted.)

Method

Wider availability of more advanced statistical techniques since 1965 has meant that we are now able to explore the pedigree data in more detail. As mentioned above there are 91 families with sufficient detail for us to be able to include them in the analysis: 62 of these index cases were boys and 29 girls. We have at least some data on 1533 relatives of these tiqueurs: 178 siblings, 36 half-siblings, 178 parents, 342 grandparents, and 799 siblings of the parents. We have used the following potential explanatory variables: subject's own sex, sex of the index case, age (classified into five groups — 0–4, 5–9, 10–14, 15–19 and 20+ years), relationship to the index case (sibling, half-sibling, parent, grandparent, parental sibling), and parental type (whether or not at least one parent of the tiqueur was affected). Examination of the raw data revealed that some of our 1533 cases had missing values on so many of these variables that including them in the analysis would have been impractical, and the results that follow are based on 1293 cases with almost complete data: 178 siblings, 22 half-siblings, 176 parents, 342 grandparents, and 575 parental siblings. As can be seen, the parental siblings are the group for which data are most often missing on the main explanatory variables. Among the 1293 relatives in our main sample there were 46 who were tiqueurs, 25 males and 21 females.

Expected frequencies calculated from the model with sex and degree of relationship included

In Table I we present the raw frequencies broken down by degree of relationship and sex.

Clarke's preliminary analysis (reported above) followed the practice of much of the literature on tics by examining the data in terms of number of families affected. As Wilson *et al* (1978) point out, the fact that a certain proportion of families have at least one affected member tells us relatively little unless we know the size of families concerned. We have therefore analysed the family data using the information on individuals; our prevalence figures may thus be compared with population values directly. We have concentrated on predicting the odds on being a tiqueur for individuals, and analysing how those odds are affected by the explanatory variables. We have used log–linear models (Bishop *et al*, 1975) to examine the effects of the explanatory variables on the odds. The main advantage of this more complex analysis is that we are examining all the possible explanatory variables simultaneously. This means that when we claim that a variable is an important predictor of the odds on being affected by a tic, we are examining the effect of that variable over and above the effect of the other explanatory variables in our model, and we are also able to examine interactions between explanatory variables.

Two of the variables give rise to problems in fitting, parental type and age. Both of these variables have a strong but artefactual association with degree of relationship. In the case of parental type it makes no sense to use this variable in the analysis of the parent data, but we have examined it for the other sets. We wished to include age as an explanatory variable, not because of its scientific interest, but to deal with the problem that younger relatives would not have passed completely through the period of risk and so would show a lower prevalence of tics than a group which was beyond a critical age (hence the choice of age strata). For this reason we only considered age as an explanatory variable for the sibling data. In order to deal with the problem of these two variables we conducted four separate preliminary analyses looking at the different degrees of relationship separately, rather than performing one large analysis. In each of these we fitted a model and then iteratively removed terms from the model, starting from the highest order interactions. Only non-significant terms were deleted, and all lower order terms forming a significant interaction were retained. This is essentially the method outlined by Brown (1976). When it became clear in these analyses that neither parental type nor age would need to be included in the final model, the motivation for the separate analyses disappeared, and we then combined all the data and proceeded with a single analysis using the same approach.

The use of log–linear models makes our method comparable with the methods used by Kidd *et al* (1980). We have used the algorithms of Haberman (1973) and Lustbader & Stodola (1981) to perform the fitting.

Results

The preliminary analyses revealed that age and higher order interactions involving age were not significant even for the

TABLE II

Proportion of tiqueurs among siblings classified by age

Age	*Tiqueurs*	*Non-tiqueurs*	*Proportion*
0–4	1	49	0.02
5–9	3	43	0.07
10–14	3	38	0.08
15–19	0	19	0.00
20+	2	19	0.11
All	9	168	0.05

(one sibling omitted—missing age)

siblings. This can perhaps be attributed to the small number of tiqueurs in each age group. There is in fact a deficiency of tiqueurs in the younger groups (Table II) but this fails to reach significance in any of our analyses.

Parental type

Parental type and higher order interactions involving parental type also failed to reach significance in the analyses of siblings, grandparents and parental siblings combined. The results are presented in Table III.

TABLE III

Proportion of tiqueurs classified by parental type

Parental sibling		
Tiqueurs	0	5
Total	119	454

Sex and degree of relationship

Sex of the proband and higher order interactions involving sex of proband failed to reach significance in any of the analyses conducted. The final simplest model which provides a good fit to the data is one in which the probability of developing a tic is seen as dependent on degree of relationship to the index case and possibly on an interaction between degree of relationship and sex of the relative. The dominant effect is that of degree of relationship (χ^2 test for including degree of relationship in the model $= 54.45$; d.f. 4, $P < 0.001$). There are more tiqueurs among the parents of the index cases, and also among the siblings. There is some suggestion in the data of an interaction between sex and degree of relationship (χ^2 test for including the interaction when degree of relationship and sex are already in the model $= 9.05$; d.f. 4, $0.05 < P < 0.1$). From inspection of the expected values calculated from the model with degree of relationship and sex included it is clear that the main cause of this apparent interaction is the different sex ratio for siblings. Just fitting sex and the component of the interaction due to siblings was significant ($\chi^2 = 6.15$, d.f. 2, $P < 0.05$). Our own feeling is that this interaction will probably not turn out to be a substantive finding, but for completeness we present the χ^3 values and the odds in Table IV.

Odds on being a tiqueur for first- and second-degree relatives

Table IV contains a summary of the two final log–linear models which we have considered. The results are in the form of the odds on being a tiqueur (the probability of being a tiqueur divided by the probability of not being a tiqueur). The table gives the odds for each degree of relationship, and also shows the relative odds (relative to siblings) for the other categories. These can then be interpreted as the increase in relative risk for each degree of relationship. So, for example, we see that the odds for parents are more than three times greater than for siblings. (The odds are conditional on the index case having been identified in the family; they cannot be interpreted as estimates of population risk.)

Birth order

In addition to the other variables mentioned we have some information on the birth order of some of the relatives. Many of the cases have missing data on this variable, but we do have usable information on a subset of the data. Table V shows the relationship between birth order and being affected by a tic for the 418 individuals for whom we have sufficient data. Adding this variable to the log-linear model reveals that there is no relationship between birth order and being affected by a tic, and there is no interaction between birth order and the other variables.

Some characteristics of the pedigrees

Direct transmission through three generations was reported in three families. In one case the male proband had an affected mother and maternal grandmother; in the second case the male proband had an affected mother and maternal grandfather; and in the third case the male proband had an affected father and paternal grandfather.

Of the 28 probands with an affected first-degree relative, 11 indicated at least one other relative who was affected. Within the 20 male probands there were eight instances of the disease being transmitted from an affected male to another male, and the affected relatives were both male and female.

TABLE IV

Odds estimated from log-linear models using degree of relationship and degree of relationship and sex

	Odds on being a tiqueur for a given degree of relationship: likelihood ratio $\chi^2=9.33$, d.f. 9	
Degree of relationship	*Odds*	*Odds relative to sibs*

	Male odds			*Female odds*	
	Odds	*Odds relative to sibs*	*Multiplier for females*	*Odds*	*Odds relative to sibs*
Sibling	0.094	—	0.126	0.012	—
Parent	0.150	1.592	1.211	0.023	1.928
Grandparent	0.019	0.200	1.211	0.003	0.243
Parental sibling	0.008	0.085	1.211	0.001	0.103

TABLE V

Proportion of tiqueurs classified by birth order

Birth order	*Non-tiqueurs*	*Tiqueurs*	*Total*
First	91	10	101
Second	91	8	99
Third	77	5	82
Fourth	54	1	55
Fifth or later	73	8	81
Total	386	32	418

There were three cases of tics in both sides of the family.

Among 91 probands there were 21 with one parent affected and two with both parents affected. Only three of the probands with an affected parent had affected siblings. Of the affected siblings, five cases came from a family in which neither parent was a tiqueur.

Discussion

The reliable identification of tiqueurs among relatives of patients is fraught with difficulties. The majority of children's tics disappear before puberty and, as in the case of enuresis, the symptom is frequently forgotten or suppressed when the history is recorded many years later. In spite of careful history-taking it is likely that many relatives who had had tics in childhood were missed. The total familial incidence was probably much higher than the figures obtained.

In the absence of trustworthy estimates of the prevalence of tics in the population it is difficult for us to justify calculating coefficients of hereditability from our data, and indeed we cannot demonstrate beyond reasonable doubt that the data show a familial pattern. If we assume that the prevalence in the population is 10%, as Wilson *et al* (1978) estimate, then the figure for parents is large enough to support the suggestion that tics are familial in origin.

Our results do not appear to indicate any straightforward genetic hypothesis. If the transmission were a simple recessive one we would have expected that the frequency of occurrence of tics would have been higher for siblings than for parents, whereas we found the reverse, even allowing for the fact that the siblings had not yet passed completely through the period of risk.

If there were two sorts of tics, hereditary and environmental, it would seem plausible that we would find differences between the families when we compared members of families where at least one parent of the child was also affected with members of the other families. In fact we found no such differences.

If transmission were multifactorial, with different thresholds for males and females, we would expect that probands of the more rarely affected sex would have more affected relatives. Our current analysis has shown that the relatives (male or female) of the girls are no more likely to be affected, thus confirming for individuals Clarke's original analysis of families. It thus seems unlikely that a single dominant gene with a multifactorial transmission can account for the results.

TABLE VI

Comparison of the numbers of relatives affected in the present study with those in the Tourette syndrome families studied by Shapiro et al (1978)

[1] Ratio of number of affected relatives to number of index cases.

The figures do not sum in columns because some patients had more than one affected relative

If there were a dominant single gene transmission (even with a reduced penetrance) we would expect to find many pedigrees with direct transmission through three generations. In fact we found only three instances in our sample. The occurrence of male parents of male probands effectively rules out the possibility of the inheritance of tics as an X-linked characteristic.

In Table VI we present a comparison of our findings with those of Shapiro *et al* (1978). They studied the relatives of 139 Tourette syndrome patients and present their results in terms of number of families with affected relatives. We have already argued that this is not the method of presentation of choice, but for comparative purposes we present our own data in the same format. Exact comparison is difficult without information on the number of relatives not affected in each category, but it is clear that the two sets of figures show good agreement. As is the case with our study, Shapiro and his colleagues found a substantial sex difference among patients, but not among relatives.

A comparison of the significant findings of the present study with those of Kidd *et al* (1980), whose sample included relatives of adults affected by Tourette's syndrome, indicates marked differences. They found own sex, sex of index case and parental type to be significant but we did not. Our own study showed that degree of relationship was significant, and that there was a possible interaction between sex and degree of relationships, but Kidd *et al* did not examine these variables. We have no convincing explanation for the resemblance between our findings and those of Shapiro *et al*, or for their joint dissimilarity from those of Kidd *et al*, other than that there are of course considerable differences between the populations, sampling methods and statistical techniques employed.

Acknowledgements

We are indebted to Sir Cyril Clarke, Emeritus Professor of Medicine, University of Liverpool for the original analysis of the tiqueur pedigrees, and for his renewed interest in the initial preparation of this paper. We also wish to thank Christine Nutting and Maureen Walton for technical assistance with the preparation of the data and manuscript.

Late Paraphrenia or the Paraphrenias?

A Descriptive Study with a 10-year Follow-up

N. L. HOLDEN

This study describes 47 cases of paranoid psychosis occurring for the first time after the age of 60. Cases were drawn from the Camberwell catchment area and were followed up for 10 years or until death. The clinical picture of patients showed few differences from those described in earlier studies. Subgroups are described with contrasting clinical features and differing outcome. The findings suggest that late paraphrenia is a heterogenous syndrome giving the appearance of a spectrum of overlapping conditions with paranoid delusions.

Roth (1955) defined late paraphrenia as "a well organised system of paranoid delusions with or without auditory hallucinations existing in the setting of a well preserved personality and affective response". For their later study Kay & Roth (1961) modified the definition of paraphrenia to be "a suitable descriptive term, without prejudice as to aetiology, for all cases with a paranoid symptom complex in which signs of organic dementia or sustained confusion were absent and in which the condition was judged from the content of the delusional and hallucinatory symptoms not to be due to a primary affective disorder".

Post (1966) used wider criteria for his study of *Persistent Persecutory States in the Elderly* in which he included all paranoid states arising after 60 years of age which were unrelated to affective illness. Although up to 30% of his cases had definite or possible signs of organic brain damage, he suggested that "no support was found for the existence of a specifically organic or 'symptomatic' chronic paranoid psychosis". Kay (1972) suggested the existence of symptomatic schizophrenias in the elderly, similar to the cases occurring in the younger patients studied by Davidson & Bagley (1969), and found it likely that these cases with organic changes should make up a proportion of cases of late paraphrenia. In contrast, Grahame (1984), looking at the incidence of first-rank symptoms in a group of paraphrenics, treated the group as homogeneous, concluding that their nature was that of schizophrenia.

In the last two decades, concepts of nosology and aetiology have changed, with a greater awareness of the need to respect the complexity of interaction between organic and functional components in the elderly patient. The American Psychiatric Association's DSM-III (1980) has introduced a radical widening of the concept of organicity with organic delusional syndrome and organic affective syndrome as organic equivalents to functional schizophrenia and affective disorder. The homogeneity of disease entities in the elderly has been eroded, and replaced by the concept of a spectrum of heterogeneity. Studies such as those by Jacoby *et al* (1981), which described a subgroup of elderly depressives with CAT scan changes and a differing prognosis, and by Bergmann (1971), which identified a group of late onset neurotics with a distinct prognosis, are examples of this.

This study was carried out as a fresh look at paranoid states in the elderly, seeking to apply the current concepts of psychiatric nosology to patients clinically recognised as late paraphrenics. The issues of homogeneity and organicity were examined and a description of subgroups in relation to clinical features, aetiology and outcome was attempted.

Method

Using the Camberwell Register and the Maudsley Hospital Case Register, the case notes of all new cases diagnosed as functional paranoid psychoses over the age of 60, presenting in the years 1971 to 1975, from the Camberwell Area, were reviewed. Three cases with a history dating back before the age of 50 were excluded, as were five misdiagnosed cases which were felt to be secondary to dementia or acute toxic confusional states. These diagnoses were made clinically on the basis of the mental state and physical examinations, the history and investigations. Cases with a mental test score of 20 or less (out of 43) on the Gresham Ward Questionnaire (GWQ), (Notes on Eliciting and Recording Clinical Information, 1973), a routinely used questionnaire assessing orientation, general knowledge and memory, were excluded.

Forty-seven cases of persistent paranoid psychosis were identified and were followed up for 10 years or until death, using all available records (hospital, general practice, social services and the Register of Deaths) and by interviewing the next of kin and the survivors. Interview was possible in 14 of the 20 cases alive at 10 years and the remaining six had died between the end of 10 years and follow-up. Information from the clinical records was collected on the patient's background, initial presentation and outcome (including the nature and course of further illnesses). The patient's interview was carried out using an open-ended clinical interview, covering the current mental state, and the history whenever possible.

Reviewing the initial presentation of the 47 cases, five cases were felt to be due to depression with paranoid delusions (an 'affective' group) with clinical features of depression and holothymic delusions. A further five cases formed a 'symptomatic' group in that they appeared to have an association with chronic physical illness (syphilis; myeloproliferative disease; carcinoma of prostate with stilboestrol therapy; chronic heart failure and pernicious anaemia with neurological involvement). This left 37 cases, fulfilling Roth's criteria (1955) for late paraphrenia, as well as Post's (1966) criteria for 'persistent persecutory states in the elderly'. Statistical analysis of the data from this group was carried out to find associations between presentation, background and outcome variables.

These 37 paraphrenics were then further divided on the basis of organicity. Thirteen cases, progressing to dementia within 3 years, according to their clinical state and mental test scores, were incorporated into an 'organic' group, leaving 24 cases with 'functional' paraphrenia, fulfilling Kay & Roth's (1961) criteria.

The data from the 'organic' group was compared with that of the 'functional' group, and a search was made for significant associations between variables within the groups.

This group of 'functional' paraphrenics was retrospectively divided into further subgroups. Five cases formed a 'schizoaffective' group (with at least one subsequent episode being diagnosed as affective disorder), and the remaining 19 cases were divided by the presence or absence of Schneiderian first-rank symptoms into a 'schizophreniform' group (10 cases) or into a 'paranoid' group (nine cases). This created six subgroups of the original 47 cases of paranoid psychosis (schizophreniform, paranoid, schizoaffective, organic, symptomatic and affective). Significant associations and differences between the variables of these subgroups were investigated using the χ^2 test and t-test.

Results

All the cases presented over a 5-year period and were drawn from a population of 28,195 persons over 60 in the Camberwell area. Therefore the incidence for the wider group of paraphrenics ($n=37$) is 26 new cases per 100 000 at risk per year, whilst the incidence for the definitely 'functional' group ($n=24$) is 17 new cases per 100 000 per year.

Comparing the 'functional' group of paraphrenics ($n=24$) with the 'organic' group ($n=13$), there were no significant differences regards the characteristics at presentation except for the presence of lower GWQ scores in the latter group ($P<0.001$). The mean ages were 68.5 years (range 60–79) and 72.5 years (range 60–82) for the 'functional' and 'organic' groups respectively, and the sex ratios, male to female were 1:7 to 1:3. There was a preponderance of patients from the lower socioeconomic groups, and 46% of both groups were socially isolated (no relatives or friends giving regular social contact or support).

A family history of psychiatric illness (a third schizophreniform) was found in 42% of the 'functional group' and 23% of the 'organic' group. Deafness, visual impairment and physical disability (as noted clinically) were found in 25%, 25% and 17%, respectively, of the 'functional' group and 46%, 46% and 15% of the 'organic' group. 42% of the 'functional' group reported major disturbances of their childhood environments (such as separation from their parents by death or divorce, or adverse relationships with one or more parents or step-parents) compared with 31% of the 'organic' group, and precipitants to the illnesses were felt to have been present in 38% and 23% respectively ('precipitants' included all severe stresses temporally related to the onset of the illness).

All patients had, by definition, catathymic delusions which were not felt to originate solely from the prevailing mood. First-rank symptoms were present in 63% of the 'functional' group and 31% of the 'organic' group, whilst auditory, visual and somatic hallucinations were present in 83%, 13% and 8% of the former group, and in 62%, 38% and 8% of the latter group, respectively.

There were significant differences in the outcome of the two groups. After the index admission, 84% of the 'functional' cases returned home, compared with 46% of the 'organic' cases ($P<0.05$), the remainder in each case going to residential care. Of the 'functional' group, 33% had full recovery with insight and 21% without insight, whilst none of the 'organic' cases recovered full insight, and only 8% made a full recovery without insight ($P<0.05$).

By definition, the 'organic' group started dementing within 3 years, and all were institutionalised during the 10-year study period, compared with only 25% of the 'functional' group. In spite of no significant age difference, the survival of the 'functional' group was significantly better than the 'organic' group at 10 years ($P<0.05$) although there was no difference at 5 years. The 'functional' group had an average of 1.6 episodes (range 1–5) whilst the 'organic' group had a mean of 2.4 episodes (range 1–7) (non-significant).

Looking for associations within the 'functional' group, it was found that significantly fewer of those with first-rank symptoms had deafness ($P<0.05$), and that those with major disturbances of their childhood were less likely to have a precipitating stress before their illness ($P<0.05$). Those with childhood disturbances also had an increased chance of institutionalisation and survived less time at home ($P<0.05$). The presence of auditory hallucinations predicted a good response to treatment ($P<0.05$).

In the wider group of paraphrenics ($n=37$) made up of the 'functional' and 'organic' groups combined, it was found that increasing age was significantly associated with increased prevalence of deafness ($P<0.05$) and visual hallucinations ($P<0.05$). Those with a GWQ score of less than 30 had significantly less childhood environmental

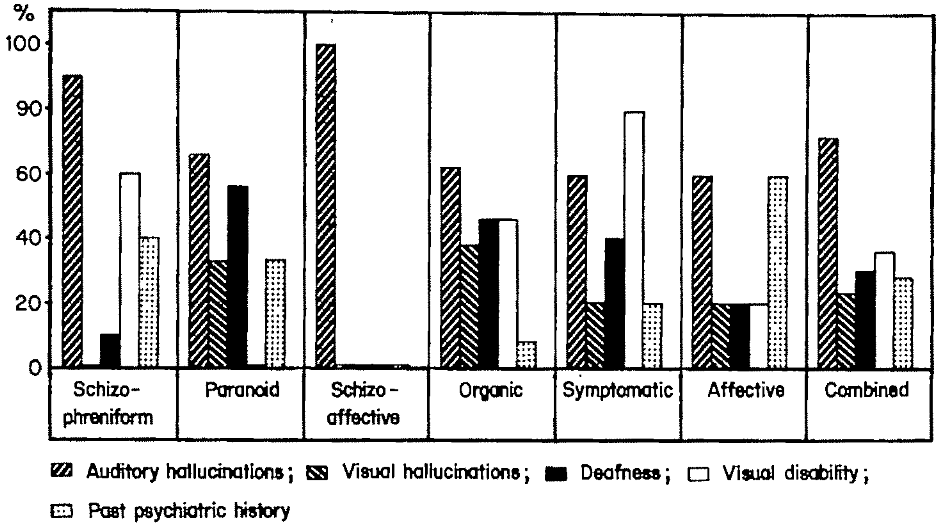

FIG. 1 Characteristics of subgroups at presentation.

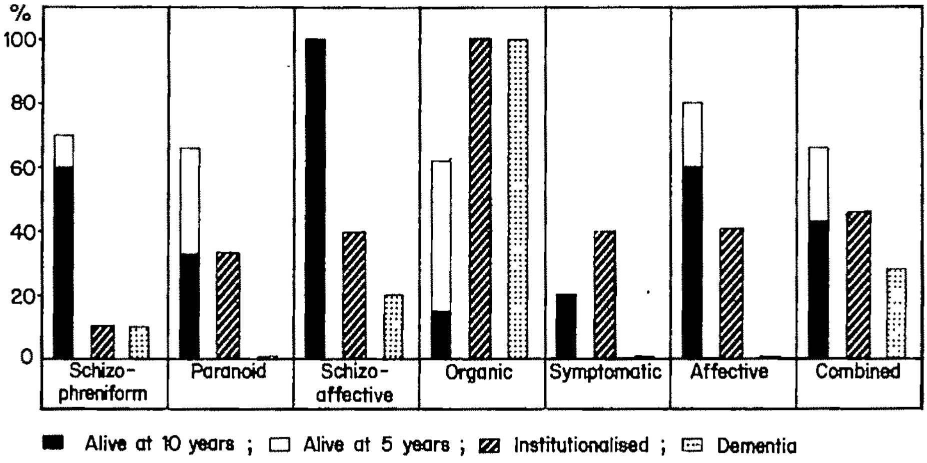

FIG. 2 Outcome of subgroups during the 10-year follow up.

disturbance ($P<0.05$) and significantly fewer males had such childhood upsets ($P<0.05$). Patients with a family history of psychiatric disorder had significantly less visual disability ($P<0.05$). The presence of first-rank symptoms was significantly associated with the absence of deafness ($P<0.01$). Social isolation was associated with increased prevalence of deafness ($P<0.05$).

Older age was associated with an increased rate of death by 10 years ($P<0.01$), increased institutionalisation (especially early) ($P<0.01$) and a worse response to medication ($P<0.05$). A GWQ score between 20 and 30 (out of 43) was associated with dementia ($P<0.001$) and institutionalisation ($P<0.01$) whilst visual hallucinations predicted higher mortality ($P<0.05$). Those with a previous history and those who developed insight following their index admission had better survival at home ($P<0.05$).

Comparing the six subgroupings, (schizophreniform, paranoid, schizoaffective, organic, symptomatic and affective) described above, the differences in characteristics on presentation are illustrated by Fig. 1, a histogram showing the percentage of patients with each symptom. (First-rank symptoms are not included as they are used to define the subgroups.) Similarly the outcome of the subgroups is shown in Fig. 2. The schizophreniform group showed less institutionalisation ($P<0.001$), more visual disability ($P<0.01$), fewer visual hallucinations ($P<0.05$), a better treatment response ($P<0.05$) and a better survival at 10 years ($P<0.05$). The paranoid group showed less visual disability ($P<0.01$), survived longer at home ($P<0.01$), had fewer children ($P<0.05$) and had a trend ($P<0.06$) towards having fewer episodes. The schizoaffective group had better survival to 10 years ($P<0.05$), surviving longer at home ($P<0.01$), had more frequently a good response to treatment ($P<0.05$) and had fewer children ($P<0.05$). The affective group with paranoid depressions had more children ($P<0.05$) and survived longer at home ($P<0.01$).

The organic group was associated with more visual hallucinations ($P<0.05$), a worse response to treatment ($P<0.05$), higher mortality by 10 years ($P<0.05$), and poor survival at home ($P<0.01$) with increased incidence of institutionalisation ($P<0.001$). The symptomatic group had more children ($P<0.05$), more visual hallucinations ($P<0.05$), greater visual disability ($P<0.01$) and higher mortality by 10 years ($P<0.05$).

The schizophreniform group has more first-rank symptoms than the paranoid group by definition, but in addition has significantly more visual disability ($P<0.04$) and less childhood environmental disturbance ($P<0.05$) than the latter group. Institutionalisation was greater in the organic group than the symptomatic group ($P<0.05$).

Discussion

Although this study suffers from the same limitations as other retrospective studies, the quality and thoroughness of the initial assessments were good. The demographic data, clinical features and outcome of the cases are in broad agreement with previous studies, showing that this is a representative sample of paraphrenics. The patients were drawn from the Camberwell catchment area of the Maudsley Hospital and can be expected to be a reasonably complete sample. Community surveys such as that by Kay *et al* (1964) concluded that other than a few 'chronic, mild or incipient forms' most major psychoses were known to the hospital services. The Camberwell area is typical of Inner London, and has a large Afro-Caribbean population. However, most of these are still of a younger age group, and only one West Indian female with paraphrenia was identified. The first admission age-specific rate per 100 000 was found to be between 17 and 26, depending on definitions used; rates similar to those quoted for 1966 by Kay (1972).

Studies of paranoid states in the elderly are partly hampered by the different criteria used in the previous studies. The differences between the concepts of 'late paraphrenia' (Kay & Roth, 1961), which excludes organic paranoid states, and 'persistent persecutory states of the elderly' (Post, 1966) which includes them, have not been clearly resolved. In this study, the narrower, 'functional' group ($n=24$) corresponds to 'late paraphrenia' whilst the wider group, including both 'functional' and 'organic' groups ($n=37$) corresponds to 'persistent persecutory states'.

In comparing the two elements, 'functional' and 'organic' of the wider group, it becomes clear that the two are indistinguishable on clinical characteristics at presentation, except for an increased likelihood of lower mental test scores in the 'organic' group. However, the 'organic' group has a significantly worse outcome in all respects. This is very much in line with the opinions of Kay (1972), but differs from Post's (1966) finding that there was no specific organic chronic paranoid psychosis.

Poor outcome, perhaps as a result of organicity, was predicted in the wider group ($n=37$) by old age, visual hallucinations, the absence of previous history and the failure to regain insight. Within the 'functional' group ($n=24$), with most organic elements excluded, good response to treatment was predicted by the presence of auditory hallucinations and increased institutionalisation was predicted by the presence of childhood environmental disturbances.

Looking at the associations within the wider group, there is a suggestion that there are endogenous, reactive and organic elements contributing to the clinical picture of the condition. A patient with a preponderance of one element, tended to show less evidence of the others. Hence patients with lower mental test scores at presentation (suggesting organicity) have significantly less childhood disturbance, whilst features indicative of endogenous elements, such as a positive family history and the presence of FRS are associated with significantly less visual disability and deafness respectively (possible reactive elements).

Similarly, looking at the associations within the 'functional' group, the reactive and endogenous elements can again be seen. First-rank symptoms remain associated with less deafness, and childhood disturbances are associated with significantly fewer precipitants.

The discussion above of endogenous, reactive and organic elements in the paraphrenic syndrome led to the division of the total sample into the subgroups. In this the schizophreniform group approximates most closely to late-onset endogenous schizophrenia, the paranoid group to reactive forms, whilst organicity plays a major role in the symptomatic and organic groups. These groupings are arbitrary, but nevertheless have some validity according to the significant differences between the groups, not totally explained by their criteria. However, in comparison, when the divisions suggested by Post (1966) and Kay & Roth (1961) were applied to this sample, they gave no significant findings whatsoever.

In short, this study gives some evidence that paraphrenia is not a clinically homogenous entity, and suggests that organicity (as perceived in DSM-III) can play a substantial role, with a different outcome for those who are older, those with slight decrease of mental functioning, and those with visual hallucinations. It also suggests that there may be value in looking at those cases with and without first-rank symptoms, and schizoaffective change. The study suffers from the problems of being partly retrospective, and from the fact that the initial assessment of cases is now 10 years out of date. It needs to be repeated prospectively, using a sample of paraphrenics diagnosed by structured interview assessment, and assessed with computerised tomography for brain density and ventricular-brain ratio. In such a study, heterogeneity might be illustrated more objectively by a cluster analysis revealing distinct clusters at various levels.

Acknowledgements

I would like to express my thanks to Dr K. Bergmann for his help and guidance with this study, and to Mrs P. Place for her secretarial help.

The Nithsdale Schizophrenia Survey

VI. Relatives' Expressed Emotion: Prevalence, Patterns, and Clinical Assessment

R. G. McCREADIE and A. D. T. ROBINSON

A review of all known schizophrenics ($n = 142$) in Nithsdale, Scotland, found 50% were living with relatives or friends. Of these, 32% had high contact with a relative showing high expressed emotion (EE); put another way, 87% of all Nithsdale schizophrenics were not living in a high contact/high EE family. Parents were more critical than spouses, and more showed emotional over-involvement. A retrospective review showed a trend, not of statistical significance, towards a higher admission rate to in-patient care in patients from high EE homes. Of relatives believed by a consultant psychiatrist to be neither critical nor hostile, 80% fell into the low EE category, but only 44% thought hostile or critical belonged to the high EE category; that is, the clinician had a wider view of high EE than the Camberwell Family Interview. Relatives' scores on a short patient-rejection scale were higher in high EE than in low EE relatives, but the wide scatter of scores suggested the scale could not be used to identify an individual relative with high EE.

Reports over 25 years from the MRC Social Psychiatry Unit in London have suggested the prognosis of schizophrenic patients discharged from hospital may depend on their living arrangements. Patients living with relatives who show high expressed emotion (EE) are more likely to relapse, especially if face-to-face contact between patient and relative is high and the patient is unprotected by maintenance antipsychotic medication (Brown *et al*, 1962, 1972; Vaughn & Leff, 1976). These findings have become of increasing clinical relevance in recent years as in both the UK and USA family therapy which includes education, relatives' groups and family sessions has been shown to reduce contact and lower EE, and thus substantially reduce relapse rates (Leff *et al*, 1982, 1985; Falloon *et al*, 1982, 1985).

Both the UK and USA studies examined patients in an urban setting. A study in Chandigarh, Northern India found different levels of expressed emotion (Leff, 1986); whether this was due to rural or cultural factors is not certain. The present study is the first to examine schizophrenics living in a rural area in the West. It is also the first to assess the *prevalence* of high EE in a community; in contrast with previous studies it does not confine itself to patients recently admitted to in-patient care. By assessing prevalence the amount of work likely to face a NHS clinician willing to embark on prophylactic family therapy can be estimated. The study also describes patterns of EE in different types of relative, and examines, retrospectively, rates of admission to in-patient care in patients living on their own, and with different categories of relative.

If clinicians are prepared to carry out family therapy they must be able to recognise high EE. EE is currently assessed by the Camberwell Family Interview (CFI), which cannot be used without specialised training and is time consuming; it is therefore not suitable for use in everyday clinical practice. Are there any shortcuts in the assessment of EE? The present study examines two possibilities, firstly an experienced clinician's hunch, and secondly a short 'patient rejection' scale administered to relatives by a community psychiatric nurse.

Method

Patients

Patients were drawn from Nithsdale, a rural, historically ancient and geographically discrete part of Dumfries and Galloway Region, Scotland. Those included were all in-patients, day-patients and out-patients of Crichton Royal Hospital, Dumfries, who on the census date (1 July 1985) had a firm case record diagnosis of schizophrenia and whose home address was in Nithsdale. Also, all general practitioners in the area replied to a questionnaire which identified other schizophrenics known to the practice and receiving treatment but not known to the hospital. The census identified 142 schizophrenics; as the population of Nithsdale is 56 000, this gives a point prevalence of 2.53

per 1000 of the total population. Sixty-eight per cent fulfilled the Feighner criteria for 'definite' or 'probable' schizophrenia (Feighner *et al*, 1972).

At the time of the census 20% were long-stay in-patients, 28% lived alone or in lodgings, and 2% lived with relatives under 18 years of age. Fifty per cent ($n=72$) were living with adult relatives or significant others and it was these on whom the present study focused. Forty nine per cent of such patients were male (mean age 42 years, s.d. 12 years, range 21-66 years; mean length of illness, as estimated from first psychiatric hospital contact, 14 years, s.d. 10 years, range 1-40 years) and 51% female (mean age 50 years, s.d. 13 years, range 27-79 years; mean length of illness 18 years, s.d. 12 years, range 2-48 years).

Scrutiny of case records identified all Nithsdale schizophrenics admitted to psychiatric in-patient care in the year preceding the census, 1 July 1984-30 June 1985.

Relatives

The type of relative with whom the 72 patients were living is shown in Table I. More males than females were living with parents (χ^2 6.75: $P<0.01$). Relatives of 12 patients were not interviewed: six patients had refused to take part in any of the previous Nithsdale surveys; a general practitioner refused access to a seventh patient; three patients refused access to relatives; and two relatives refused to be interviewed. Of the 12 patients, two had had no previous psychiatric admissions and the mean time from the census to the previous admission in the remaining ten was 12 years (s.d. 8 years, range 2-26 years).

TABLE I
Patients' living arrangements

Patient lives with: %	*Total* ($n=72$)	*Male* ($n=35$)	*Female* ($n=37$)
Parents	41	57	24
Spouse	42	34	49
Child(ren)	4	0	8
Other relative	6	6	5
Friend	7	3	14

Assessment

One of us (A.D.T.R.), trained in the use of the CFI by Dr Christine Vaughn, carried out all interviews which on all but three occasions took place in the patients' homes over a 3-month period following the census. Interviews were taped and an assessment made from the recordings of the five main components of EE, namely criticism, hostility, emotional over-involvement, warmth and positive comments. The amount of face-to-face contact between relative and patient during a typical week was also assessed through the construction of a time budget; more than 35 hours per week indicates high contact (Vaughn & Leff, 1976). The husband or wife of a married patient was always seen; where an unmarried patient lived with both parents, both mother and father were interviewed. In all, 70 relatives or friends were seen. A relative fell into the high EE category if he had a score of 6 or more critical comments, any degree of hostility, or a rating of 3 or more on emotional over-involvement (EOI) (Leff *et al*, 1982).

At the same time as the CFI ratings were made the consultant psychiatrist (R.G.McC), responsible for the patients' clinical management and blind to the ratings, made his own assessment of expressed emotion through the use of a simple 4-point global scale:

> I think this relative (i) is probably neither critical nor hostile (group 1 relatives), (ii) is possibly neither critical nor hostile (group 2), (iii) is possibly critical and/or hostile (group 3), (iv) is probably critical and/or hostile (group 4).

To make the assessment as simple as possible, no attempt was made to rate EOI. Over the same period, community psychiatric nurses visited relatives in their homes and asked them to complete a patient rejection scale (PRS) (Kreisman *et al*, 1979*). This is a 24-item questionnaire containing such statements as "I am very disappointed in my . . ."; "I wish my . . . had never been born". The relative is invited to respond to each statement in one of seven ways ranging from "I feel this way 'always'" through 'sometimes' to 'never'. Each item is scored 1-7 and a grand total obtained (range 24-168); a lower score indicates less hostility.

Results

Prevalence and patterns of high EE

At the time of the survey 58% ($n=35$) of the 60 patients were living with low EE relatives, 42% ($n=25$) with at least one high EE relative, and 32% ($n=19$) with at least one high EE relative with whom they were in face-to-face contact for more than 35 hours each week. Thirty relatives showed high EE. The breakdown by type of EE was as follows: criticism, as evidenced by a score of 6 or more critical comments, without EOI, as evidenced by a rating of less than 3, was shown by 10% of relatives ($n=7$), criticism and EOI by 21% ($n=15$) and EOI alone by 11% ($n=8$). Hostility, as evidenced by a score of 1 or more, shown by 8% ($n=6$) was never found without criticism. Sixteen of 21 mothers (76%) interviewed showed high EE, three of six fathers (50%) (that is, 70% of parents showed high EE); one of nine wives (11%), four of 14 husbands (29%) (that is, 22% of spouses); four of nine other first degree relatives (44%); two of three more distant relatives (67%); none of eight friends showed high EE. Parents had significantly higher scores when compared with spouses in mean number of critical comments (5.67 (s.d.4.79) vs 2.82(2.29): t-test, $t=2.60$, $P<0.02$), and also more showed EOI (63% vs 13%: $\chi^2=10.89$; $P<0.001$). There were no statistically significant differences in the percentage showing hostility (11% parents ($n=3$) vs 4% ($n=1$)) but the numbers in each group were very small.

Patients living in high EE homes, in low EE homes or on their own did not differ in: sex distribution, length of illness, and number of previous admissions. Patients living on their own were older than those living in high EE homes

---

*The questionnaire has been expanded somewhat since the first version was published (full details on request to Dr D. Kreisman, New York State Psychiatric Institute, New York, 10032) (mean 51 years vs 43 years; t-test: $t=2.65$, $P<0.02$). More patients in high than in low EE homes lived with parents (68% vs 14%; χ^2 15.88; $P<0.001$).

Admissions to in-patient care

Scrutiny of case records showed that all Nithsdale schizophrenics admitted to in-patient care in the year preceding the census ($n=27$, 24% of all non long-stay in-patients) did so as a result of an exacerbation of a chronic schizophrenic illness or a fresh episode. There was no difference between admissions and non-admissions in: age, sex distribution, marital status and length of illness. Admissions had had more previous admissions than non-admissions (mean 7.3 vs 4.9; t-test: $t=2.12$, $P<0.05$).

TABLE II

Admission of Nithsdale schizophrenics to in-patient care in previous year

Living arrangement	*Total number of patients*	*Number of patients admitted*	*Percentage of patients admitted*
Lives alone	42[1]	9	22
No medication	14	4	29
Receiving medication	27	5	18
Low EE family	35	9	26
No medication	14	6	43
Receiving medication	21	3	14
High EE family	25	9	36
No medication	6	1	17
Receiving medication	19	8	42
High EE/high contact family[2]	19	7	37
No medication	4	1	25
Receiving medication	15	6	40

1. Medication unknown in one patient.
2. More than 35 hours per week in face-to-face contact.

Patients were then grouped on the basis of domiciliary status and whether they had received maintenance anti-psychotic medication in the year preceding the census or at least until the time of hospital admission (Table II). Admission rates for the three main groups (patients living on their own, in low EE homes and in high EE homes) ranged from 22% to 36%; the trend, not statistically significant, was towards a higher admission rate in patients from high EE homes. Admission rates for patients in high and low contact with high EE relatives were virtually the same. There were no significant differences between relatives of patients admitted and not admitted in mean number of hours face-to-face contact with patients and mean scores on criticism, hostility, emotional over-involvement, warmth and positive comments sub-scales. A trend in patients living on their own or in low EE homes was that admission rates were lower in patients on anti-psychotic medication (Table II); in contrast the trend in high EE patients was that admission rates were higher in patients on medication. No trend, however, reached statistical significance.

Comparison of CFI with consultant's assessment and PRS

The consultant psychiatrist rated 54 of the 70 relatives; he believed his knowledge of the remainder was so slight that an assessment could not be attempted. He assigned 17 relatives to group 1 ("probably neither critical nor hostile"), 12 to group 2, 14 to group 3 and 11 to group 4 ("probably critical and/or hostile"). When groups 1 and 2 were combined, it was found that 23 out of 29 relatives (80%) fell into the low EE category as assessed by the CFI; when groups 3 and 4 were combined, 11 out of 25 (44%) fell into the high EE category. Concordance rates were only marginally or not improved when relatives in groups 1 and 4 were compared respectively with those in low and high EE categories, and when groups were compared with relatives categorised by the criticism and EOI sub-scales of EE. The number of relatives showing hostility on the CFI ($n=4$) was too small to warrant examination of concordance rates but two fell into group 3 and two into group 4.

Fifty-eight relatives completed the PRS; the remainder were not known to the community psychiatric nurses. Mean scores on the hostility questionnaire for different categories of relative as determined by the CFI are shown in Table III. Although there were statistically significant differences between mean scores in different EE categories, there was such a wide scatter of scores in high EE relatives (see standard deviations in Table III) that it was not possible to determine a cut-off point on the PRS above which most high EE but few low EE relatives would be found.

TABLE III

Scores on patient rejection scale

Type of relative as determined by Camberwell Family Interview	*Number of relatives*	*Rejection score* *Mean score*	*s.d.*	*Student's 't'*	*P*
High expressed emotion	25	68	27	2.05	<0.05
Low expressed emotion	33	56	18		
Hostile[1]	5	93	11	3.61	<0.001
Not hostile	53	58	21		
Critical[2]	17	76	25	3.40	<0.01
Not critical	41	55	19		

1. Any degree of hostility on CFI
2. Six or more critical comments on CFI

Discussion

Relatives of 12 patients were not interviewed and some might belong to the high EE category. However, either patients had no history of admission to a psychiatric hospital or had not been admitted for many years. If there is a relationship between high EE, relapse and subsequent in-patient care it is likely few of these relatives fell into the high EE category.

The study, the first prevalence survey of high EE, found that in a community of schizophrenics 50%

were living with relatives or friends and of these, 32% lived in high contact with high EE relatives, the family structure believed by Leff and colleagues to be most conducive to schizophrenic relapse. However, put another way, 87% of all Nithsdale schizophrenics were *not* living in a high contact/high EE family. In terms of absolute numbers, therefore, it is unlikely that at any given time many Nithsdale schizophrenics have to face this sort of family life. If these results obtain in other parts of the country, and if NHS clinicians wish to embark on prophylactic family therapy with schizophrenics at risk, then the amount of work involved is not likely to be great. It is possible of course that within an individual the level of EE fluctuates over time and that a higher or lower prevalence of high EE might have been found on another date. However, with highly enmeshed families (high EE, high contact), EOI in one study barely changed in relatives where no therapeutic intervention took place, at least over a 9-month period (Leff *et al*, 1982). Criticism appears less stable; a considerable reduction occurred over 9 months in some relatives where patients markedly improved (Brown *et al*, 1972).

A common family structure in Nithsdale is the male schizophrenic living with elderly parents (McCreadie, 1982); such a patient may be at high risk as the present survey found parents were more critical and over-involved than spouses. Why this should be so is not clear. It has previously been suggested that more emotion is expressed by those with low rates of contact with friends and relatives (Brown *et al*, 1972). Perhaps parents are more isolated than spouses, most of whom were born and brought up in Nithsdale and possibly had other supportive contacts more readily available outside the nuclear family.

Comparison of the present findings with other studies is very difficult, firstly because the Nithsdale survey examines prevalence while the others examined relatives of patients recently admitted to in-patient care, and secondly because different cut-off points in the subscales of criticism and EOI were used at different times to determine the presence or absence of high EE. At the suggestion of Dr Leff (pers. comm.), the fairest comparison is to use a cut-off of 6 for criticism and 4 for EOI (although 3 has been used in this and later studies); and to consider only relatives of Nithsdale schizophrenics recently admitted to in-patient care, that is, during the previous year. The recalculation of results suggests the prevalence of high EE in rural Nithsdale (50%) might be similar to that in urban London (57%) but much higher than in Chandigarh, (23%; cut-off of 3 for EOI) and lower than in California (67%).

The results of the retrospective review must be treated very cautiously because, as discussed above, EE may in some cases fluctuate over time and if relatives had been assessed at the time of the patients' admission more might have shown high EE than in the prevalence survey. Nonetheless the retrospective results are of some interest. Although in the year previous to the survey there was a trend towards increased admission rates among schizophrenics living in high EE families there were no statistically significant differences in admission rates between patients living on their own or with relatives, between patients living with high and low EE relatives and between patients having little or much contact with high EE relatives. This contrasts sharply with relapse rates over 9 months in the prospective studies reported by Vaughn & Leff (1976). In these studies, 13% of patients discharged to low EE homes but 51% of patients discharged to high EE homes relapsed. Also, medication in the present study did not appear to exert a prophylactic effect in patients living with high EE relatives; in contrast, in the studies of Vaughn & Leff, 92% of patients discharged on no medication to high contact/high EE homes relapsed. However, the numbers of patients in the different Nithsdale subgroups are perhaps too small to warrant serious statistical analysis (for example there were only four patients in the high contact/high EE/no medication group).

It may be that other more important determinants of relapse swamp the contribution of family life in a community of schizophrenics. Patients admitted over the preceding year had had more previous admissions than patients who were not admitted; this may simply reflect severity of illness. Also, life events which are not assessed by the CFI can affect relapse rates (Leff & Vaughn, 1980). Alternatively, might there be protective factors in a rural community such as Nithsdale which do not exist in an inner-city area such as Camberwell? Most schizophrenics in Nithsdale were born and brought up in the area and many still have some contact with acquaintances, friends and more distant relatives outside the nuclear family home. Also, there is a well developed community psychiatric nursing service, a considerable number of patients are regular attenders at the day hospital, and most attend out-patient clinics. Perhaps such contributions outside the home are more widespread and better developed than in an urban area; advice, encouragement and support from these people may help to protect against the hostility, criticism and over-involvement of close relatives.

Neither the clinician's hunch nor the PRS proved to be an adequate shortcut to the assessment of high EE. If the consultant believed a relative was neither hostile nor critical, then it was highly likely that the relative fell into the low EE category as determined by the CFI. However, he had less success in determining which relatives had high EE. He appeared to have a much wider concept of hostility and criticism than that determined by the CFI and thus assigned many low EE relatives to the high EE category. If on the basis of his clinical hunch he and his team were to embark on family therapy for schizophrenics living with high EE relatives a substantial number of low EE families would find themselves in treatment—perhaps no bad thing.

The PRS completed by relatives certainly distinguished in a statistical sense between high and low EE categories. However, because of the wide scatter of scores on the questionnaire in the high EE category, there was no clear cut-off point above which the clinician could confidently assert most high EE but few low EE relatives would be found. The PRS, therefore, may be of use for research purposes but is not appropriate in an everyday clinical setting where the purpose is to identify an individual relative with high EE. Statistical probability does not yield precise prediction.

As an important by-product of the study, valuable insights were gained into the families of the Nithsdale schizophrenics and we would like to conclude by recording some of our more vivid impressions. Interviewing the family and friends of a given patient was a dialogue about the lives of people who have taken on a considerable burden of care with varying degrees of willingness. The impression left was of people struggling, but often succeeding in coming to terms with a major change in a child or spouse, a change that left that person unpredictable, sometimes dangerous. One father said that his world had shrunk to the small but chaotic world of his daughter. The most contented homes were often the group homes; it is surprising that in place of the expected emotional blunting there was warmth and positive regard. While many experiences were adverse, humour was not lacking, which was to be expected from a couthie people such as live in Nithsdale. Where a schizophrenic was married, the overall impression of the marriages was of stability with the offspring well cared for. Maybe the stigma helps to draw a family together to withstand any external threat. Any adverse effect of caring for schizophrenic children did not seem to be reflected in the mothers either. Two were aged over 90; both gave vivid interviews.

To see people in their homes gives an insight rarely gained in the out-patient department and a willingness by a doctor ('busy people') to take an interest in home life was remarked on favourably many times. Advice is needed for next-of-kin and must be greatly helped by knowing home circumstances (Kuipers & Bebbington, 1985).

Acknowledgements

We wish to thank the patients and their relatives for their cooperation; Dr J. Leff and Ms J. Harvey for constructive criticism; Sister R. Love, Sister D. Paterson and Charge Nurse D. Smith for administering the Patient Rejection Scale; and Miss P. Cowan and Mrs M. McCormick for secretarial assistance.

Specific and Non-specific Effects of Educational Intervention with Families Living with a Schizophrenic Relative

J. V. SMITH and M. J. BIRCHWOOD

A brief educational intervention with families living with a schizophrenic relative is described and evaluated in terms of benefits for relatives' well-being and patient recovery. Education led to considerable knowledge gains and to reductions in relatives' reported stress symptoms and fear of the patient. There was a trend for relatives to be more optimistic concerning their role in treatment. At 6 months follow-up, only knowledge gains were maintained; however, relatives' perceptions of family burden were significantly reduced. The evidence suggests that family education may be useful both as a cost-effective intervention in its own right and in facilitating a more receptive attitude to subsequent family intervention.

Over the past two decades with the introduction of neuroleptic medication and the emphasis on de-institutionalisation there has been an increased pressure to discharge patients from hospital into the community. However, lack of adequate community-based medical and social provision has inevitably placed the burden of care on the patient's family; it has been suggested that over 50% of schizophrenic patients return to live with families (Goldman, 1980; Holden & Lewine, 1974). Families are therefore taking on much of the burden of care for their relatives particularly concerning the management of disturbed behaviour, often in the absence of sufficient information, skills and support (Carstairs *et al*, 1985). For many families the impact of this responsibility can be very distressing, and can lead to a high level of intra-familial tension and individual stress symptoms (Birchwood, 1983; Gibbons *et al*, 1984).

In addition to the needs of the individual with schizophrenia (not addressed here) there would, therefore, appear to be justification for directing attention to the needs of the supporting family both during the initial crisis and thereafter. There has, until recently, been a general lack of professional awareness and responsiveness to the family's needs in this respect. One significant aspect of this neglect has been the lack of time spent by professionals providing basic information about the illness, its treatment and practical advice concerning home management. Yet the need for, and benefits from, family-education are evident. In addition to meeting family needs, education may have beneficial effects for the schizophrenic member. Non-compliance with medication has been shown to be an important factor in schizophrenic relapse which family- (and patient-) education may help to ameliorate. Family-education has also been a common component in three large-scale family interventions which have reported the successful short-term control of relapse (Goldstein & Kopeikin, 1981; Leff *et al*, 1982; Falloon *et al*, 1982).

The specific role of education in these interventions is unclear. Berkowitz *et al* (1984) reported that in the Leff *et al* (1982) intervention, education led to their high EE (high relapse risk) group 'knowing more about diagnosis and management' and increased their optimism; other long-term attitude changes were confounded with the later intervention. However, comparisons of high and low EE families prior to the intervention had revealed no differences in these characteristics. McGill *et al* (1983) reported that their educational intervention led to parents acquiring knowledge 'approximating that of mental health professionals' and these knowledge gains were maintained 9 months after intervention. Non-specific effects other than knowledge acquisition were not assessed.

Education alone could, therefore, meet many of the needs of families (except the important one of in-depth management advice) – however, its function in the context of a large-scale family intervention remains uncertain. The present study was therefore undertaken to examine the efficacy of education *alone* by observing the specific (knowledge acquisition) and non-specific (stress reduction, attitude change) effects immediately and 6 months after intervention. In order to test whether information *per se* is important as opposed to its delivery by professional personnel, half of the families received information in booklet form through the post. Both groups were required to undertake homework exercises designed to maximise information assimilation and to prompt relatives to apply the information to their own situation.

Method

Subjects

Twenty-three families who had a schizophrenic relative participated in the study. The families were drawn from a random sample of patients known to the hospital. Of this sample, six patients were in hospital at the time of the study. (Of the original sample, nine families refused to participate in the study and six families dropped out prior to intervention; there were no drop-outs during the intervention period.) Criteria for selection of patients were: evidence of one or more 'first-rank' symptoms of schizophrenia (Schneider, 1959) observed at onset in the case notes; living at home or in close contact with the family (5 or more days per week) and stabilised on depot or oral neuroleptic medication. The sample consisted of 40 family members (28 parents, seven spouses and five other relatives) who were all English speaking. Forty-four per cent of the families were from social class level 3, the remainder being evenly distributed across social class groups 1, 2 and 4; however, only one family was from social class group 5. The schizophrenic sample, consisting of 18 males and five females, were a relatively chronic group with a mean age of 36.4 years (s.d. ± 14), mean illness duration of 7.9 (s.d. ± 6.8) years and mean number of 3.7 (s.d. ± 3.8) admissions. The majority were unmarried (15 of 23).

Design

Families were randomly assigned to either a group or a postal intervention condition. The education package was delivered in both intervention conditions at weekly intervals over a 4-week period.

Intervention

The aims of the intervention were to:

(a) improve relatives understanding of schizophrenia, its nature, symptoms and treatment
(b) improve relatives 'cognitive mastery' of their own situation by encouraging relatives to apply the information to their own circumstances (mainly through an instrumental component in the form of homework assignments).
(c) improve the quality of the relationship and reduce alienation between patient and relative by changing relatives' attitudes towards, and improving understanding of, schizophrenia
(d) emphasise the importance of maintaining relatives' personal well-being.

The intervention did not cover issues relating to behavioural management except in very broad terms.

The information given to relatives in both conditions was divided into four separate sections covering:

(a) concepts of schizophrenia, epidemiological data and possible causal factors.
(b) the symptoms of schizophrenia
(c) treatments and outcome
(d) hospital and community resources available and basic management guidelines.

(See Appendix for a more detailed description of the information covered in each of these sections.)

This information was presented in the form of four typed booklets corresponding to the four information sections outlined. The information was written in simple English and tailored as far as possible, to be comprehensible to the average family. A readability analysis (Flesch, 1948) showed that the booklets could be understood by individuals of average IQ (overall reading ease score = 56.75; IQ > 103).

Group condition

Those family members assigned to the group intervention participated in four weekly educational sessions conducted by the primary therapist (J.S.). The sessions were in a semi-structured seminar format involving oral presentation of the information as well as audiovisual aids. A video film entitled *Coping with Schizophrenia* (Birchwood, 1983) was used to illustrate common schizophrenic symptoms and behaviours. The content of the four sessions corresponded to the four information sections previously described. Family participation was encouraged through general question and answer discussion – each session lasting 60–90 minutes. At the end of the session, each family member received a booklet corresponding to the material covered in that particular session and a written homework exercise which they were invited to complete. These were designed to encourage families to apply the information they had received to their own situation.

Postal condition

Family members assigned to the postal intervention received a typed information booklet (corresponding to each of the information sections described previously and to that received in the group intervention condition) through the post at weekly intervals over a 4-week period. A covering letter accompanied each of the booklets which briefly outlined the information booklet and invited the family members to complete the corresponding 'homework' exercise attached.

Measures

All family members were assessed before and immediately after the educational intervention and at 6 months follow-up. The assessment instrument comprised a six-part paper and pencil questionnaire designed to assess:

Knowledge acquisition

This consisted of an 18-item multiple choice questionnaire designed to assess family knowledge and understanding about schizophrenia – in particular it concerned demography, aetiology, symptoms, medication and relevant hospital procedures.

Beliefs about schizophrenia and its treatment

This consisted of four 5-point scales separately assessing the family's beliefs and expectations about their role in treatment, effectiveness of medical treatment, likelihood of improvement and the control that the patient has over his symptoms.

Worry and fear

This consisted of two 5-point scales assessing aspects of the family's perception of the individual in terms of the amount of worry and fear about the 'individual and his behaviour'.

Behavioural disturbance

The symptom-related behavioural disturbance scale (SBDS) developed by Birchwood (1983) was employed. This is a 22-item measure of severity of patient disturbance. The reliability of this measure has been demonstrated in terms of inter-rater reliability ($r = 0.90$) and internal coherence (Chronbach's $\alpha = 0.84$). The scale correlates $r = 0.6$ with scales derived from the PSE.

Stress

This was measured using the symptom rating test (SRT) developed by Kellner & Sheffield (1973), modified and validated by Cochrane (1980), a 30-item measure of stress symptoms in the relatives incorporating anxiety, depression, somatic and inadequacy subscales.

Family distress

The family distress scale (FDS) developed by Pasamanick *et al* (1967), was employed. This is a 22-item scale which measures the impact of having a schizophrenic relative in the family in terms of the extent of disruption on family life, embarrassment and the concern of self and others. (Chronbach's $\alpha = 0.91$ using data from this study).

Results

Three (intervention style × test occasion) factorial analyses of variance with test occasions as a repeated measure were carried out on the pre-education, post-education and 6 months follow-up scores. There were no significant differences in any of the variables measures between group and postal relatives at baseline, except that postal relatives were significantly more worried ($t = 2.47$, d.f. = 38; $P < 0.01$).

Knowledge acquisition

The knowledge scores of both sets of relatives significantly increased from baseline to post-education ($F = 51.80$, d.f. = 1,38, $P < 0.001$). These improvements in knowledge from baseline were maintained at 6 months follow-up ($F = 51.38$, d.f. 1,38, $P < 0.001$). 'Group' relatives acquired significantly more knowledge than 'postal' relatives ($F = 5.22$, d.f. = 1,38, $P < 0.05$). This significant difference in knowledge between the two sets of relatives remained at 6 months follow-up ($F = 14.50$, d.f. = 1,38, $P < 0.01$). (See Table I, Fig. 1).

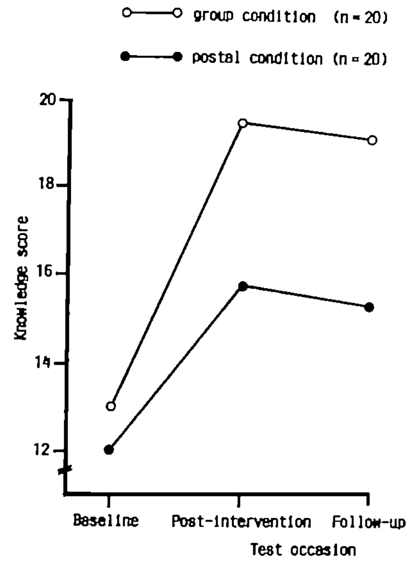

FIG. 1 Mean knowledge score for group and postal relatives across test occasions.

In the group relatives there was a mean improvement in knowledge on the questionnaire of 27% (from 58% to 85% following education) while in the postal group there was a mean improvement in knowledge on the questionnaire of 16.5% (from 52% to 68.5% following education.) These gains were maintained at a 6 month follow-up. Immediately following the educational intervention, 90% of the group relatives possessed relatively 'sophisticated' knowledge about schizophrenia (i.e. more than 70% correct) compared with only 60% of the postal relatives. This difference in degree of knowledge remained at 6 months follow-up.

Information acquired was evenly spread across the five main areas; demographic data, aetiology, illness (course and symptoms) hospital procedures and medication. Interestingly, 75% of families had little understanding about the function of medication prior to education. Post-education, 67% of families possessed a good knowledge about the effects of medication (score >3 out of 4).

Belief systems of relatives about schizophrenia

There were no significant differences between baseline scores and either post-education or follow-up scores for either group on any of their beliefs concerning the effectiveness of treatment, the likelihood of improvement or the control that the patient possessed over his symptoms. However, the two sets of relatives did differ in their belief concerning the family's role in treatment following education which was revealed in a significant interaction effect ($F = 5.37$, d.f. = 1,38, $P < 0.05$) (See Table I, Fig. 2).

TABLE I
Mean scores with standard deviations on each of the variables for group and postal intervention

	Group intervention						*Postal intervention*					
	Before		*After*		*Follow-up*		*Before*		*After*		*Follow-up*	
Variables	*Mean*	*s.d.*	*Mean*	*s.d.*	*Mean*	*s.d.*	*Mean*	*s.d.*	*Mean*	*s.d.*	*Mean*	*s.d.*
Knowledge	13.20	5.24	19.55	3.33	19.10	3.61	12.00	4.08	15.75	3.27	15.30	3.01
Belief:												
family's role	2.55	0.99	3.00	1.03	2.95	0.89	2.95	1.05	2.70	0.92	2.90	0.97
Fear	0.95	0.88	0.70	0.73	1.05	0.88	1.25	1.16	0.90	0.97	0.60	0.75
SRT	14.00	9.78	11.95	7.67	15.35	10.60	15.95	8.50	15.15	8.92	15.40	9.19

SBDS	22.50	12.45	21.20	11.32	17.35	9.62	24.50	10.90	25.00	11.63	20.00	13.65

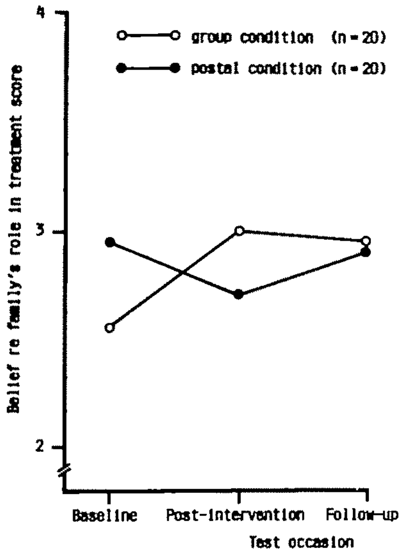

FIG. 2 Mean belief scale score concerning the family's role in treatment for group and postal relatives across test occasions.

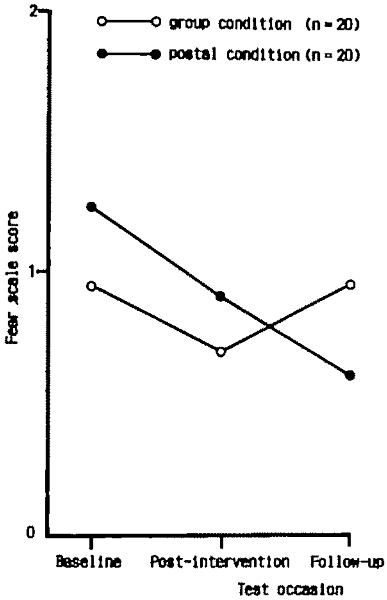

FIG. 3 Mean fear scale score for group and postal relatives across test occasions.

Results of t-tests revealed that there was a trend for group relatives to be more optimistic concerning the family's role in treatment ($t = 1.40$, d.f. = 38, $P < 0.10$). The scores of postal relatives did not significantly differ from baseline. This interaction effect disappeared at 6 month follow-up.

Worry and fear

Fear scores reflecting fear concerning safety of self, others and property were significantly reduced across both sets of relatives from pre to post as a result of education ($F = 5.63$, d.f. = 1,38, $P < 0.05$). Group relatives were not significantly different from postal relatives. However, the sets of relatives differed in their fear scores at 6 months follow-up compared to post-education reflected in a significant interaction effect ($F = 6.4$, d.f. = 1,38, $P < 0.05$). (See Table I, Fig. 3).

Results of t-tests revealed that the postal relatives continued to be significantly less fearful compared to baseline ($F = 6.05$, d.f. = 1,38, $P < 0.05$), while the fear scores for the group relatives returned to baseline levels.

Postal relatives worried more than group relatives at baseline and following education ($F = 5.78$, d.f. = 1,38, $P < 0.05$). However, this significant difference in worry scores between the two sets of relatives was not maintained at 6-month follow-up.

Psychological distress in the relatives

Stress scores on the Symptom Rating Test were significantly reduced across both groups of relatives from baseline to post-education ($F = 5.28$, d.f. = 1,38, $P < 0.05$). Neither set of relatives showed a significantly greater reduction in stress symptoms than the other. Reduction in stress symptoms was consistent across all four symptom rating test subscales: anxiety, depression, somatic and inadequacy. Those relatives who had the highest stress scores at baseline showed the biggest reduction in stress symptoms following education ($r = 0.39$, d.f. $= 38$, $P < 0.01$). The reductions observed at post-education were not maintained at 6 months follow-up where scores had returned to baseline levels. (See Table I, Fig. 4). The return to baseline level was consistent across all four subscales.

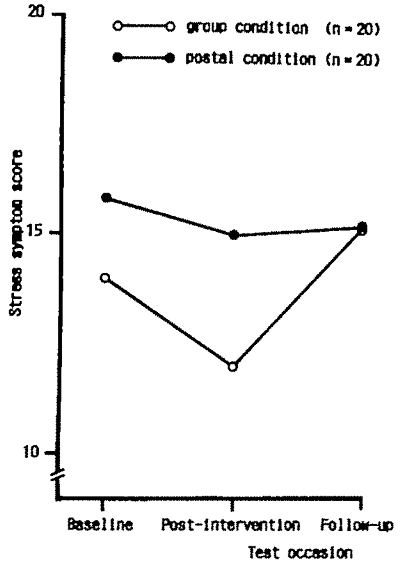

FIG. 4 Mean stress score for group and postal relatives across test occasions.

Burden on the family

There were no significant differences from baseline scores in reported burden (FDS) following education for either set of relatives. However, there were significant reductions in reported burden across both groups from the baseline score to follow-up ($F = 21.08$, d.f. $= 1{,}38$, $P < 0.001$) and post-education scores to follow-up ($F = 7.4$, d.f. $= 1{,}38$, $P < 0.01$). (See Table I, Fig. 5).

Symptom related behavioural disturbance (SBDS)

Where ratings of level of patient disturbance were made by two members of the same family the ratings were found to be significantly correlated ($r = 0.70$, d.f. $= 14$, $P < 0.01$). Ratings for relatives from the same family were therefore combined for the purposes of analysis.

There were no significant differences from baseline scores in level of patients' disturbance following education or at 6 months follow-up for either group. Level of patient disturbance as indexed by scores on the SBDS were found to be significantly correlated with family burden scores on the FDS ($r = 0.72$, d.f. $= 38$, $P < 0.01$).

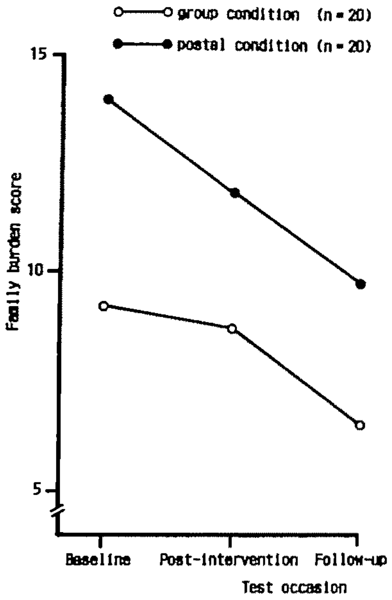

FIG. 5 Mean family burden scores for group and postal relatives across test occasions.

Correlational analyses

Between knowledge acquired and attitude change, stress and burden

The change in knowledge scores was not found to be significantly correlated with either the change in fear scores or the change in stress symptom scores observed following education. The change in knowledge scores was also not found to be significantly correlated with the change in perceived family burden observed at 6 months follow-up.

Between social class and knowledge scores

Social class was found to be significantly negatively correlated with initial knowledge scores ($r = 0.35$, d.f. $= 38$, $P < 0.05$) i.e. relatives from social class groups 1–3 had more knowledge concerning schizophrenia compared with groups 4 and 5, prior to the education course. Social class group was not significantly correlated with any of the specific or non-specific effects observed following education.

Between duration of illness and change in attitude, stress and burden

Correlational analysis revealed that duration of illness was not significantly correlated with any of the specific or non-specific effects observed following education.

Discussion

The four session education course led to considerable acquisition and retention of information across all participants and to actual reductions in relatives' stress symptoms and fear of the patient. Significantly, there was no correlation found between amount of knowledge acquired and these non-specific effects. Group relatives recalled more information about schizophrenia than postal relatives and there was a trend for the former to be more optimistic about the family's role in exerting control over the situation. At 6 months follow-up, only knowledge gains were maintained across all participants; all non-specific effects had disappeared, with the exception that postal relatives remained less fearful. However, it was noted that all relatives were reporting significantly less burden on the family. Similarly, no correlation was found between the amount of knowledge acquired following education and the reduction in perceived burden observed from baseline to follow-up.

The independent variables can be divided up into 'content' and 'context' of delivery. It is important to try to distinguish those effects which are influenced by content and those by contextual variables from a therapeutic viewpoint. The postal delivery of information served as partial control for certain 'placebo' elements in the group education package. In the group condition, there were certain additional elements, specifically, the presence of a therapist, other group members and repetition with clarification of the information being conveyed. The majority of specific and non-specific effects obtained were the *same* across both conditions with the exception that group relatives acquired significantly more knowledge and showed a trend towards being more optimistic concerning the family's role in treatment.

It seems likely that 'context' as well as 'content' contributes to knowledge acquisition. Pure information content common to both groups is clearly the crucial element in knowledge acquisition *per se*. However, contextual factors would appear to have a role in further enhancing knowledge assimilation conceivably through the combined effects of repetition and clarification of information – and the opportunity to listen to and discuss views with the therapist and other group members.

Since all non-specific effects observed were the same across postal and group conditions they could only be accounted for by information content or by placebo elements *common* to both conditions such as relatives' expectations, motivation and attention to problem. (However, group context may have played a significant role in further encouraging optimism through the opportunity provided to meet and listen to a therapist and other group members). It is difficult if not impossible to tease out the specific contributions of information content from these general 'placebo' effects. If contextual factors are crucial to the non-specific effects observed, the question is raised as to whether, aside from academic interest, one should be looking for ways to encourage rather than to eliminate such effects. Given the well-documented lack of information currently given or available to patients and their families (as the pre-knowledge scores demonstrate), information courses would appear to be a useful and cost-effective measure to disseminate information widely and easily. However, it must be borne in mind that these knowledge gains were observed in a general sample drawn from the community containing only six patients at acute admission. It is difficult without further study to assess whether the results are generalisable to families receiving education during the acute phase.

The value of patient education is an important but separate issue (not addressed here). In the authors' experience, it is adviseable that patient and family education are kept separate since the presence of the individual with schizophrenia can inhibit the relative's freedom to air sensitive issues and concerns and can be potentially disruptive in circumstances where the individual lacks insight into the illness. The impact of patient education is currently being addressed in other work by the authors.

It is interesting to note that 75% of the families possessed little understanding about the function of medication prior to education, a factor which may contribute to the widespread problem of medication non-compliance. Thus the provision of information about medication to the patient and his family holds out the prospect of encouraging compliance to medication regimes.

Education, however, is not purely an academic exercise to increase knowledge. In fact, the value of education would not seem to lie solely in knowledge acquisition *per se*, since information gained was not correlated with any of the non-specific effects. It may be argued that since no correlation emerged between information retained and non-specific effects, content is irrelevant as a medium of change. However, what may be important is the subjective effect of *being* or *feeling* more knowledgeable rather than the degree of improvement in knowledge itself. The subjective effect may act to improve relatives 'cognitive mastery' and perceived ability to influence the situation and thereby reduce their feelings of uncertainty and helplessness (cf. reductions in fear and the trend towards increased optimism). There may also be hidden direct effects of being more knowledgeable by filling in idiosyncratic knowledge gaps about their patient which in turn may serve to reduce feelings of stress and increase feelings of control over the situation. For example, in one case the family did not understand the relationship between the individual talking to himself and hearing voices; in another, the patient's refusal to eat meals cooked by his parents was initially viewed as a comment on their cooking rather than a behavioural sequel to a delusion of persecution.

These effects are clinically important because they may serve to reduce alienation of the family from the individual and encourage more positive relative–patient interaction and willingness to help the patient, factors which may mitigate against intra-familial tension. Education also served to improve relatives level of stress and perceived burden which may otherwise constrain the family's ability to provide a supporting rehabilitative environment. Specifically, a reduction in stress may enable relatives to become more tolerant and accepting, characteristics which again have been noted in low risk family environments (Greenley, 1979; Kuipers, 1979). Unfortunately, these effects were transient and their therapeutic impact limited, although the intervention was sufficient to reduce perceived family burden over 6 months. We would hesitate to suggest therefore that a brief educational intervention could substitute for more intensive management-focused interventions since the majority of benefits were short-term and insufficient in themselves to satisfy relatives' needs for specific management advice. (Many relatives requested specific advice about how best to manage problems at home following education.) Overall, the results suggest that a brief educational intervention may serve to 'prepare the ground' in terms of enabling assimilation and adherence to subsequent intervention of a management kind, although the latter must be undertaken promptly to capitalise upon the short-term changes observed (Birchwood & Smith, 1987). It seems likely that the potential contribution of an initial education phase in family intervention programmes may be in its enabling effect, encouraging factors which facilitate and removing practices which constrain effective management and communication (Birchwood & Smith, 1987).

It is possible that education incorporating basic management guidelines might be a sufficient stimulus in itself for certain families of limited experience (i.e. those families of younger acute patients of more recent onset) to develop their own problem-solving skills and resources to cope with and help their schizophrenic relative. This suggestion draws support from the successful, brief (6-week) intervention study conducted by Goldstein and Kopeikin (1981) which combined initial education aimed at improving understanding of schizophrenia with the development of management strategies to deal with stressful situations in the family. Despite its brief nature this intervention appeared to have had a significant effect on relapse, using a sample two-thirds of whom were first episode patients. The Goldstein study suggests that the period immediately after onset may represent the best time to conduct a family intervention before relatively permanent response characteristics set in.

The nature and method of delivery of education packages to date has been fairly arbitrary and varied widely across intervention studies. The experimental manipulation of method of delivery in the present study underlines the need to consider this more carefully. Although the results would seem to indicate that access to written information *per se* is as effective as group education and offers itself as a less costly alternative, one would hesitate to advocate 'bibliotherapy' on its own. The weaknesses of this approach lie in the lack of flexibility for information clarification and adaptation to individual needs and the absence of opportunity to listen to and discuss the information with a therapist and other group members, which would appear to be crucial for the full enabling potential of education to be realised. Work is currently underway by the authors to replicate and develop this study, comparing the effects of different methods of information delivery in combination with the experimental manipulation of an instrumental component in the form of homework assignments.

Appendix

The four information sections were as follows:

Section 1

The first section contained a brief outline as to how the concept of schizophrenia was developed and some epidemiological data about who could develop schizophrenia. Simple explanations of possible causal factors, e.g. the role of genetic and biochemical abnormalities were given, although the lack of conclusive evidence in this area was emphasised. The role of possible environmental stresses including family factors in the development and course of the illness were outlined. Although the families were reassured that they were not responsible for causing the illness, their important role in the recovery process was emphasised. Finally, a guarded but hopeful prognosis for the majority of patients was provided.

Section 2

The second section focused on the nature of schizophrenia, describing common symptoms and behaviours in terms of disturbances in thinking, feelings and behaviour as experienced by patients and observed by relatives. Variability in symptom patterns between patients was emphasised. Various familiar terms e.g. 'acute', 'chronic', 'positive symptoms', 'negative symptoms', 'relapse', 'remission', were elucidated. It was also stressed that negative symptoms should not be regarded as inevitable.

Section 3

The third section described the function of the relevant psychiatric services and the role of neuroleptic medication in acute and maintenance phases. Routine hospital procedures were outlined and difficulties in diagnosis were discussed. There was special emphasis on medication describing the various types of drugs usually prescribed, their purpose and their common side-effects. The effectiveness of drug therapy particularly with positive symptoms of schizophrenia and in preventing relapse was emphasised. Relatives were encouraged to discuss any queries or worries about medication with the prescribing doctor.

Section 4

The fourth section was concerned with helping relatives to identify support services in terms of hospital and community resources available. (Local and national branch addresses of various organisations including self help and family support groups were supplied and a short reference list to encourage further reading was provided). Finally, some very general advice was given to encourage relatives to look after their own needs. This advice encouraged families:

(a) To look after their own needs by carrying on with or taking up activities that they used to do. As part of this, relatives carried out a homework exercise in which they articulated their past and ideal life-styles.
(b) Not to centre their lives around the patient too much.
(c) Not to worry about giving the individual responsibilities around the house e.g. household tasks, but not to overburden him immediately after discharge.
(d) To try to plan and do things with the patient which the whole family enjoyed e.g. trips out.
(e) To map out their social support network and to talk about their problems and difficulties with friends.
(f) To expect bad times when things fail and expect stress, frustration and some unhappiness.

Acknowledgements

The authors would like to thank Dr Ray Cochrane, Head of Department of Psychology, University of Birmingham, Mr Keith Winter, Top Grade Clinical Psychologist, at Barnsley Hall Hospital, Bromsgrove and those families who took part in the study for their invaluable help and co-operation with this research project.

A Comparative Trial of a New Antidepressant, Fluoxetine

S. LEVINE, R. DEO and K. MAHADEVAN

This clinical trial of a new antidepressant, fluoxetine, shows it to be as effective as a standard tricyclic drug, imipramine. It is effective as a single daily dose and is free of any significant side-effects. It is less sedative and appears to cause fewer problems of weight increase. The three scales used to assess efficacy showed a very positive correlation.

While the development of the tricyclic range of antidepressants constituted the main breakthrough in the pharmacotherapy of depressive illness, the search has continued for more effective and safer antidepressant drugs. The main focus of attention in the new generation of antidepressants has been to isolate molecules which have a specific effect on different parts of the monoamine system of neurotransmission. Studies have shown that 5HT deficiency plays an important role in the psychobiology of depressive illness (Asberg *et al*, 1976; Van Praag, 1977).

Fluoxetine has a biochemical and pharmacological profile which is characterised by its selectivity of action in blocking the re-uptake of 5HT without influencing the noradrenaline or acetylcholine systems. So the efficacy of this drug would confirm the importance of this neurotransmittor in the aetiology of depressive illness and such specificity of action would avoid the unpleasant anticholinergic side-effects of the tricyclic drugs.

Pharmacokinetic studies in both humans and animals show fluoxetine to be rapidly absorbed after oral administration, with peak plasma concentrations occurring 6 h after administration. A plasma half-life of 3–4 days makes a single daily dose possible. It is detoxified mainly in the renal system. Radioactive assays showed 65% is recovered in the urine and about 12% from faeces. Blood concentrations and half-life are the same in elderly patients and the drug has no influence on ethanol metabolism (Lemberger *et al*, 1985).

A double-blind clinical trial was undertaken to evaluate clinical efficacy and safety of fluoxetine in comparison with a standard tricyclic antidepressant, imipramine, in the treatment of depressive illness.

The opportunity was taken to compare the relationship of some standard measures of depressive illness, both observer based – Hamilton Depression Rating Scale (Hamilton, 1960) and Montgomery Asberg Depression Scale (Montgomery & Asberg, 1979) – and a self-rating scale – Levine Pilowsky Depression questionnaire (Pilowsky *et al*, 1969).

Method

Patients

All 60 patients participating in this study fulfilled the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1975) for major depressive illness with a minimum score of 17 on the Hamilton Depression Rating Scale. Patients were excluded from the study if they suffered from significant physical illness, had any history of drug abuse or schizophrenia, or had a duration of illness of more than one year. Table I describes the characteristics of the cohort and the type of depression as allocated by the LPD questionnaire, which separates cases of endogenous depression without observer bias (Pilowsky & Boulton, 1970).

All patients had been drug-free for at least 1 week and on entering the trial they were randomly allocated to either fluoxetine or imipramine according to a double-blind parallel group experimental design. Signed informed consent was obtained from all patients after the trial procedure had been fully explained.

The trial was undertaken in two clinical centres. Of the patients who completed the trial 22 received fluoxetine and 28 received imipramine and both groups were highly comparable for sex, age, type of depression, duration of illness and previous history of depressive illness as described in Table I.

On each occasion when a patient attended, enquiry was made about the development of side-effects. This was done for all patients entering the trial. Ten patients withdrew from the trial before completion: either because they did not attend (four of these were on fluoxetine, one on imipramine) or because they did not feel they were benefiting (two on fluoxetine, one on imipramine), and (two taking fluoxetine) because they developed minor side-effects, namely palpitations, tremor, headache, and peculiar taste.

Treatment

Capsules were taken three times per day and contained either fluoxetine (40 mg) as a single morning dose, or imipramine (75 mg) in three divided doses. After the first

TABLE I

less than 3 months	3	2
3–6 months	22	24
6–12 months	5	3

week, flexibility of dosage was permitted and the dose could be increased to fluoxetine (60 mg) again as a single morning dose or imipramine (150 mg) in three divided doses. Nineteen patients received the higher dose of fluoxetine and 15 patients the higher dose of imipramine. Temazepam was permitted for night sedation.

Assessments

Response to treatment was assessed by the Hamilton Depression Rating Scale (HRS), Montgomery Asberg Depression Rating Scale (MADRS) and by a self-rating questionnaire, the Levine Pilowsky Depression questionnaire (LPD), after 1, 2, 4 and 6 weeks.

Pulse rate, blood pressure and weight were assessed at the beginning, after 2 weeks and after 6 weeks of the trial. Full haemotological and biochemical screening was also carried out at these times.

Results

Clinical efficacy

Table III shows the initial severity and response as measured on the three scales, for all cases and for cases of endogenous depression as categorised by the LPD scale. Table II shows the number of patients who reached a satisfactory end point as measured on each scale.

1. Fluoxetine vs imipramine t-test (Wilcoxon) = NS

Side-effects

There were no major side-effects and Fig. 1 shows the profile of minor side-effects present in the total sample. None of these were sufficiently troublesome to influence compliance, except in the two cases who withdrew. The only difference was in the existence of tremor, which was four times more common with fluoxetine than with imipramine ($P<0.01$).

Discussion

The results show that fluoxetine is as effective an antidepressant as imipramine and that the rate of response is very similar. Although most clinical trials of antidepressant drugs report improvement in 70–80% of patients, effective cures as measured by achieving low end-point scores on the scales used are about 40–50% of cases treated. This trial produced effective cures in the dosages used in only such a proportion of cases suggesting that 5HT deficiency is not the whole story in the biochemistry of depressive illness. It would be of interest to carry out a cross-over trial in non-responding patients to elucidate whether a subgroup of pure 5HT deficient cases exists.

There were no major side-effects with fluoxetine, and haematological and biochemical screening showed no significant abnormalities. The minor side-effects profile is entirely different from imipramine and confirms that fluoxetine neither produces significant anticholinergic side-effects nor any significant drowsiness, or impairment of function. On the contrary, it appears to produce a slight alerting effect as assessed by the increased feelings of tremor, insomnia and nervousness.

There has been a suggestion that fluoxetine causes weight loss due to suppression of appetite. It was noted that 65% of patients on fluoxetine lost weight, compared with 20% on imipramine, and conversely 65% of patients on imipramine gained weight while only 25% on fluoxetine did so. The mean loss on fluoxetine was 0.63 kg and the mean gain on imipramine was 0.82 kg ($P<0.05$). This finding may be of importance in long-term therapy.

The three methods of clinical assessment were subjected to rank correlation coefficient analysis and Table IV shows the results confirming a very strong positive linear correlation and, therefore, the close comparability not only of the observer rating scales, but also of the self-rating scale with both of them. Previous studies have shown the comparability of MADRS and LPD with HRS and other scales (Kearns *et al*, 1982; Levine, 1975), but this is the first comparison of the LPD scale with MADRS. The suggestion that self-rating scales and observer-based rating scales may be measuring different variables (Prusoff *et al*, 1972) does not seem to be borne out by this study.

TABLE IV
Comparability of rating scales

	(Pearson's Test)
HRS vs MADRS	0.95 ($P=0.0001$)
LPD vs MADRS	0.83 ($P=0.0001$)
LPD vs HRS	0.78 ($P=0.0001$)

Further Studies of Vanadium in Depressive Psychosis

G. J. NAYLOR, F. M. CORRIGAN, A. H. W. SMITH, P. CONNELLY and N. I. WARD

Three studies are reported. In study 1, vanadium concentration was estimated by neutron activation analysis in hair, whole blood, serum and urine from 13 patients suffering from depressive psychosis and then when on recovery. Vanadium concentration of hair, whole blood and serum decreased significantly with recovery, but there was no significant change in 24-h urinary excretion or in renal clearance of vanadium. In study 2, vanadium concentration was estimated by neutron activation analysis in serum and urine of 31 patients with depressive psychosis and of 27 normal controls. Mean renal clearance of vanadium was significantly lower and mean serum vanadium concentration significantly higher in depressed patients than in controls. Mean 24-h excretion of vanadium did not differ between the two groups. Vanadium excretion did not correlate with urine volume, with serum concentration or with age. In study 3, erythrocyte Na-K ATPase activity and serum vanadium concentrations were estimated in 58 patients. There was a strong negative correlation between the two, supporting the suggestion that changes in tissue vanadium concentration may explain the changes in sodium transport which occur in depressive psychosis.

In depressive psychosis intracellular sodium is raised (Coppen & Shaw, 1963), probably secondary to reduced active transport of sodium across membranes, e.g. plasma to CSF (Coppen, 1960), from saliva (Glen *et al*, 1969), out of erythrocytes (Naylor *et al*, 1973) and across the rectal mucosa (Peet, 1975). In the erythrocyte the reduction in active transport of sodium is probably secondary to reduced activity of Na-K ATPase (sodium potassium sensitive adenosine triphosphatase) (Naylor *et al*, 1973) not to reduction in number of Na-K ATPase molecules (Naylor *et al*, 1980).

It has been suggested that this change in sodium transport is secondary to raised tissue concentrations of vanadium (vanadate ion inhibits Na-K ATPase) in depressive illness (Naylor & Smith, 1981*a*). High vanadium concentrations seem to be of aetiological importance since methods designed to reduce them are antidepressant, e.g. ascorbic acid (Naylor & Smith, 1981*a*), methylene blue (Naylor & Smith, 1981*b*, Naylor *et al*, 1986) and EDTA (Naylor & Smith, 1981*a*; Kay *et al*, 1984) and some drugs used in depressive psychosis (e.g. lithium, carbamazepine) reverse the inhibition of Na-K ATPase by vanadate (Naylor *et al*, 1981; Naylor, 1984). Assay of tissue concentrations of vanadium presents considerable problems primarily because of the very low concentrations present in tissues and hence values reported have varied widely. Many techniques have been used, even enzyme methods, but the two techniques now most widely in use are atomic absorption spectrophotometry and neutron activation analysis. There is also uncertainty about which tissues are best sampled for estimation of trace element status: e.g. some suggest hair but others disagree.

Dick *et al* (1982) reported that plasma vanadium concentration, estimated by atomic absorption spectrophotometry, was significantly higher in depressed patients than in normal controls. Naylor *et al* (1984), using neutron activation analysis to assay vanadium, reported that serum and whole blood vanadium concentrations were higher in a depressed group than in a recovered or normal group. Similarly Conri *et al* (1986) found higher serum vanadium concentrations in depressed patients than in normal controls. In contrast, Ali *et al* (1985) using neutron activation analysis found no difference between whole blood vanadium of depressed, recovered and control subjects. None of these studies used the same patients when ill and on recovery.

Although it has been suggested that changes in vanadium concentration may account for the changes in sodium transport, the only experimental evidence for this is the report of a significant negative correlation between the erythrocyte Na-K ATPase activity and serum vanadium in a small group of short cycle manic depressive patients (Dick *et al*, 1982).

The present paper reports three separate studies.

(1) Change in tissue vanadium concentrations on recovery from depression, using the same patients when depressed and on recovery.

(2) Urinary excretion of vanadium in depressed patients compared with that of normal controls.
(3) Correlation of serum vanadium with erythrocyte Na-K ATPase in depressed patients.

Method

Study 1: Change in tissue vanadium concentrations with recovery from depression

Shortly after admission, physically healthy female patients suffering from a depressive psychosis were admitted to a metabolic ward for at least 4 days before samples were taken. During the time in the metabolic ward patients had a fixed intake of Na, K and calories but a free, though recorded, fluid intake. The only drug they received was nitrazepam 10 mg as night sedation. After the samples were taken, patients returned to the admission ward, where they were treated as necessary by a variety of antidepressant regimes. When they had fully recovered they were again admitted to the metabolic ward for a further 4 days when the regime, including diet, drug treatment, etc was the same as on the first occasion.

Each patient was seen separately for diagnosis by two psychiatrists. All patients fulfilled the Feighner criteria (Feighner *et al*, 1972) for depression and all were given an ICD diagnosis of manic depressive psychosis—depressed type by both psychiatrists. Patients who did not fulfil these diagnostic criteria were excluded. During the time in the metabolic ward, they were rated twice daily by trained nursing staff on a 7-point global scale and on the day of blood sampling they also completed the Beck self rating inventory (Beck *et al*, 1961).

Two samples of fasting venous blood were taken at 09:00, one into sodium heparin and the other into a plain tube. Vacutainers were used to minimise risk of contamination. After the blood in the plain tube had clotted, it was centrifuged and the serum removed and saved. A sample of hair, about the size of the small finger, was taken from the nape of the neck close to the scalp, placed in a polythene bag and saved. A 24-h urine collection was made (patients only had access to a dry toilet), the volume noted, the sample well mixed and aliquots taken. All samples were stored at −20° C until the study was complete and then transported to the laboratory for analysis (i.e. depressed and recovered patient samples were analysed together as one batch).

Study 2: Urinary excretion of vanadium

The patients were severely depressed in-patients either at Royal Dundee Liff Hospital or Murray Royal Hospital, Perth. Patients were interviewed by one of the authors. All patients were suffering from manic depressive psychosis—depressed type (ICD 296.1). All were rated above 6 on the Newcastle Scale (Carney *et al*, 1965) and all fulfilled the Feighner Criteria for Depressive Illness (Feighner *et al*, 1972). Patients with physical illness were excluded from the study. Patients received only nitrazepam for at least 3 days before urine and blood sampling.

The controls were physically healthy, drug-free subjects who were not related to the patients but were mainly, though not only, hospital staff.

A 10 ml sample of venous blood was taken into a plain glass container with no anticoagulant. After clotting, the sample was centrifuged, the serum removed and stored at −20° C for later analysis.

A 24-h collection of urine was made on each subject: urine was collected in polythene bottles with 20 ml of 5% EDTA as preservative. The collection was well mixed, the volume measured and aliquots taken and saved at −20° C for later analysis. Samples from patients and controls were accumulated over the same time. Serum and urine samples were saved until the study was complete. Patient and control samples were analysed together in one batch.

Study 3: Correlation of erythrocyte Na-K ATPase activity and plasma vanadium concentration

A 10 ml sample of venous blood was taken at 09:00 into sodium heparin from each of 58 physically healthy female in-patients. The diagnostic procedure was the same as in the other two studies—all patients fulfilled the Feighner criteria and all were suffering from manic depressive psychosis—depressed type. As in study 1, all patients were maintained in a metabolic ward for at least 4 days before blood sampling and the only drug they received was nitrazepam. In contrast to study 1, only one sample was taken from each patient but patients were at different phases of the illness, i.e. not only acutely depressed and recovered but many were partially recovered.

Blood was centrifuged, plasma removed and Na-K ATPase assayed on the erythrocytes. Plasma was stored at −20° C for later estimation of vanadium concentration: again these were saved until the study was complete and analysed together as one batch.

Biochemical method

Estimation of vanadium concentration

A 5–10 ml urine sample was 'concentrated' to 1 ml under an i.r. lamp (12–24 h) enclosed in a dust-free partial vacuum chamber, placed within a controlled fumehood (Clean Room Construction Ltd) environment. An adequate proof of this technique is shown by the analysis of National Bureau of Standards, Standard Reference Material Bovine Liver (NBS-SRM, 1577) reported elsewhere (Ward *et al*, 1979; Ward, 1983). The 'concentrated' urine or blood serum sample underwent wet destruction of the organic content using a teflon bomb with subsequent ion-exchange separation using hydrated antimony pentoxide (Ward & Ryan, 1979). Neutron activation analysis measurements for vanadium were made after 300-s irradiation, 60-s decay and 300-s count using the ^{52}V nuclide 3.8 min half-life at 1434 keV gamma-ray energy. The detection limit for this method is 0.0002 ug/g. All samples were analysed blind to the clinical classification.

TABLE I

Concentration of vanadium in tissues of patients when ill and on recovery (probability by two-tail 't' test for correlated means)

Erythrocyte Na-K ATPase Activity

Erythrocyte membranes were prepared from washed cells by haemolysis in 10 mmol/litre tris-HCl buffer, pH 7.4 (Dick *et al*, 1969) for estimation of Na-K ATPase activity and were then assayed by a modification of the method of Bonting (1970), whereby the phosphotungstate formed was estimated by extraction into ethylacetate and measured at 310 nm with a UV spectrophotometer. The whole procedure was carried out in duplicate.

Results

Study 1: Change in tissue vanadium concentrations with recovery from depression

Samples were collected from 13 female patients (seven unipolar, six bipolar) mean age 57.6-13.3 years. In all three tissues, (hair, whole blood and serum) the concentration of vanadium decreased signficantly with recovery (Table I). Concentration of vanadium in hair decreased in 11 of the 13 patients, in whole blood in 10 of the 13 patients, and in serum in 12 of the 13 patients. Results were similar in both the unipolar and bipolar group.

The concentration of vanadium in urine on recovery was significantly lower ($P<0.05$) than that when depressed but there was no statistically significant change in urine volume, 24-h urinary excretion of vanadium or renal clearance of vanadium.

There was no significant correlation between measures of depression, e.g. Beck self rating inventory and any of the vanadium estimations.

Study 2. Urinary excretion of vanadium

Samples were obtained from 31 patients (29 females, two males) with mean age 54.7 ± 12.9 years and from 27 controls (24 female, three males) with mean age 50.5 ± 11.2 years.

The results of patients and controls are shown in Table II. There was no significant difference between urine volumes of patients and controls. Mean urinary vanadium concentration of the depressed group (5.93 ± 1.50 ng/ml) was not significantly different from that of the control group (6.24 ± 3.00 ng/ml). Similarly, the total vanadium excreted in 24-h did not differ significantly between the two groups. In contrast, mean serum vanadium concentration was significantly higher in the depressed group (5.01 ± 1.16 ng/ml) than in the control group (4.30 ± 1.13 ng/ml: $P<0.05$). The 24-h vanadium clearance was calculated: there was a highly significant difference between that of patients (1820 ± 520 ml) and that of controls (2430 ± 790 ml: $P<0.002$).

Eleven of the patients were bipolar and 20 unipolar. There was no significant difference between any of the urinary values of the bipolar and unipolar patients.

There was no significant correlation between serum vanadium concentration and urine concentration or 24-h vanadium excretion. There was, however, a strong negative correlation between 24-h urine volume and urine vanadium concentration (normals, $r=-0.61$, $n=27$, $P<0.001$; patients, $r=-0.69$, $n=31$, $P<0.001$).

Study 3. Correlation of erythrocyte Na-K ATPase activity and plasma vanadium concentration

Samples were obtained from 58 female depressed patients and erythrocyte Na-K ATPase activity and plasma vanadium estimated. Mean erythrocyte Na-K ATPase activity was 1.26±0.37 mmol PO4/litre RBC/h and mean plasma vanadium 4.62±1.30 ug/litre. There was a strong negative correlation between plasma vanadium concentration and erythrocyte Na-K ATPase activity ($n=58$, $r=-0.41$, $P<0.002$).

Discussion

The first study confirms earlier studies which had suggested that tissue concentrations of vanadium are raised in depression compared with recovery. All patients were in a metabolic ward for at least 4 days before the assays. Published data on vanadium content of food is conflicting and appears to depend, in part, on where it is grown. It was not possible, therefore, to give patients a known vanadium intake but since patients ate exactly the same diet for 4 days before each assay, the intake of vanadium over that time was the same on each occasion. It is possible, however, that 4 days of controlled diet was not long enough for patients to reach equilibrium. Depressed patients prior to admission are likely to have a reduced dietary intake and moderate weight loss which is reversed on recovery. Whether weight loss can bring about an increase in tissue vanadium concentration and therefore explain the findings in the first study (e.g. by loss of muscle but without excretion.of the released vanadium) is not known but seems unlikely in view of the urinary excretion of vanadium. It is more probable that reduced food intake leading to weight loss is likely to be accompanied by reduced vanadium intake with consequent reduction in tissue concentration.

Previous drug intake of patients also complicates the interpretation of the results. Although patients were drug free, apart from benzodiazepines, for at least 4 days prior to assessment, this may have been inadequate to obviate drug effects. In animals, the biochemical changes induced by psychotropics often persist for 2 weeks or more after administration and it is known that some psychotropic drugs affect vanadium metabolism, e.g. lithium and carbamazepine inhibit vanadium induced inhibition of Na-K ATPase. However, there are ethical difficulties in withholding drugs from severely depressed patients for prolonged periods for the sake of research. Since the first assay was carried out shortly after admission to hospital, the drugs the patient took before admission may be important but it is not only difficult to establish what drugs they were prescribed, it is impossible to determine with certainty which drugs they actually swallowed. As with virtually all clinically based research of this nature it must, therefore, remain a possibility that some of the changes found could be drug-induced. However, it must also remain a possibility that such putative drug-induced changes are the means by which the drugs exert their therapeutic effects.

The changes in tissue concentrations were shown in a tissue which reflects short-term changes, i.e. serum and also a tissue which reflects long-term changes, i.e. hair. Changes in hair must have occurred early after admission since the sample from the recovered patients must have been growing for several weeks before full recovery. It was of interest that, although tissue concentrations changed, there was no significant change in 24-h renal excretion of vanadium. However, if patients were stable and presumably in balance on each occasion, one would not expect the 24-h urine excretion to differ if the intake was the same. The renal clearance did show a non-significant ($P<0.1$) increase with recovery.

In estimating 24-h excretion, accuracy of urine collection is essential. It seems unlikely in the second study that the collections of the patients were any less complete than those of the normals; there was no significant difference between 24-h urine volumes; correlation of vanadium concentration with urine volume was strongly negative in both groups; it was more difficult for normal controls to make a full collection, e.g. while at work, than for patients who only had access to a dry toilet. More important, concentrations of many other elements were estimated (e.g. K, Al, Ba, etc) in the urine and there was no evidence of a consistent trend for patients to have a reduced 24-h urinary excretion of these, i.e. no evidence that 24-h urine collections in the patients were less complete than those of controls. Studies, like the present one, which compare patients with controls must be interpreted with some caution because of the uncertainty of the comparability of the two groups, i.e. controls differ in several ways other than mood from patients, e.g. activity, diet, sleep pattern, etc. However, mean serum concentrations of vanadium in this study (patients 5.01±1.16 ng/ml, controls 4.30±1.13 ng/ml) were remarkably similar to those obtained in a previous separate study (patients 5.09±1.80 ng/ml, controls 4.13±1.13 ng/ml) (Naylor *et al*, 1984).

The results of study 2 suggest that the renal clearance of vanadium is reduced in depressive psychosis, compared with normal controls but no significant change in renal clearance occurred in the first study with recovery although tissue concentrations fell. It is possible that the results of the first study simply failed to reach statistical significance ($P<0.1$) but it appears that renal clearance in the recovered patients was still lower than that of controls. It is possible that the differences were due to differences in diet between patients and controls, since it is not possible to control dietary vanadium but this would more likely affect tissue concentrations than renal clearance: serum concentrations of recovered and control groups were similar although renal clearance still differed. Without further research on the mode of renal excretion of vanadium the present results can only be taken as suggestive that changes in renal excretion of vanadium may occur in manic depressive illness and warrant further investigation. However, there are other possible ways for vanadium concentration of tissues to change, e.g. by change in absorption from the gut, change in dietary intake, change in tissue binding, etc. These possibilities also require investigation.

There is now reasonable agreement that the active sodium transport (measured as transport or Na-K ATPase activity) of erythrocytes is reduced in depressive psychosis and increases with recovery. The suggestion, that changes in vanadium concentrations are involved in this, is strengthened by the finding of a strong negative correlation between plasma vanadium concentration and Na-K ATPase activity. The relatively high correlation with plasma levels was perhaps surprising since vanadate acts on the inside of a cell membrane, not the outside, most intracellular vanadium is in the form of vanadyl which is much less inhibitory of sodium transport and the correlations were on inter- not intra-patient measures.

It is possible that changes in vanadium in depressive psychosis are an unimportant secondary phenomenon but this is unlikely since methods which reduce vanadate concentration appear to be antidepressant (Naylor & Smith, 1981*a*; Kay *et al*, 1984). How vanadium relates to symptoms is uncertain but there are several ways in which it is known to interrelate with neuronal function. Vanadate ion is a potent inhibitor of the sodium pump (Cantley *et al*, 1977) and the distribution of sodium and potassium is involved in the conduction of the nerve impulse and is involved in both release and uptake of amines at synapses. Vanadate is bound directly by noradrenaline and noradrenaline will reverse the vanadium-induced inhibition of the sodium pump. Vanadate ion also directly affects amine metabolism: large doses of vanadium given to rats produce changes in cerebral catecholamines and indolamines (Witkowska & Brzyzwiski, 1979), and vanadium compounds, both pentavalent and tetravalent, directly catalyse oxidation of some catecholamines and of 5-hydroxytryptamine. Depression or melancholia is often given as one of the symptoms of vanadium poisoning (Witkowska & Brzyzwiski, 1979). However, it is not an inevitable symptom of vanadium poisoning and therefore patients with depressive psychosis must have some other abnormality to account for their vulnerability to raised vanadate levels. There have been reports of genetic abnormalities in β-adrenoceptors (Wright *et al*, 1984) in acetyl choline receptors (Nadi *et al*, 1984) and in Na-K ATPase (Naylor & Smith, 1981*c*) in manic depressives which may be of relevance.

This paper offers further evidence that vanadium metabolism is altered in depressive psychosis. The results confirm the suggestion that tissue levels of vanadium fall with recovery from depression and support the suggestion that changes in vanadium concentrations are responsible for the change in sodium transport reported in depressive illness. The results suggest that changes in renal excretion of vanadium may occur. This area of investigation warrants further study.

Epidemiology of Puerperal Psychoses

R. E. KENDELL, J. C. CHALMERS and C. PLATZ

Computer linkage of an obstetric register and a psychiatric case register made it possible to investigate the temporal relationship between childbirth and psychiatric contact in a population of 470 000 people over a 12-year period resulted in 54 087 births: 120 psychiatric admissions within 90 days of parturition. The 'relative risk' of admission to a psychiatric hospital with a psychotic illness was extremely high in the first 30 days after childbirth, particularly in primiparae, suggesting that metabolic factors are involved in the genesis of puerperal psychoses. However, being unmarried, having a first baby, Caesarian section and perinatal death were all associated with an increased risk of psychiatric admission or contact, or both, suggesting that psychological stresses also contribute to this high psychiatric morbidity. Women with a history of manic depressive illness, manic or depressive, had a much higher risk of psychiatric admission in the puerperium than those with a history of schizophrenia or depressive neuroses, and the majority of puerperal admissions met Research Diagnostic Criteria for manic or depressive disorder. Probably, therefore, puerperal psychoses are manic depressive illnesses and unrelated to schizophrenia.

The effect of childbirth on psychiatric morbidity has been studied many times, and it is well established that the incidence of psychotic illnesses rises dramatically in the first few weeks or months after childbirth, and that such illnesses are commoner in women with a previous history of psychiatric illness, and commoner in primiparae than in multiparae. The magnitude of this increased risk of psychosis, and its duration, have, however, not yet been quantified with any accuracy, nor is it yet clear whether obstetric and demographic variables other than parity influence the risk. Three requirements have to be met before these issues can be settled. First, the puerperal psychoses studied must be drawn from a geographically defined population. It is not sufficient simply to study all women admitted to a particular hospital or mother-and-baby unit unless that hospital or unit has a precisely defined catchment area which it does not share with any other hospital or unit. Secondly, obstetric and other risk factors cannot be identified with any confidence unless accurate information is available about the incidence of these factors in the same geographically defined population and time period in women who do not develop psychiatric disorders. Thirdly, because some of the most important potential risk factors, like perinatal death, are fairly rare events, large populations may need to be studied.

A computer linkage of separate psychiatric and obstetric registers provides an effective means of meeting these three requirements. We have previously reported such a study, involving linkage of the Edinburgh Psychiatric Case Register (EPCR) and Scottish maternity discharge data, based on the 35 729 episodes of childbirth taking place in a geographically defined population of 470 000 over a 7-year period (Kendell *et al*, 1981*b*). The present investigation is an extension and amplification of that 1981 study, based on the 54 087 episodes of childbirth occurring in the same population over an 11-year period. It involves four main improvements or innovations. The larger numbers make it easier to estimate the risks associated with comparatively rare events like perinatal death and twin delivery. The longer time period makes it possible to estimate the 'relative risk' associated with childbirth much more accurately. The combination of larger numbers and a longer time period makes it possible to compare the risk of a puerperal psychosis in women with earlier admissions, unrelated to childbirth, with psychiatric disorders of different kinds. And lastly, because the EPCR was expanded in 1978 to cover all psychiatric contacts as well as all admissions, it is now possible to examine risk factors for out-patient or general hospital contact as well as for psychiatric admission.

Method

The catchment area of the Royal Edinburgh Hospital includes the whole of the city of Edinburgh (population 470 000). The EPCR has recorded data on all admissions from this population since 1 January 1970 and on all psychiatric contacts (as out-patient, domiciliary visit or general hospital ward referral) since 1 January 1978. The Information Services Division of the Scottish Health Service has collected extensive information on all hospital deliveries in Scotland (which in Edinburgh are over 98% of all deliveries) since 1 January 1971. The study covered the 12-year period from 1 January 1970 to 31 December 1981. Information was extracted from the EPCR on all women with a psychiatric admission or other psychiatric contact during this 12-year period who were aged 15–44 inclusive and living within the city at the time of admission or contact. This file was then linked to a similar file extracted from the maternity discharge records, containing data on all episodes of childbirth in any of the five obstetric units in or near Edinburgh during the 11-year period from 1 January 1971 to 31 December 1981 in which the mother's home address was within the city. In this way all Edinburgh women with both a psychiatric contact and an episode of childbirth between 1 January 1970 and 31 December 1981 were identified. The record-linkage system used was the same as that used in the original 1981 study and is described by Heasman & Clarke (1979). It uses surname, maiden name, initials, sex and date of birth as identifying characteristics and the Russell Soundex Code, which makes allowance for common misspellings, for matching. The program actually assigns each pair of women an estimate of the likelihood that the two individuals – the mother and the psychiatric patient – are the same person. There were 154 doubtful matches. These were checked by reference to the original psychiatric and obstetric case-notes and in most cases it was possible to say confidently whether the two belonged to the same individual. Seventy of the 154 were correct matches, 79 were incorrect and 5 remained doubtful. The 70 correct matches were retained and the other 84 discarded.

TABLE I

Temporal relationship between psychiatric admission and childbirth

Time period (successive 90-day periods)		*Number of psychiatric admissions in the three successive 30-day periods*					
		All diagnoses			*Functional psychoses*[1]

Temporal relationship between childbirth and psychiatric admission

In order to assess the effect of childbirth on admission rates we examined the distribution of psychiatric admissions in the 2 years before and the 2 years after parturition. As details of psychiatric admissions were available for the 12-year period 1970–1981 inclusive this meant examining the distribution of admissions in women with an episode of childbirth in the 8-year period from 1972–1979. The distribution of the psychiatric admissions of these women was calculated for 24 successive 30-day periods both before and after parturition, counting each episode of childbirth within that 8-year period separately. The results are shown in Table I and Fig. 1(a). As most other investigators have found, and as we ourselves found in our earlier study, there is a dramatic rise in the admission rate in the first few months after childbirth. The average number of admissions a month in the fifteen 30-day periods before the onset of pregnancy is 10.0 and the average number a month in the nine 30-day periods during pregnancy is 7.11. The latter is significantly lower than the former (Mann Whitney $U=33$ and $P<0.05$); that is, as Pugh *et al* (1963) found in Massachusetts, pregnancy is associated with a significant reduction in the admission rate. In the first 30 days after childbirth there are nearly seven times as many admissions as the average monthly admission rate before pregnancy (68 *v.* 10). Although this very high admission rate is not sustained, the admission rate after childbirth remains higher than it was before the onset of pregnancy for at least 2 years. Even if the first 90 days after childbirth are discounted, the average admission rate thereafter (i.e. in the last twenty-one 30-day periods) is significantly higher than that in the fifteen 30-day periods before the onset of pregnancy (13.0/month *v.* 10.0/month; Mann Whitney $U=82.5$ and $P=0.016$). It is also worth noting that the 'excess' of admissions in the first 90 days after childbirth is far greater than the 'deficit' of admissions during pregnancy. In other words, the excess after childbirth is far too great to be explained by the postponement of a proportion of pregnancy admissions.

Table I and Fig. 1b show the number of admissions with a hospital discharge diagnosis (ICD-9 criteria) of some kind of functional psychosis. The effect of childbirth on the psychosis admission rate is even more dramatic than on the overall admission rate. The average rate of psychosis admissions before pregnancy is 2.07/month and the average during pregnancy is 2.0/month, virtually identical. There are then 51 psychosis admissions in the first 30 days after parturition, more than in the whole of the previous 2 years. Although the admission rate falls fairly rapidly thereafter it remains significantly higher throughout the 2-year period after childbirth than it had been before. Even if the first

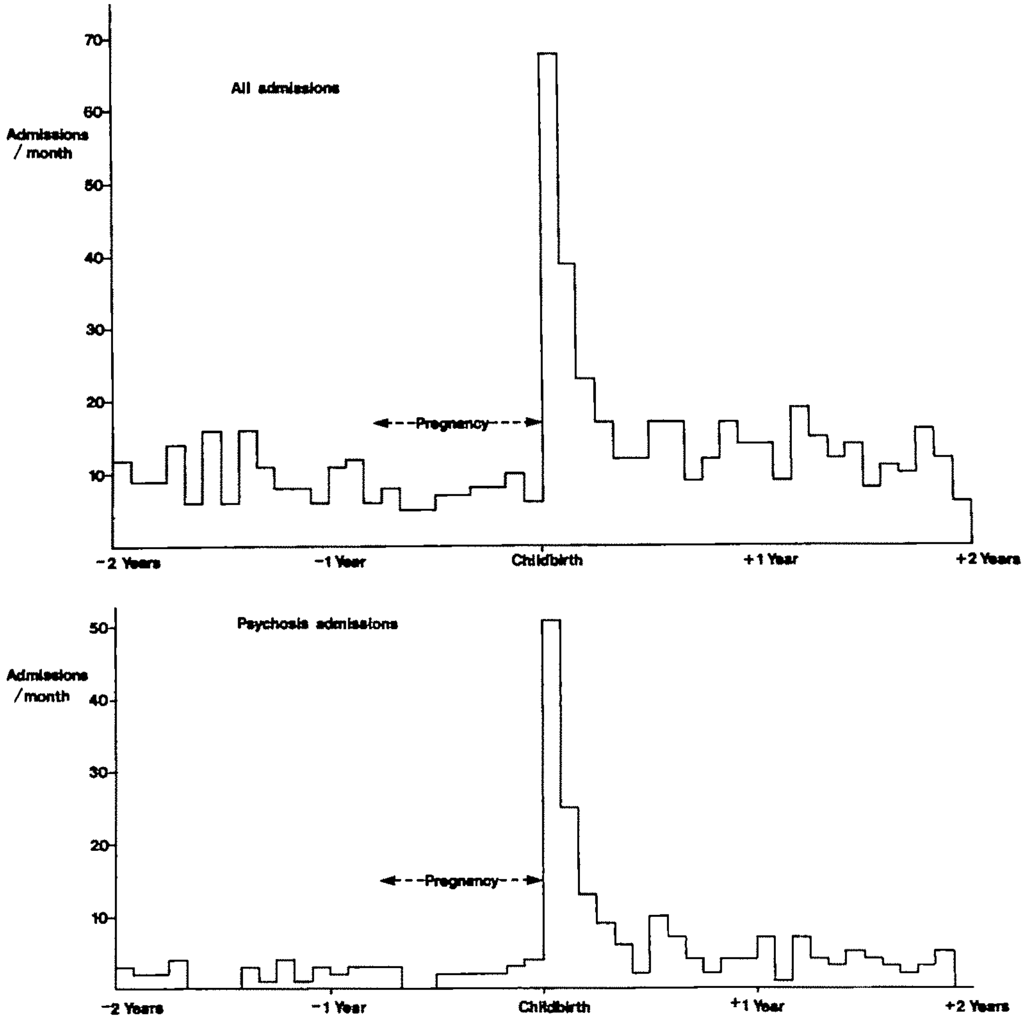

FIG. 1 Temporal relationship between psychiatric admission and childbirth: (a) all admissions; (b) psychosis admissions.

90 days after childbirth are excluded, the average admission rate in the following twenty-one 30 day periods is 4.38/month, compared with 2.04/month in the twenty-four 30-day periods before childbirth (Mann Whitney $U=107$ and $P=0.001$).

The relationship between age and psychiatric admission rate is considered in Appendix 1.

Relative risk associated with childbirth

The ratio of the number of admissions immediately after childbirth to the average admission rate beforehand is a measure of the 'relative risk' associated with childbirth and its magnitude is of considerable importance. In fact the relative risk varies considerably depending on the length of time over which it is measured, on whether one considers all psychiatric admissions or only psychoses, and on whether one considers all mothers or only primiparae. For psychiatric admission the relative risk is $43.3/10.0=4.3$ over the first 90 days, and $68/10.0=6.8$ over the first 30 days. For admission with a psychosis the relative risk is $29.7/2.07=14.3$ over 90 days, and no less than $51/2.07=24.6$ over the first 30 days. These estimates are all somewhat inflated, however, because not all the women living in the register catchment area at the time of delivery would have done so throughout the preceding (or the following) 2 years, and any psychiatric admissions they might have had while living elsewhere would not have been recorded. As a result the average admission rates calculated for the 15 months before pregnancy – the denominator of the ratio from which the relative risk is derived – will be too low. We know from a follow-up study of the women concerned that 18% (21 of the 120, with three untraced) had left the catchment area

TABLE II

Increased risk of psychiatric admission associated with pregnancy and childbirth[1]

	Relative risk[2]	*Attributable proportion*[3]
Admission during pregnancy	0.65	—
Admission with a psychosis during pregnancy	0.88	—
Admission within 90 days of childbirth	3.8	0.74
As above – primiparae only	5.8	0.83
Admission within 30 days of childbirth	6.0	0.83
As above – primiparae only	10.9	0.91
Admission with a psychosis within 90 days of childbirth	12.7	0.92
As above – primiparae only	17.8	0.94
Admission with a psychosis within 30 days of childbirth	21.7	0.95
As above – primiparae only	35.0	0.97
Admission within 2 years of childbirth, excluding the first 90 days	1.3	0.10
As above – primiparae only	1.1	0.09
As above – multiparae only	1.4	0.28
Admission with a psychosis within 2 years of childbirth, excluding the first 90 days	2.1	0.52
As above – primiparae only	1.8	0.46
As above – multiparae only	2.3	0.56
Admission within 2 years of childbirth (including the first 90 days)	1.6	0.38
Admission with a psychosis within 2 years of childbirth (including the first 90 days)	3.5	0.72

1. The base rates, calculated from the average admission rate/month in the 15 months before the beginning of pregnancy and corrected as described in the text were 29.48 admissions per 100 000 women per month and 6.10 psychotic admissions per 100 000 women per month.
2. Ratio of the admission rate in the time period in question to the admission rate of the same population of women before pregnancy.
3. Proportion of admissions in the defined period after childbirth which are directly attributable to the effect of childbirth.

within 2 years of childbirth. If we assume that the same proportion entered the catchment area within the 2 years before childbirth, and did so at a constant rate, both the denominator and the numerator can be corrected for this source of error. This correction reduces the relative risk of admission calculated over the first 30 days by about 12%, and over the first 90 days by about 11%.

The relative risks listed in Table II have all been corrected in this way. Pregnancy is associated with a relative risk of less than 1, and this reduction is more substantial for all admissions than for psychotic admissions. The relative risk of admission is high in the first 90 days after childbirth and higher still in the first 30 days. In this immediate post-partum period it is increased further if only psychotic admissions are considered, and is also considerably higher in primiparae than in multiparae. The effects of shortening the time period from 90 days to 30, of focusing upon primiparae, and of focusing on psychotic admissions are additive, so that the highest relative risk of all – the remarkable value of 35.0 – is the risk for a woman with no previous children of being admitted with a psychotic illness in the first 30 days after childbirth.

These remarkably high relative risks are shortlived, as Fig. 1 illustrates. However, the relative risk remains raised for at least 2 years after parturition. Even if the first 90 days after childbirth are excluded, the relative risk of psychiatric admission is 1.3 (i.e. 30% above the risk before the onset of pregnancy) throughout this 2-year period and the relative risk of admission with a psychotic illness is higher still at 2.1 (i.e. 110% above the risk before pregnancy). And at this stage the relative risk is higher in multiparae than in primiparae rather than the other way about, both for admission and for admission with a psychosis (see Table II).

(All these calculations of relative risk ignore the fact that some women would have had more than one episode of childbirth during the 4-year period of study. Second episodes of this kind would be equally common before and after the index episode and would tend to elevate the admission rate, particularly in the following 3 months. The overall effect of this complication would be to reduce the before/after difference; that is, the true relative risks will be somewhat *higher* than the values in Table II suggest.)

Temporal relationship between childbirth and psychiatric contact

Because the EPCR only started to record psychiatric contacts other than admissions (i.e. out-patient contacts, general hospital ward referrals and domiciliary visits) on 1 January 1978, data were only available for the 4 years 1978–1981. For this reason we only examined the distribution of 'new contacts' (defined as any psychiatric contact other than admission without any other psychiatric contact in the previous 90 days) over the 12 months before and the 12 months after childbirth. Even this limited analysis could only be based on 2 years' births; that is, episodes of childbirth in 1979 and 1980. The results are shown in Table III and the general pattern is the same as it was for admissions. The average number of new contacts a month in the twelve 30-day periods before parturition is 7.08. The monthly average is higher before pregnancy than during pregnancy (8.67 *v.* 6.56) but the difference is not significant. The number of new contacts a month rises sharply after childbirth. The rise is not so dramatic as for psychiatric admissions, but even so there are more new contacts in the first 90 days after childbirth than in the whole 9 months of pregnancy. Furthermore, as for admissions, the new contact rate remains higher than it was before childbirth even after this first 90 days. The average number of new contacts a month in the last nine 30-day periods

TABLE III
Temporal relationship between new psychiatric contacts (other than admissions) and childbirth

Time period (successive 90-day periods)		*Number of new contacts in the three successive 30-day periods*		
	−4	12	7	7
	−3	6	10	7
Pregnancy	−2	3	5	10
	−1	6	6	6
	+1	25	19	16
	+2	7	9	9
	+3	16	10	10
	+4	8	7	8

is 9.33, compared with 7.08 in the twelve 30-day periods before childbirth (Mann Whitney $U=25$ and $P<0.05$).

Risk factors for psychiatric admission or contact in the puerperium

At present there is no consensus on the maximum interval between childbirth and psychiatric presentation during which an illness should be designated as puerperal. Some authors, like Tetlow (1955) and Paffenbarger (1964), accepted as puerperal any illness leading to hospital admission within 6 months of delivery. Others, like Brockington *et al* (1982), have argued that the term should be restricted to illnesses starting within 2 or 3 weeks of delivery. The evidence presented in Tables I and III and Fig. 1 strongly suggests that 90 days is the most appropriate cut-off point if the time of psychiatric admission or contact is to be the criterion. Although the admission rate is highest of all in the first 30 days after childbirth and falls steeply thereafter, it is still higher between 60 and 90 days than at any time during the 2 years before childbirth and any time in the subsequent 21 months. Moreover, this is so not only for psychiatric admissions as a whole, but for psychoses on their own, and for psychiatric contacts as well. Between 90 and 120 days, however, the admission rate is no higher than in several later months, and again this is so for psychoses and psychiatric contacts as well. For this reason, as in our 1981 study, we define the puerperium as lasting for 90 days and therefore looked for risk factors for admission within that 90-day period.

In the 11-year period 1971–1981 inclusive, 120 episodes of childbirth were followed within 90 days by the mother's admission to the Royal Edinburgh Hospital without that woman having been a psychiatric patient within the last 90 days of her pregnancy. (These 120 episodes of childbirth involved 116 different mothers; four had two puerperal admissions within this 11-year period. For 74 of the 116 it was their first psychiatric admission; 34 had had previous non-puerperal admissions, three had had previous puerperal admissions and four had had both puerperal and non-puerperal admissions previously.) These 120 puerperal admissions came from the 54 087 births to women living in the city of Edinburgh within that 11-year period. The overall risk of puerperal admission is therefore 2.2 per 1000 births.

The RDC diagnoses of these 120 admission are shown in Table IV. As most others who have used RDC (Spitzer *et al*, 1978) have found, the majority of patients have affective disorders, either depressive or manic, and patients fulfilling criteria for schizophrenia are rare. There are, however, a substantial number of patients with illnesses which are psychotic but which do not fulfil criteria for any recognised disorder, and so have to be assigned to the residual category of unspecified functional psychosis.

The time of onset of the symptoms of these 120 patients relative to childbirth is shown in Table V. In early half the onset was within the first week after childbirth and in nine the onset had occurred before childbirth, though in most cases with a further exacerbation afterwards. There was no strong tendency for the onset to occur on any particular post-partum day. The third day (12 patients) and the seventh (13 patients) were the commonest, so our previous suggestion (Kendell *et al*, 1981*a*) that the mood disturbance on the fifth post-partum day coincides with the peak time of onset of puerperal psychoses is not supported. Nor was a 'lucid interval' always present; in eight patients the onset was on the first or second post-partum day. (The 71 patients in this series who were admitted to hospital in the 7-year period 1971–1977 inclusive have been described in detail previously (Dean & Kendell, 1981).)

[1] Only recorded in 1975–81.

As extensive obstetric and demographic data (known locally as SMR2 data) are recorded on the maternity discharge sheet for all episodes of childbirth, it was possible to compare the incidence of a wide range of potential risk factors in the 120 puerperal admissions and the remaining 53 967 births which were not followed by psychiatric admission. The results are presented in Tables VI and VII. As can be seen from Table VI, parallel comparisons were also carried out for three subgroups of the 120 admissions: (a) those with psychotic symptoms (defined as hallucinations, delusions, incoherent or grossly thought-disordered speech, mutism or consistently bizarre behaviour); (b) those whose illness started within the first 15 days after childbirth; and (c) those who fulfilled the criteria of Perris & Brockington (1981) for a cycloid psychosis. These three subgroups were not mutually exclusive. In fact 40 women had psychotic symptoms as well as an onset within 15 days of childbirth, and all the cycloid women were also psychotic by definition. Membership of these subgroups was determined – as were the RDC diagnoses and the timing of the onset of symptoms – by detailed examination of the original medical and nursing case-notes. This means, of course, that some women who perhaps should have been assigned to one or more of these subgroups were not because the relevant information was not recorded in their notes.

During the 4 years 1978–1981 inclusive there were 50 psychiatric contacts by women with a home address in the city of Edinburgh which occurred within 90 days of childbirth, were not followed by admission to hospital and had not been preceded by any psychiatric contact within the last 90 days of pregnancy. The role of the potential risk factors was examined in these 50 women in the same way as in the 120 in-patients, except that the control population was restricted to the 18 358 births to Edinburgh women occurring in the 4-year period 1978–1981.

Table VI lists all the statistically significant differences obtained between any of these five patient groups and the controls. Several of them involve marital status. There is an excess of widowed, separated or divorced mothers both in admissions and in contacts, and an excess of single mothers in admissions with an onset of symptoms within 15 days of childbirth. Mainly as a consequence of these differences, currently married women are significantly under-represented in the 'all admissions' and 'onset within 15 days' groups. Strangely, the obstetric register does not record parity as such, though it does record the number of living children and the number of previous pregnancies. The group of all admissions and each of its three subgroups show a significant excess of mothers with no living children. The cycloid psychosis and onset within 15 days subgroups also contain a significant excess of women with no

1. These items were only recorded in 1975–1981.
2. These items were only recorded in 1971–1979. For this reason it was not feasible to compare 1978–1981 contacts with controls.

The three subgroups of admissions (those with psychotic symptoms, those with an onset within 15 days, and cycloid psychoses) were also compared with the controls on all the variables shown here but none of the differences was statistically significant.

previous pregnancies. A strikingly high proportion of the psychiatric contacts followed Caesarian section. In our 1981 study, psychiatric admissions had also shown a statistically significant excess of Caesarian sections. This time they failed to do so, though the psychotic subgroup came close ($\chi^2 = 3.58$ and $0.1 > P > 0.05$ with 1 d.f.). Both elective sections and operations after a trial of labour contributed to the observed excess. There was a significant excess of perinatal deaths (i.e. stillbirths and neonatal deaths combined) in both admissions and contacts. There were also two quite unexpected findings. There was a significant excess of female babies in the psychotic admissions, and an incidence of prior spontaneous abortion significantly *below* chance expectation in both the psychotic and onset within 15 days subgroups of admissions.

Obstetric and other variables for which there was no statistically significant difference between the controls and any of the five patient groups are listed in Table VII. The mother's age, the length of gestation, the baby's birth weight, most aspects of the mother's obstetric history and a wide range of complications of pregnancy and delivery appear to have no influence on the risk of psychiatric morbidity in the puerperium. Nor do twin births or sterilisation after delivery.

Influence of previous psychiatric illness

The linkage of the EPCR and the maternity discharge (SMR2) data described above identified 486 women who between 1 January 1971 and 31 December 1981 had had a psychiatric admission before their first episode of childbirth (though they might have had other children before the obstetric register came into being on 1 January 1971). The existence of this large number of women with psychiatric illnesses severe enough to warrant hospital admission before childbirth made it possible to estimate the risk of developing a puerperal psychosis (defined as a psychiatric admission within 90 days of parturition) after subsequent pregnancies and to compare that risk in different diagnostic categories. The results are shown in Table VIII. It is clear that different diagnostic categories are associated with quite different risks, and that these are highest for manic/depressive illnesses (21.4% of deliveries in women with prior manic or circular illnesses being followed by a

TABLE VIII
Incidence of psychiatric admission in the puerperium in women with a prior history of psychiatric disorders of different kinds

Diagnostic category	*ICD-9 code*	*Number of women*	*Episodes of childbirth*	*Puerperal admissions*	*Risk of admission (%)*
Schizophrenia	295	22	29	1	3.4
Manic depressive: depressed	296.1	23	30	4	13.3
Manic depressive: manic or circular	296.0 296.2–5	10	14	3	21.4

All other diagnosis	—	352	462	19	4.1
Totals	—	486	638	29	4.5

psychiatric admission, and 13.3% of deliveries in women with previous depressive illnesses). The difference between the risk conferred by a previous manic depressive illness (ICD-9 296.0–5) and that conferred by other diagnostic categories is highly significant ($P = 0.00008$). So too is the difference between the risks conferred by manic depressive and schizophrenic illnesses ($P = 0.026$), and between those conferred by manic depressive illnesses and depressive neuroses ($P = 0.0005$). (All probabilities are two-tailed and derived by Fisher's Exact Test.) On the other hand the risks associated with schizophrenia and with depressive neuroses do not differ appreciably from those associated with the residual group of 'other diagnoses' (mainly neurotic illnesses, personality disorders and adjustment reactions). Even so, the risk associated with a prior psychiatric admission for any disorder other than a manic depressive illness (22 of 594, or 3.7%) is many times higher than the risk of 2.2 per 1000 births associated with childbirth as a whole. (Note that all these risks are based on the assumption that no-one either entered or left the register catchment area between their original psychiatric admission and their subsequent deliveries. They therefore provide only rough estimates of absolute risks, but should still give accurate estimates of comparative risks.)

Discussion

One of the main purposes of this study was to identify obstetric and social factors associated with an increased, or decreased, risk of psychiatric illness in the puerperium in the hope that the nature of these risk factors would shed light on the aetiology of puerperal disorders. It is already well established that primiparous women are at increased risk of puerperal psychoses and we demonstrated in our 1981 study that this finding could not be attributed simply to the avoidance of further pregnancies by women who had suffered a puerperal psychosis after their first. This heightened risk in primiparae is confirmed once more. All admissions and each of the three subgroups of these (i.e. psychotic illnesses, illnesses with an onset within 15 days of childbirth and cycloid psychoses) showed a statistically significant excess of mothers with no living children. Psychiatric contacts, on the other hand, did not.

There are also important relationships with marital status. Many investigators from Esquirol (1845) onwards have reported that puerperal psychoses are commoner in unmarried mothers, and our 120 psychiatric admissions contained a highly significant excess of women not currently married, though mainly because of an excess of widowed, divorced or separated women rather than of single women. The fact that the subgroup of admissions with psychotic illnesses does not contain any significant excess of unmarried women suggests that this might simply be a nosocomial effect; that is, that puerperal admissions contain a high proportion of unmarried mothers simply because women living alone with no husband to support them are more likely to be admitted to hospital if they become psychiatrically disturbed in the puerperium. However, the fact that psychiatric contacts also show a significant excess of widowed, divorced or separated women makes this unlikely. If women without husbands are admitted to hospital preferentially, psychiatric contacts should, if anything, show a deficit rather than an excess of mothers not currently married. All admissions, and each of their three subgroups, also contain a higher proportion of single women than the controls, though this is only statistically significant for those with an onset within 15 days. None of these relationships between psychiatric morbidity and marital status can be explained as a secondary consequence of age differences between patients and controls, for there were no age differences.

In our 1981 study we found Caesarian section to be a risk factor for psychiatric admission and for the most severely ill patients this relationship was significant at the 1% level. The fact that this relationship disappears with the larger numbers available here suggests that it may have been a chance finding. This is unlikely to be so, however, because there is, quite independently of that earlier finding, a highly significant excess of Caesarian sections in the psychiatric contacts. Moreover, the excess of Caesarian sections in the psychotic subgroup of admissions only just fails to achieve statistical significance ($P<0.10$).

The significant excess of perinatal deaths in both admissions and contacts is an important finding which did not emerge in our previous analysis, almost certainly because at that stage we had insufficient numbers for significant relationships with rare events like perinatal death to emerge. The relationship has, however, been reported before, by both Vislie (1956) and Paffenbarger (1964). Twin delivery, though, still fails to emerge as a risk factor. The disproportionate number of female children in all five patient groups is puzzling. Despite the fact that it reaches statistical significance in the psychotic subgroup of admissions, this is almost certainly a chance finding, for it has not been found in previous studies of puerperal psychoses. The significant *deficit* of mothers with a past history of spontaneous abortions in the psychotic and onset within 15 days subgroups of admissions is also unexpected, but cannot be dismissed so easily. It may, of course, be a chance finding, for it has not been reported before and the relationships are only significant at the 5% level. However, previous investigators have not had sufficiently accurate control data to be capable of identifying any such relationship, so the possibility that a hormonal environment which protects against abortion somehow increases the risk of puerperal psychosis, or vice versa, should not be dismissed.

We conclude, therefore, partly on the basis of these results and partly on the basis of the literature (reviewed by Kendell, 1985) that having a first baby, not having a husband at the time of childbirth, perinatal death and Caesarian section all increase the risk of serious psychiatric morbidity in the puerperium. All four of these situations were confidently identified by a representative group of 85 normal postpartum women as increasing the psychological stress of childbirth (see Kendell *et al*, 1981*b*), which suggests that psychological stresses of readily understandable kinds play a part in the genesis of all or most of these puerperal disorders. We deliberately refer to puerperal psychiatric disorders in general because the data summarised in Table VI do not suggest that the correlates of psychiatric admission are particularly different from those of psychiatric contact, or that in-patients with psychotic symptoms or with an onset within 15 days of childbirth are obviously different from in-patients as a whole. Although there is no evidence from these data that the incidence of perinatal death is raised in women with psychotic illnesses, or that primiparae are at increased risk of psychiatric contact, the general pattern of relationships is much the same across all five patient groupings. However, in addition to these indications that psychological influences are important, there is very substantial evidence that constitutional factors are involved in the genesis of puerperal psychoses, and probably also of puerperal depressions. Almost everyone who has studied the issue has found that a previous personal history or a family history of psychotic illness increases the risk of puerperal psychosis, and also that the occurrence of one puerperal psychosis increases the risk of a second – from 1 in 500 to 1 in 7 or even less (see Kendell (1985) for a summary of this evidence). The evidence is less clear-cut in the case of milder puerperal depressions, but here too most investigators have reported that a past history of psychiatric disorder increases the risk.

The large number of births and the comparatively long time period studied here has made it possible to calculate fairly accurate admission rates before and during pregnancy and at various intervals after childbirth. From these rates reasonably accurate estimates of the 'relative risk' associated with pregnancy and childbirth can therefore be calculated. As Pugh *et al* (1963) found in Massachusetts, the admission rate during pregnancy is significantly lower than the admission rate over the previous 15 months, with a relative risk of only 0.65. However, there is little fall during pregnancy in the admission rate for psychotic illnesses. This suggests that the fall in the overall admission rate may be a nosocomial effect rather than the result of any real reduction in psychiatric morbidity. That is, it seems likely that, whereas women who develop psychotic illnesses during pregnancy are still admitted to hospital, those with milder disorders are not, perhaps because the patient herself or her doctor hopes that she will recover spontaneously after delivery. Certainly prospective clinical studies suggest that overall psychiatric morbidity rises rather than falls during pregnancy (e.g. Kumar & Robson, 1984).

The 'relative risks' for psychiatric admission after childbirth and the corresponding 'attributable proportions' listed in Table II are far higher than those calculated in other settings for the contribution of psychological stresses to the genesis of psychiatric disorders. The relative risks of various events for depressive, neurotic and schizophrenic illnesses reviewed by Paykel (1978) varied from 1.6 to 7.6, and those calculated more recently for affective disorders in the community by Surtees *et al* (1986) were within the same range. Parasuicide is the only psychiatric phenomenon for which psychological stresses have been shown to have a higher relative risk – of 10.0 by Paykel *et al* (1975) – and even this is quite modest compared with the values of up to 35 obtained here. The most likely explanation of this difference is that childbirth is not acting primarily as a psychological stress. The relative risk is far higher, and the duration of that increased risk more shortlived, because the mechanism responsible is metabolic rather than psychological. Other explanations are possible, however. The magnitude of any estimate of relative risk will be influenced by the length of time over which it is estimated, and in general the shorter the time period the higher the relative risk. Most of the estimates reviewed by Paykel were based on periods of 3–9 months, considerably longer than the 30- and 90-day periods considered here. Perhaps significantly, the high relative risk of 10.0 for the role of life events in the genesis of parasuicide obtained by Paykel *et al* (1975) was based on a time period of only one month. Childbirth also differs from most of the other events known, or suspected, to contribute to the aetiology of psychiatric disorders in occurring at a precise time, in affecting only one person, and in having its occurrence routinely recorded for the population as a whole. These unique advantages obviously make it easier to calculate relative risks accurately than is possible for other events such as bereavement or becoming unemployed. It is possible, therefore, though we ourselves do not think it likely, that technical differences of this kind may be responsible for the striking difference in the magnitude of the relative risks associated with childbirth and other stressors.

This evidence of a dramatic increase in the incidence of psychiatric disorder in the first 90 days after childbirth should not lead us to overlook the fact that the psychiatric admission rate remains significantly higher than it was before pregnancy for at least 2 years after childbirth. The psychiatric contact rate also remains significantly raised for at least 1 year. Because only 4 years' data were available for analysis it was not possible to calculate accurate relative risks for psychiatric contacts, but the relative risk for psychiatric admission in the 2 years after childbirth was 1.6 and the relative risk for psychotic admission 3.5 (see Table II). This means that childbirth makes an appreciable impact on the long-term as well as on the short-term risk of psychiatric admission. If a woman has three children during the 20 years of her active reproductive life (and assuming that her 'base rate' remains stable during that period), her risk of having a psychiatric admission during this 20-year period relative to her risk had she remained childless is at least $[(1\times14)+(1.6\times2\times3)]/20=1.18$, and the relative risk of her being admitted with a psychotic illness is at least $[(1\times14)+(3.5\times2\times3)]/20=1.75$. This means that having three children increases her risk of being admitted to a psychiatric hospital at some time in this 20-year period by at least 18%, and her risk of being admitted with a psychotic illness by at least 75%, and these are minimum values because the period of increased risk may well last for longer than 2 years after each birth.

It is not clear why the risk of psychiatric admission should remain elevated for so long after childbirth. Relapses of puerperal illnesses will make some contribution, but only in the early months after delivery. The birth of a child is, of course, often associated with other important changes in a woman's life. These may involve the loss of a job, of financial independence, of social contacts and of freedom, and a changed marital relationship, and any or all of these may be important stresses. However, such changes are much more likely to occur after the birth of the first than after the birth of later children and, as the relative risks listed in Table II show, after the first 90 days the persisting risk of admission is greater for multiparae than primiparae. If equally extensive data had existed for all psychiatric contacts (i.e. as out-patients or general hospital ward referrals) as were available for psychiatric admissions it would have been possible to calculate how great a contribution having two or three children made to a woman's risk of having any kind of psychiatric contact during her reproductive years. It is a pity this was not possible, for in most discussions of the reasons for women having a higher psychiatric morbidity than men, and for married women having a higher morbidity than single women, surprisingly little attention is usually given to the effects of childbirth. In a previous study based on a small cohort of 2257 women, 'new psychiatric contacts', three-quarters of which were as out-patients, were actually more frequent in the second year after childbirth than in the first, suggesting that the risk of psychiatric contact may remain raised for as long, and be raised just as much, as that of psychiatric admission (Kendell *et al*, 1976).

Social factors are usually invoked to explain the difference in psychiatric morbidity between married and unmarried women, but the findings discussed above suggest that much of the excess morbidity in married women may be attributable to childbirth (and its secondary social consequences). This possibility is supported by the findings of a recent study in north Edinburgh of the prevalence of psychiatric symptoms in the community (Surtees *et al*, 1983). As the prevalence rates set out in

TABLE IX

Distribution of psychiatric cases in a population sample of Edinburgh women of childbearing age[1]

Marital status	*Psychiatric cases* *Number of children* *None*	*One*	*Two*	*Three*	*Total*
Single	8/95 (8%)	0/7	0/2	—	8/104 (8%)
Married	5/78 (6%)	8/59 (14%)	9/66 (14%)	3/19 (16%)	25/222 (11%)
Widowed, separated divorced or co-habiting	5/28 (18%)	7/13 (54%)	4/9 (44%)	4/9 (44%)	20/59 (34%)
Total	18/201 (9%)	15/79 (19%)	13/77 (17%)	7/28 (25%)	53/385 (14%)

[1] These 385 women are a representative sample of women aged 18–45 in a female population of 91 000 in north Edinburgh (see Surtees *et al*, 1983). Psychiatric cases were defined by the Research Diagnostic Criteria of Spitzer *et al* (1978).

Table IX show, the higher morbidity of married women than of single women is entirely due to those with children, for the morbidity of childless married women is actually slightly lower than that of single women. There is, however, no evidence from these data that having two or three children is associated with any higher morbidity than having one.

Although the findings presented here cannot settle the vexed question of how puerperal psychosis should best be defined, they can help to clarify the issues involved. If puerperal psychoses are to be defined in terms of the time interval between parturition and admission to a psychiatric hospital, cogent evidence is presented here that the maximum interval between the two should be 3 months. Brockington *et al* (1982) have argued that the interval between parturition and the onset of symptoms is more important, and that this should not be longer than 2 or 3 weeks. There is no doubt that its time of onset is a more fundamental characteristic of an illness than the time at which it results in admission to hospital. The time of onset is, however, not always easy to determine. Cernik and Brockington achieved an inter-rater reliability of only 0.61 (Cohen's Kappa) in a series of over 100 patients with puerperal illnesses (Brockington *et al*, 1982). Moreover, it is not uncommon for women to become mildly depressed or anxious in late pregnancy and then to deteriorate suddenly and develop psychotic symptoms a week or two after delivery. Their psychosis is puerperal but their original mood disturbance was not.

In general, the time of onset of symptoms will probably be the better criterion in clinical studies, while the timing of psychiatric admission or contact may be the best or the only criterion available in epidemiological studies. In practice, however, there may be little difference between the two criteria discussed here, namely an *onset* within 3 weeks of childbirth and *admission* within 90 days of childbirth. Only 45 (38%) of the 120 patients admitted within 90 days of childbirth described here had an onset more than 15 days after childbirth, and only 24 (20%) an onset more than 30 days afterwards.

The finding that the increase in the risk of psychiatric admission in the puerperium associated with a history of a previous psychiatric admission varies considerably with the diagnosis made at the time of that admission is one of the most interesting and novel findings of this study. A previous manic depressive illness, either depressive or manic, involves a much higher risk than a previous schizophrenic illness or a previous depression diagnosed as a depressive neurosis (ICD-9 300.4). Indeed, these latter two diagnoses carry no greater risk than earlier admissions with a diagnosis of personality disorder or adjustment reaction. Other investigators (e.g. Bratfos & Haug, 1966; Reich & Winokur, 1970) have already shown that a previous manic depressive illness greatly increases the risk of a puerperal psychosis, but as this was demonstrated in the context of a follow-up study of manic depressive patients it was not possible for these researchers to determine whether the risk was restricted to manic depressive illnesses or shared with other disorders. The results obtained here show that the risk is considerably greater after a manic depressive illness than after any other psychiatric disorder. This adds further weight to the existing clinical evidence (the fact that most puerperal psychoses meet research criteria for affective disorders) and genetic evidence (e.g. Whalley *et al*, 1982) that the majority of puerperal psychoses are simply manic depressive illnesses precipitated by childbirth. Conversely, the fact that an earlier schizophrenic illness was not associated with an increased risk of puerperal admission, coupled with the fact that only four of the 120 puerperal admissions met RDC for schizophrenia, adds to the evidence that, despite their sometimes floridly psychotic presentation, the great majority of puerperal psychoses are unrelated to schizophrenia. It is important to appreciate, too, that childbirth need not have played any role in the aetiology of those four schizophrenic illnesses despite the fact that they resulted in admission to hospital within 90 days of parturition. As the 'attributable proportion' listed in Table II shows, 26% of admissions within 90 days of childbirth (100% minus 74%) are not attributable to that event, and four patients constitute only 3.3% of 120. In fact, two of the four mothers with schizophrenic illnesses were already chronic schizophrenics before their index pregnancy, and the illness of the third did not begin until 57 days after delivery. Only one of the four developed a schizophrenic illness *de novo* within a few days of childbirth and she eventually made a full recovery with no recurrence in the next 6 years.

Acknowledgements

We are grateful to the Lothian Health Board's Computer Services Unit and to the Information Services Division of the Scottish Health Service for providing the data on which this study was based, and to the Scottish Office Computer Service for linking the two data sets. We are also grateful to Professor Norman Kreitman and his colleagues for their helpful advice, and for the data shown in Table IX.

Appendix 1

Relationship between age and psychiatric admission rate

A test was made of the possibility that the unexpected long-term difference in admissions before and after childbirth might be due to a steadily increasing psychiatric admission rate in women of childbearing age unrelated to childbirth; that is, these women might have had higher admission rates in the last 21 months of the 4-year period of study than in the first 15 months simply because they were by then 2½ years older. The total numbers of admissions of married women between 1970 and 1981 were obtained from the EPCR for six consecutive age groups from 15–19 years to 40–44 years, and admission rates per 1000 population were calculated from these, using the mean of 1971 and 1981 census figures. There was indeed a steady increase in the admission rate over this age range, but the rate of increase calculated from a linear regression equation was only 1.6% per year. Even over 2½ years, therefore, the increase would be only 4%, which is trivial compared with the observed increase of 30%.

Characteristic Plasma Hormone Changes in Alzheimer's Disease

J. E. CHRISTIE, L. J. WHALLEY, J. BENNIE, H. DICK, I. M. BLACKBURN, D. H. R. BLACKWOOD and G. FINK

A systematic endocrine investigation in dementia, depression and control subjects showed that plasma growth hormone (GH) was higher in the morning and plasma TSH concentrations were higher throughout the day in Alzheimer-type dementia (ATD) than in age-matched depressed patients (MDD), and plasma TSH concentrations were also higher throughout the day in female ATD compared with age-matched female control subjects. The increased plasma TSH concentrations could not be due to reduced negative feedback because plasma T_3, T_4 and rT_3 were in the normal range. Plasma concentrations of oestrogen-stimulated neurophysin (ESN) were lower throughout the day in ATD compared with MDD and controls and lower in the morning compared with other dementias. The high plasma GH and TSH concentrations in ATD may reflect the reduced hypothalamic content of somatostatin in ATD, and the reduced concentrations of ESN may reflect reduced cholinergic activity in ATD brain. These selective hormonal changes provide a useful diagnostic test for Alzheimer's disease.

The neuropathological (Ishii, 1965) and some of the neurochemical features of Alzheimer-type dementia (ATD) affect not only the cerebral cortex but also subcortical structures, including the hypothalamus, in which there is a reduction of choline acetyltransferase (Davies, 1979), noradrenaline (Yates *et al*, 1981) and of somatostatin concentrations (Davies *et al*, 1982). Somatostatin is also reduced in CSF in patients with ATD (Wood *et al*, 1982). Acetylcholine, noradrenaline and somatostatin are involved in the control of the secretion of pituitary hormones (Reichlin, 1985), and the aim of the present study was to determine whether in ATD the central changes in these neurotransmitters are reflected in the basal secretion of pituitary hormones.

There have been few previous neuroendocrine studies in ATD. The majority of the studies have focused on the dexamethasone suppression test (DST), and a high incidence of early escape from dexamethasone suppression has been reported in patients with presenile (Raskind *et al*, 1982; Balldin *et al*, 1983) and senile ATD (Spar & Gerner, 1982; Coppen *et al*, 1983). Samorajski *et al* (1982) reported raised plasma prolactin concentrations in patients in hospital with senile dementia, but this finding was not confirmed in presenile ATD (Balldin *et al*, 1983); and in a study of a small number of patients, Hyyppa *et al* (1980) found the CSF prolactin concentrations were lower in patients with cerebral atrophy. Reduced sleep-related secretion of growth hormone (GH) was described in three ATD patients as compared with three age-matched control subjects (Davis *et al*, 1982).

The present study was designed to test hypotheses that plasma concentrations of pituitary hormones would (a) reflect changes in central neurotransmitters that occur in ATD and (b) prove useful in the differential diagnosis of ATD from other causes of dementia and depression, which is sometimes difficult, especially in elderly patients. The study compared hormone profiles in patients with presenile onset of ATD with those of major depressive disorders (MDD), other types of dementia and control subjects. ATD of presenile onset was studied because although the reduction in choline acetyltransferase is similar in older compared with younger patients with ATD (Yates *et al*, 1983*b*), younger patients with ATD have a more extensive loss of noradrenaline (Yates *et al*, 1983*b*; Rossor *et al*, 1984) and somatostatin (Pierotti *et al*, 1986).

Method

Alzheimer's type dementia

Patients who had developed symptoms suggestive of dementia before the age of 65 were admitted to hospital for investigation. The diagnosis of ATD was based on:

(a) onset of symptoms under the age of 65 with dysmnesia as the initial feature and with steadily progressing dementia
(b) absence of a history suggestive of another type of dementia or focal neurological signs or hypertension
(c) CT scan within normal limits or showing cerebral atrophy and showing no additional pathology
(d) EEG showing no focal abnormalities
(e) normal ECG, haematological, biochemical and CSF clinical investigations.

The 18 patients who met these criteria for ATD and were admitted to the study were all free of psychotropic drugs for at least 6 months before and throughout the duration of the study. They were assessed using the following psychological tests:

(a) orientation (Wechsler, 1955)
(b) short-term memory, forward and backward digit-span (Wechsler, 1955)
(c) long-term memory, Logical Memory (Wechsler, 1955) and Paired Associates Learning (Isaacs & Walky, 1964)
(d) agnosia – common objects; pictures; colours; auditory agnosia; tactile agnosia; naming of body parts (Eisenson, 1954)
(e) apraxia – hand position; finger flexion; use of objects; intrasensitive gestures (Kimura & Archibald, 1974).

Severely demented hospitalised patients were excluded but a wide range of severity of dementia was represented within the ATD population. Two patients were still in regular employment, three others were living alone while the remainder required the close support of relatives to remain in the community. The patients were reassessed 12 months later and only if the diagnosis remained unchanged were they included in the study.

Other dementias

Demented patients who after full investigation, failed to meet the criteria for ATD were included in the study and formed a dementia group who were unlikely to have ATD. Five of the nine patients had focal changes on the CT scan suggestive of vascular disease and were given a diagnosis of multi-infarct dementia. Two patients presented with personality and behavioural changes which were more pronounced than memory impairment. Both showed frontal lobe patterns of response in psychological tests and the provisional diagnosis was Pick's disease. One patient had the typical features of Huntington's chorea and a positive family history, while another patient had dementia associated with bilateral spasticity in the lower limbs, with a diagnosis thought to be disseminated sclerosis. All nine patients were free of psychotropic drugs for at least 6 months before the study.

Depressed patients

Patients with symptoms of a depressive illness, who had been free of antidepressant and neuroleptic drugs for at least 6 months, were selected from routine admissions to the Royal Edinburgh Hospital. The 16 patients admitted to the study remained free of antidepressant and neuroleptic drugs for the duration of the study. Eight patients were totally drug-free, seven patients received night sedation in the form of a benzodiazepine or chloral hydrate and one patient had received a recent course of ampicillin.

The depressed patients were all interviewed using the Present State Examination (PSE) Wing *et al*, 1974) within a few days of admission to hospital and were also assessed using the Hamilton Depression Rating Scale (Hamilton, 1960). The data from the PSE and clinical case records were assessed independently by two psychiatrists, and patients were classified according to the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1978). All 16 patients met the criteria for major depressive disorder (MDD), 14 endogenous and two probable endogenous subtype. Depressive delusions or hallucinations were present in ten patients, who therefore met criteria for MDD psychotic subtype.

Control subjects

The 37 control subjects – hospital staff and non-hospital-associated volunteers – were in good health and had not been taking any medication, including oral contraceptives, for at least 6 months.

Age and sex

Table I shows the mean age, age range and male/female composition of the patient groups and control subjects. Seven depressed patients and 11 control subjects were of similar age to the ATD patients. In the instances when plasma concentrations of a hormone showed a significant correlation with age within the total control population, only the age-related groups were used in statistical comparisons. Comparisons of plasma concentrations of luteinising hormone (LH) between ATD and control subjects were made only in post-menopausal women.

TABLE I
Patient and control populations

				Age (years)	
	n	*Male*	*Female*	*Mean ± s.d.*	*Range*
Alzheimer's disease (ATD)	18	5	13	61.0 ± 5.4	53–70
Major depressive disorder (MDD)	16	8	8	45.5 ± 12.6	25–72
MDD patients of similar age to ATD patients	7	3	4	56.6 ± 7.7	49–72
Other dementias	9	4	5	64.6 ± 8.7	44–72
Control subjects	37	14	23	39.9 ± 13.4	18–63
Control subjects of similar age to ATD patients	11	2	9	56.6 ± 5.6	48–63

Informed consent

All patients and control subjects consented to the study procedures, which they understood were undertaken only for research purposes. In cases where there was any doubt about a patient's understanding, the agreement of a close relative was sought before the patient was included.

Blood sampling

An in-dwelling cannula was inserted at approximately 06:40, kept patent by heparinised saline and left in place until 24:00. Blood samples were taken at 07:00, 07:30 and 08:00 (morning), 15:00, 15:30 and 16:00 (afternoon), and 23:00, 23:30 and 24:00 (evening). This blood sampling technique, designed to take account of the diurnal and pulsatile pattern of hormone secretion, allowed calculation of mean values for morning, afternoon and evening periods. In 15 ATD, 13 MDD and 9 other dementia patients a dexamethasone suppression test was carried out after the initial sampling day. Dexamethasone, 1 mg in a syrup, was given at 24:00 and blood samples were taken the following day at 08:00, 16:00 and 23:00. Blood samples were collected in lithium heparin-coated tubes containing 100 k IU Trasylol, and kept at 4°C before and during centrifugation. Plasma was stored at −40°C until assay.

Hormonal assays

Plasma hormone concentrations of GH, TSH, prolactin (PRL), LH and oestrogen-stimulated neurophysin (ESN) were determined using the NIADDK radioimmunoassay kits. The reference preparations were as follows: for GH, HS2243E; for TSH, WHO 1st IRP 68/38; for PRL, NIAMDD-HPRL-RP-1 (AFP-2312C); and for LH, LER-907. The reference preparation for ESN was that given to NIADDK by Dr A. Robinson, University of Pittsburg. Anti-rabbit gamma globulin (Scottish Antibody Production Unit (SAPU), Carluke, Scotland) at a final dilution of 1/100 was used as a second antibody. All samples were measured in duplicate. The sensitivity of the assays (90% B/Bo) were 1.6 mU/litre for GH (100 μl sample); 0.8 mU/litre for TSH (200 μl sample); 70 mU/litre for PRL (50 μl sample); 0.60 U/litre for LH (100 μl sample); and 85 pmol/litre for ESN (100 μl sample). The intra-assay coefficients of variation (COV) were 7.1% (low pool - 5.3 mU/litre and 7.4% (high pool - 40.0 mU/litre) for GH; 6.2% (low pool - 4.1 mU/litre) and 6.0% (high pool - 13.8 mU/litre) for TSH; 6.6% (low pool - 182 mU/litre) and 5.4% (high pool - 1.31 U/litre) for PRL; 7.4% (low pool - 1.34 U/litre) and 3.4% (high pool - 3.35 U/litre for LH; and 5.8% (low pool - 332 pmol/litre) and 4.9% (high pool - 672 pmol/litre) for ESN. The inter-assay COV were 8.4% (low pool) and 7.4% (high pool) for GH; 7.0% (low pool) and 9.1% (high pool) for TSH; 9.9% (low pool) and 8.4% (high pool) forPRL; 10.3% (low pool) and 8.9% (high pool) for LH; and 8.4% (low pool) and 7.8% (high pool) for ESN.

Total cortisol concentrations were determined by radioimmunoassay using a modification of the method of Seth & Brown (1978) with an antiserum (SAPU), raised in sheep against cortisol-3-O-carboxymethyloxime-bovine serum albumin. Anti-sheep/goat serum (SAPU) at a final tube dilution of 1/83 was used as the second antibody. The sensitivity of the assay (90% B/Bo) was 11.6 nmol/litre cortisol. The intra-assay COV were 2.2% (low pool - 153 nmol/litre), 2.8% (middle pool - 310 nmol/litre) and 3.2% (high pool - 560 nmol/litre). The interassay COV were 4.6% (low pool). 2.68% (middle pool) and 6.34% (high pool).

Statistical analysis

The distributions of the mean morning (07:00, 07:30 and 08:00), afternoon (15:00, 15:30 and 16:00) and evening (23:00, 23:30 and 24:00) plasma concentrations of cortisol, GH, TSH, PRL, LH and ESN in patients and control subjects were significantly skewed. The cortisol data were log-transformed to approximate normality, and the significance of the differences in the mean plasma cortisol concentrations between ATD, MDD, other dementias and control subjects was determined by one-way analysis of variance and the multiple range test of Duncan (1961). The distributions of the other hormones, however, remained skewed despite transformation, and the Mann–Whitney *U* test was used to determine the significance of differences between the values. In all 96 comparisons were made between the groups; thus by chance alone up to five significant differences would be expected (four at $P<0.05$ and one at $P<0.02$). In the ATD group, correlations between the mean morning, afternoon and evening plasma GH, TSH, cortisol, PRL and ESN concentrations were made using Spearman's Rank Correlation coefficient (30 comparisons). Also, within the ATD group, mean morning, afternoon and evening concentrations of GH, TSH, cortisol and ESN were correlated with psychological test scores (60 comparisons).

Results

Relationship between age, sex and plasma hormone concentrations in control subjects

Plasma cortisol and plasma ESN concentrations were not significantly correlated with age. Afternoon plasma GH concentrations decreased with age (morning, $r=-0.24$, NS: afternoon, $r=-0.30$, $P<0.05$; evening, $r=-0.23$, NS). Morning and afternoon plasma TSH concentrations (morning, $r=0.36$, $P<0.02$; afternoon, $r=0.31$, $P<0.02$; evening, $r=0.24$, NS) increased with age, and afternoon plasma prolactin concentrations (morning, $r=-0.02$; afternoon, $r=0.35$, $P<0.02$; evening, $r=0.16$) also increased with age. We concluded that plasma GH, TSH and prolactin concentrations correlated with age and that comparisons between ATD and other groups would require age-matching.

Plasma concentrations of TSH, cortisol and ESN were similar in male and female control subjects at all three time periods. Plasma GH concentrations were higher in female as compared with male control subjects in the evening only ($P<0.01$) and plasma prolactin concentrations were higher in female compared with male control subjects in the afternoon ($P<0.02$). When the female control population was divided into pre- and post-menopausal groups, the post-menopausal women, as expected, had higher plasma LH concentrations at all three times of day ($P<0.02$) than the pre-menopausal women.

Growth hormone

Table II shows that plasma GH concentrations in the morning were significantly higher in ATD as compared with age-related control subjects ($P<0.02$) but not different from age-related MDD. Female ATD patients had higher morning ($P<0.02$) and afternoon ($P<0.05$) plasma GH concentrations than age-related female control subjects. The other dementia group had GH concentrations similar to those in control subjects.

TABLE II

Plasma GH and TSH concentrations in Alzheimer presenile dementia, other dementias and age-matched control subjects

Thyroid-stimulating hormone

Table II shows that the plasma TSH concentrations were higher at all three time periods in ATD compared with age-related MDD (morning, $P<0.002$; afternoon, $P<0.02$; evening, $P<0.05$). Female ATD patients had significantly higher plasma TSH concentrations throughout the day compared with age-related female control subjects (morning, $P<0.05$; afternoon, $P<0.05$; evening, $P<0.02$), and morning TSH concentrations were greater than 6 mU/litre in seven of 13 (54%) ATD women but only in one female other dementia patient and no female MDD patients or control subjects. The other dementia patients had plasma TSH concentrations similar to those in control subjects. Plasma triiodothyronine (T_3) and thyroxine (T_4) and reverse triiodothyronine (rT_3) concentrations were similar in ATD and age-related control subjects (ATD, mean ± s.e., $T_4 = 96.4 \pm 5.7$ nmol/litre, $T_3 = 1.58 \pm 0.09$ nmol/litre, $rT_3 = 0.30 \pm 0.05$ nmol/litre; control subjects, mean ± s.e., $T_4 = 99.5 \pm 4.5$ nmol/litre, $T_3 = 1.73 \pm 0.07$ nmol/litre, $rT_3 = 0.22 \pm 0.01$ nmol/litre). All subjects had T_3 and T_4 concentrations within the normal laboratory range. One ATD patient had very high plasma TSH concentrations (mean for the day 98.5 mU/litre) but normal T_3, T_4 and rT_3 concentrations and no clinical features of hypothyroidism. This patient's thyroid status was reassessed over a 4-year period, during which she developed no features of hypothyroidism, her T_3 and T_4 remained within the normal range and her plasma TSH concentrations gradually declined to a value of 10.9 mU/litre.

Cortisol

At all three time periods, MDD had higher plasma cortisol concentrations than control subjects ($P<0.05$) but not significantly greater than ATD (Table III). In the evening, ATD patients and also the other dementia patients had significantly higher plasma cortisol concentrations than control subjects ($P<0.05$).

After the administration of dexamethasone, three of 15 ATD patients (20%) had a 16:00 cortisol concentration greater than 138 nmol/litre and the 23:00 post-dexamethasone cortisol was also raised in these three patients. In patients with MDD, six of 13 (46%) had 16:00 cortisol concentrations greater than 138 nmol/litre. In the other dementia group three of 9 patients (two Picks and one Huntington's) had 16:00 cortisol concentrations greater than 138 nmol/litre. The ATD patients had a lower ($P<0.05$) 16:00 post-dexamethasone cortisol concentration (115 ± 57 nmol/litre) than the depressed patients (167 ± 36 nmol/litre).

Oestrogen-stimulated neurophysin

Plasma ESN concentrations (Table III) were significantly lower at all three time periods in ATD compared with MDD patients (morning, $P<0.01$; afternoon, $P<0.01$; evening, $P<0.05$) and with control subjects (morning, $P<0.001$; afternoon, $P<0.01$; evening, $P<0.001$). They were also lower in the morning ($P<0.05$) in ATD as compared with other dementia patients. The nine values for each patient or control subject were averaged and the plasma ESN concentration for the day was significantly lower in ATD compared with MDD ($P<0.001$), other dementias ($P<0.05$) and control subjects ($P<0.001$) (Fig. 1). All ATD patients had a mean plasma ESN concentration < 170 pmol/litre. The averages of the nine plasma ESN concentrations for the day for the ATD patients were also compared with the average ESN concentrations of 37 patients with psychosis, who were within the age range 50–72 years but not all of whom met the drug-free criteria. The elderly psychotic group had higher plasma ESN concentrations – 161 ± 18 pmol/litre – compared with the ATD patients – 105 ± 6 pmol/litre ($P<0.001$).

Prolactin and luteinising hormone concentrations

Plasma prolactin concentrations (mean ± s.e.) were similar in ATD (morning 493 ± 123 mU/litre, afternoon 355 ± 27 mU/litre, evening 360 ± 26 mU/litre), age-related MDD (morning 687 ± 304 mU/litre, afternoon 678 ± 313 mU/litre, evening 527 ± 158 mU/litre), other dementias (morning 403 ± 57 mU/litre, afternoon 318 ± 30 mU/litre, evening 425 ± 36 mU/litre) and control subjects (morning 344 ± 36 mU/litre, afternoon 291 ± 20 mU/litre, evening 335 ± 28 mU/litre).

Plasma LH concentrations (mean ± s.e.) did not differ significantly in post-menopausal women with ATD ($n = 11$; morning 16.4 ± 1.6 U/litre, afternoon 14.3 ± 1.1 U/litre, evening 15.0 ± 1.4 U/litre) compared with female patients with other dementia ($n = 5$; morning 11.9 ± 2.3 U/litre, afternoon 12.0 ± 1.6 U/litre, evening 12.7 ± 1.6 U/litre) and post-menopausal female control subjects ($n = 9$; morning

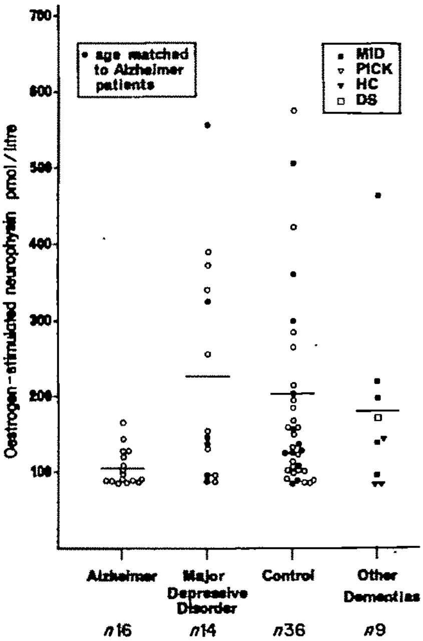

FIG. 1 Mean plasma oestrogen-stimulated neurophysin concentrations based on nine estimations in 'neuroendocrine day' studies carried out in patients with Alzheimer-type dementia (ATD) major depressive disorder (MDD) and other dementias (MID = multi-infarct dementia, Pick = Pick's disease, HC = Huntington's chorea, DS = disseminated sclerosis) and in normal control subjects: ATD *v.* controls – $P<0.001$; ATD *v.* MDD – $P<0.001$; ATD *v.* other dementias – $P<0.05$ (conversion, SI to traditional units, 1 pmol/l ≃ 0.012 μg/l).

14.6 ± 2.2 U/litre, afternoon 14.3 ± 1.9 U/litre, evening 13.9 ± 1.4 U/litre).

Relationship between plasma hormone concentrations and performance in psychological tests

Table IV shows the correlations in ATD patients between the mean plasma hormone concentrations and psychological test scores. Plasma cortisol concentrations, particularly in the evening, were inversely correlated with psychological test scores; that is, the more demented patients had higher plasma cortisol concentrations. Orientation was the only subtest which showed a positive significant correlation with afternoon and evening plasma TSH concentrations. Evening plasma GH concentrations were inversely correlated with psychological test scores. There were no significant correlations between plasma ESN concentrations and psychological test scores.

Intercorrelations between plasma concentrations of TSH, GH, cortisol, prolactin and ESN in ATD and in control subjects

Plasma cortisol concentrations in the evening were inversely related to TSH concentrations in ATD ($r = -0.50$, $P<0.05$) but not in control subjects. Plasma TSH concentrations in the morning positively correlated with PRL concentrations in ATD ($r = 0.50$, $P<0.05$). Afternoon plasma concentrations of GH correlated inversely with ESN concentrations in ATD ($r = -0.52$, $P<0.05$). In the control subjects the only significant correlation was a positive correlation between evening plasma concentrations of GH and PRL ($r = 0.83$, $P<0.001$).

Diagnostic implications

Morning plasma TSH concentrations were useful in discriminating between ATD and age-related MDD patients, with 13 ATD patients (72%) but none of the MDD patients having TSH concentration greater than 4.5 mU/litre. When morning plasma TSH and ESN concentrations (TSH > 4.5 mU/litre; ESN < 170 pmol/litre) were used to discriminate between ATD, MDD, other dementias and control subjects, 75% of the ATD patients were correctly identified, together with one patient with multi-infarct dementia and one control subject, but no MDD patients; a specificity of 86% (Fig. 2).

Discussion

The present study has identified selective changes in plasma concentrations of TSH, GH and ESN that are specific to ATD and which can be related to the

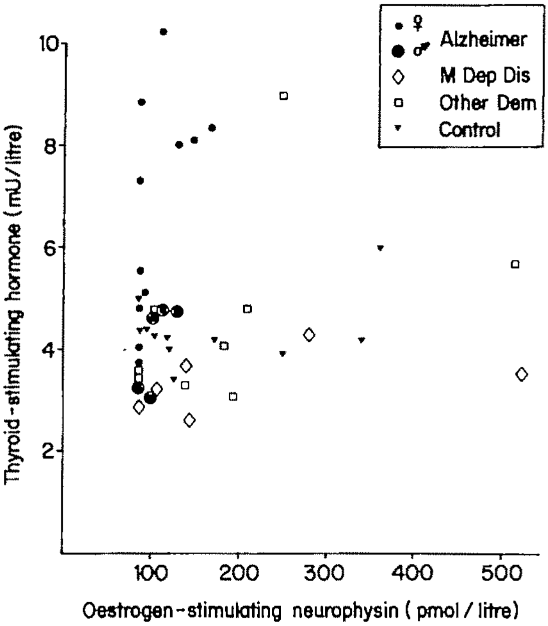

FIG. 2 Morning plasma thyroid-stimulating hormone concentrations plotted with morning oestrogen-stimulated neurophysin concentrations for patients with Alzheimer-type dementia, major depressive disorder, other dementias and control subjects.

known neurochemical deficits in ATD. Although raised plasma GH concentrations could be due to increased release of GH-releasing hormone (GHRH), it is more likely in ATD to be due to decreased release of somatostatin, which is known to be deficient in ATD. Since somatostatin also inhibits TSH, a similar mechanism may account for the increased plasma TSH concentrations in ATD. Hypothalamic TSH releasing hormone (TRH) concentrations are normal in post-mortem tissue in ATD (Yates *et al*, 1983*a*) and it is, therefore, unlikely that raised plasma TSH concentrations are due to increased release of TRH.

The increase in plasma GH and TSH concentrations is more marked in the female ATD patients. Raised morning plasma TSH concentrations are more common in women, particularly those over the age of 45 years. In the Whickham Community Survey (Tunbridge *et al*, 1977), the percentage of morning TSH concentrations greater than 6 mU/litre was 7.5% for females and 2.8% for males for the whole population, irrespective of age. The percentage of raised TSH concentrations in the age range 55–64 years was 10% for females and 1.9% for males, and in the age range 65–74 years was 8% for females and 6.9% for males. In the present study, seven out of the 13 female ATD patients (54%) had morning TSH concentrations greater than 6 mU/litre, far in excess of that expected in the general population. The increase in plasma TSH concentrations in female ATD patients appears to be central, because peripheral indices of thyroid function (T_3, T_4 and rT_3) were within the normal range and similar to those of control subjects. Plasma GH concentrations did not correlate with TSH in either ATD or control subjects, but the control of the secretion of these hormones is complex and somatostatin is only one of many factors involved (Mendelson, 1982; Scanlon *et al*, 1980). Evening plasma TSH concentrations in ATD were inversely correlated with plasma cortisol concentrations, and it is possible that raised cortisol concentrations in the more severely demented patients inhibit TSH secretion (Re *et al*, 1976).

The highly significant reduction of plasma ESN concentrations in ATD may be related to the marked deficiency in ATD brain of acetylcholine which is known to stimulate oxytoxin release (Poulain & Wakerley, 1982) and, therefore, presumably the oxytocin-associated ESN. The decreased ESN concentrations may, however, also be due to decreased synthesis of ESN itself, since in rats the staining intensity for the neurohypophysial hormones decreases progressively with age, especially in the paraventricular nucleus and in oxytocin-containing neurones (Watkins & Choy, 1980), but recent studies of human brain have failed to show any change in the area of oxytocin cells with increasing age (Fliers *et al*, 1985). Scrapie in sheep, which has some neuropathological features in common with those of ATD, causes degeneration of magnocellular neurones, with loss of neurophysin in the posterior pituitary gland (Parry & Livett, 1976).

The majority of studies report that concentrations of dopamine and homovanillic acid are normal in ATD (Yates *et al*, 1979; Mann *et al*, 1980). Consistent with this finding, plasma prolactin concentrations were similar in ATD patients and age-related controls in the present study, as well as in the study of Balldin *et al* (1983). The raised evening plasma cortisol concentrations in ATD compared with control subjects are not useful diagnostically, because the morning and evening plasma cortisol concentrations are increased in other dementias and increased throughout the day in MDD, as has also been shown to be the case in many previous studies of depression (Gibbons, 1964; Carpenter & Bunney, 1971; Sachar *et al*, 1973). Raised plasma cortisol concentrations are found in many psychotic patients, irrespective of the presence of depressed mood (Christie *et al*, 1986). The raised evening plasma cortisol concentrations in the ATD patients appears to be a feature of the more severely demented patients, with an inverse relationship between cortisol concentrations and psychological test scores. Only three of 15 ATD patients (20%) showed early escape from dexamethasone suppression, and the non-suppressors included the two most severely demented patients in the study. Previous studies in demented patients have suggested a 40–50% incidence of early escape from dexamethasone suppression (Raskind *et al*, 1982; Spar & Gerner, 1982; Balldin *et al*, 1983; Coppen *et al*, 1983), similar incidence to that reported in endogenous depression (Carroll *et al*, 1981), but the majority of patients, unlike those in the present study, were hospitalised, severely demented patients.

Plasma TSH and ESN concentrations are useful in discriminating between ATD, other causes of dementia and depression. Morning TSH concentrations greater than 4.5 mU/litre, identified 72% of ATD and no depressed patients, and the additional use of morning ESN concentrations improved the discrimination between ATD, other dementias, MDD and control subjects to a sensitivity of 75% and specificity of 86%.

These results show significant increases in the concentrations of GH, TSH and cortisol and a decrease in concentration of ESN in the plasma of patients with ATD. Increased plasma GH and TSH concentrations in ATD are consistent with reports of reduced somatostatin in post-mortem neurochemical studies, while decreased ESN may be caused by decreased cholinergic activity. The finding of predictable changes in pituitary output based on established neurochemical abnormalities supports the rationale for neuroendocrine studies in psychiatry. These characteristic hormonal changes in ATD provide the basis for psychopharmacological analysis of the central neurochemical abnormalities of ATD and offer important biological markers for discriminating between ATD, other dementias and major depression.

Acknowledgements

The authors would like to thank the pituitary hormone programme of the NIADDK (Baltimore, Md) and the Scottish Antibody Production Unit (Carluke) for the generous provision of radioimmunoassay materials, the Department of Clinical Chemistry, the Royal Infirmary of Edinburgh for measurement of T_3 and T_4 and the Clinical Research Centre (Harrow) for measurement of rT_3; Mrs M. Arkley, Mr M. Surtees, Mrs G. Sanchez-Watts and Mrs H. Wilson for their technical assistance; Mr J. Sloane-Murphy and Mrs P. Ritchie for their expert care of the patients and research assistance; Norma Brearley for the preparation of the manuscript.

Increased Plasma LH in Manic-Depressive Illness:

Evidence of a State-Independent Abnormality

L. J. WHALLEY, S. KUTCHER, D. H. R. BLACKWOOD, J. BENNIE, H. DICK and G. FINK

Basal plasma luteinising hormone concentrations and the LH responses to LH-releasing hormone injection were higher in 11 young men after recovery from mania than in 15 control subjects. Since plasma concentrations of testosterone and sex hormone binding globulin were similar in the recovered manic compared with the control subjects, the increased LH response to LHRH is likely to have been due to the priming effect of LHRH consequent on an increased release of LHRH into hypophysial portal vessel blood. Abnormal control of LHRH, and thereby LH release, is a state-independent feature in male patients with mania and may be a useful trait marker for this disorder.

Manic-depressive illness is a recurrent psychosis of unknown aetiology. Episodes of mania and depression are followed by periods of complete recovery and, in the natural history of this disorder, changes from normality to illness can take place with characteristic suddenness. Previously, we have reported that in acute mania in drug-free young men, plasma luteinising hormone (LH) concentrations were higher than in schizophrenia or in healthy control subjects (Whalley *et al*, 1985). The increase in plasma LH concentrations could not have been due to decreased negative feedback of testosterone because plasma testosterone and sex hormone binding globulin (SHBG) did not differ between groups.

The increased plasma LH concentrations in mania could be due to a central abnormality leading to increased release of LH-releasing hormone (LHRH), to increased pituitary responsiveness to LHRH, or to both, since LHRH increases the responsiveness of the pituitary gland to itself, the so-called priming effect of LHRH (Aiyer *et al*, 1974; Fink, 1979). In the present paper we have investigated whether plasma LH concentrations remain elevated after recovery from mania, which would indicate whether the abnormality is either state- or trait-dependent, and also whether pituitary responsiveness to LHRH is altered in men during the euthymic phase of manic-depressive illness.

Method

Eleven recovered manic-depressive and 15 control male subjects were studied. The recovered manic-depressive patients had sufficient case-note data to meet Research Diagnostic Criteria (RDC, Spitzer *et al*, 1975) for at least one episode of mania. All had been free of any psychotropic medication, other than lithium, for at least 2 weeks. The mean ages (±s.e.; range) for the patients were 36 years (±3.1; 25–53) and for the control group 33 years (±2.7; 19–59). All studies were started between 08:00 and 09:00 after an overnight fast. Blood samples were obtained from an in-dwelling cannula (with a heparin lock) which was placed in a forearm vein about 20 minutes before the first sample was taken. Samples were taken at the following times in relation to injection of 100 μg LHRH dissolved in 1 ml aqueous solution: (−60, −30, −5, +15, +30, +45, +60, +90, +120 and +180 minutes). Blood was collected into lithium-heparin coated tubes containing 100 Kallikrein inactivator units of aprotinin, and kept at 4°C until centrifugation at 1600*g* and 4°C. The plasma was stored at −40°C until hormone assay, as described previously (Whalley *et al*, 1985). The inter-assay (and intra-assay) coefficients of variation were as follows: LH 5.6% (3.8%); FSH 5.7% (3.6%); prolactin (2.6%); testosterone 6.8% (7.0%); SHBG 6.6% (5.8%). The maximal incremental change in plasma hormone concentration following LHRH injection was calculated as the difference between the maximum concentration during the first 90 minutes after LHRH and the concentration 5 minutes before LHRH injection. Data were log-transformed to approximate normality before comparisons between groups were made by analysis of variance for repeated measures (with the conservative Greenhouse–Geisser correction of probabilities (Winer, 1971). Student's *t*-test was used to locate the timing of significant differences.

Results

The results are shown in Fig. 1.

Basal plasma LH concentrations were significantly greater ($P<0.025$) in the recovered patients than in the control subjects. After LHRH injection, plasma LH concentrations were greater ($P<0.05$–$P<0.01$) in the recovered patients than in the control subjects at +15, +30, +45, +60, +90 and +180 min, and ANOVA with repeated measures showed a significant difference ($P<0.01$) between groups. The mean maximum increments in plasma LH concentrations were significantly greater ($P<0.01$) in the patients (mean ± s.e., 9.5 ± 1.8 *IU*/litre) than in the control subjects (5.6 ± 0.5 *IU*/litre).

Plasma FSH concentrations increased significantly (ANOVA with repeated measures, $P<0.002$) in both the patient and control groups after LHRH injection, but there were no significant differences between the two groups in either the basal plasma FSH concentrations or the maximal increments in plasma FSH concentrations.

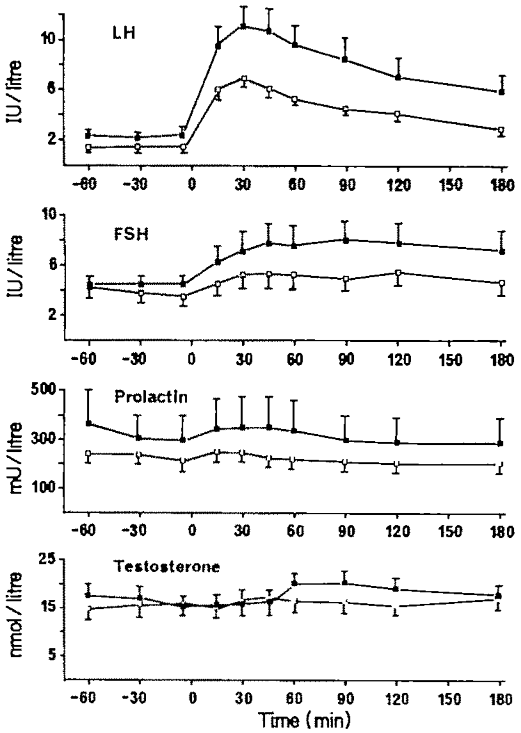

FIG. 1 Plasma concentrations of luteinising hormone (LH), follicle stimulating hormone (FSH), prolactin and testosterone in 11 recovered manic-depressive men (■——■) and 15 male control subjects (□——□) before and after 100 μg LHRH injection at 0 min.

Plasma prolactin concentrations increased slightly but significantly (ANOVA with repeated measures, $P<0.001$) after LHRH injection. There were no significant differences between the two groups.

Plasma testosterone concentrations did not change after LHRH injection and there were no significant differences between the two groups. Plasma SHBG concentrations in blood samples obtained immediately before LHRH injection (mean ± s.d.; controls, 40.1 ± 12.7 nmol/litre; patients, 40.7 ± 23.1 nmol/litre) and at the time of the maximum increment in plasma LH concentration, for each subject, did not differ between patients and control subjects.

Discussion

The fact that the plasma LH concentrations before LHRH injection were significantly greater in recovered male manic-depressive patients compared with healthy control subjects, together with our previous finding of increased plasma LH concentrations during acute mania (Whalley *et al*, 1985), suggests that increased plasma LH concentrations are a trait-dependent feature of manic-depressive illness which is independent of the state. As was the case in our previous study (Whalley *et al*, 1985), the increased plasma concentrations of LH in recovered manics could not be attributed to a failure of negative feedback, since the plasma concentrations of testosterone and SHBG were not significantly different from the values in normal subjects. The increased pituitary responsiveness to LHRH in recovered manics compared with the normal subjects could have been due to differences between the groups in plasma concentrations of sex steroids. However, since the plasma testosterone and SHBG concentrations were similar in the recovered manic and control subjects, a more likely explanation is that the responsiveness of the pituitary gland in patients with mania had been increased as a consequence of increased LHRH release and the priming effect of LHRH (Aiyer *et al*, 1974; Fink, 1979). The priming effect of LHRH has long been invoked to explain the positive correlation between basal plasma LH concentrations and the magnitude of the LH response to LHRH in man (Aiyer *et al*, 1974; Roth *et al*, 1972; Gual, 1973; Isurugi *et al*, 1973; Siler & Yen, 1973; Bell *et al*, 1973; Yen *et al*, 1973; Zarate *et al*, 1973). The cause of the increased release of LHRH in mania remains unknown but is likely to involve the stimulatory effect of either increased central α-noradrenergic activity or reduced central opioid activity (Kalra & Kalra, 1983). As was also the case in acute drug-free manic men (Whalley *et al*, 1985), there were no significant differences between the manic and control subjects in the plasma concentrations of FSH. Neither was there a between-group difference in the plasma FSH response to LHRH. Possible explanations for the dissociation between LH and FSH secretion have been discussed previously (Whalley *et al*, 1985).

Most recovered patients were on long-term lithium therapy and this could be a possible explanation of the differences between the two groups of subjects. Several factors, however, suggest that this is not the case. In our earlier study (Whalley *et al*, 1985), we detected increased plasma LH concentrations in young men with acute mania, none of whom had received lithium therapy, and there are no data available in the literature indicating that lithium increases plasma LH concentrations (Brown *et al*, 1981) or that lithium increases the LH response to LHRH (Joffe *et al*, 1986). The present study is, therefore, consistent with our earlier report, although the extent of the increase is much less in the recovered patients than in the subjects with acute mania. Our earlier findings also prompted several studies by members of our group on the effects of lithium on hypothalamic–pituitary–gonadal function. Follow-up studies on small numbers of patients with acute mania treated by lithium provided no suggestion that lithium increases plasma LH concentrations (some of these patients are reported in the earlier study by Whalley *et al*, 1985). Although lithium affects the turnover of phosphatidyl inositol (Gonzales & Crews, 1984), which in turn mediates some of the actions of LHRH (Naor *et al*, 1984), experimental studies in our laboratory show that lithium does not affect the releasing or priming actions of LHRH *in vitro* (M. Johnson, P. R. Mitchell & G. Fink, unpublished).

In sum, the present data show that increased basal plasma LH concentrations and an increased LH response to LHRH may be a state-independent feature of manic-depressive illness. The persistent abnormality may be a disorder of the central neural control of LHRH release, possibly involving monoaminergic or opioid neurotransmission. Since a catecholaminergic mechanism is also involved in the release of melatonin from the pineal gland, it is tempting to speculate that there may be an association between the two apparent trait markers of mania, the increased LH release which we reported and the supersensitivity to light in terms of melatonin release reported recently (Lewy *et al*, 1985).

Lithium in the Treatment of Aggression in Mentally Handicapped Patients

A Double-Blind Trial

M. CRAFT, I. A. ISMAIL, D. KRISHNAMURTI, J. MATHEWS, A. REGAN, R. V. SETH and P. M. NORTH

In a double-blind trial lasting 4 months in 42 mentally handicapped patients, the effect of lithium on aggression was assessed in comparison with placebo. In the lithium-treated group, 73% of patients showed a reduction in aggression during treatment. There were significant differences in mean weekly aggression scores and in the frequency of aggressive episodes between the lithium and placebo groups. Side-effects were noted in 36% of the lithium group (and 20% of the placebo group), but were mainly transitory. There were no episodes of toxicity, and no patients had to be withdrawn from the trial. Lithium appears to be worth a 2-month trial in such patients, where repeated aggression has not been relieved by more appropriate placement, occupation or company.

Lithium has been reported to reduce aggressive behaviour in prisoners and delinquents (Sheard, 1971; Tupin *et al*, 1973; Sheard, 1975; Sheard *et al*, 1976) and in mentally retarded patients (Forssman & Walinder, 1969; Dostal & Zvolsky, 1970; Morrison *et al*, 1973; Cooper & Fowlie, 1973; Micev & Lynch, 1974; Worrall *et al*, 1975; Lion *et al*, 1975; Goetzl *et al*, 1977; Dale, 1980; Sovner & Hurley, 1981; Craft & Mathews, 1984; Tyrer *et al*, 1984). In 1981, Sovner & Hurley reviewed the publications to date on the use of lithium carbonate in mentally handicapped individuals and concluded that more controlled studies needed to be carried out before any definitive statements about lithium's effectiveness could be made. The object of this work was to assess the efficacy of lithium carbonate in the control of aggression in mentally handicapped patients, under the conditions of a double-blind trial against placebo.

Method

Five centres participated in the trial, contributing a total of 42 patients. All were in-patients, exhibiting levels of aggression or self-mutilation severe enough to require routine drug therapy. Patients were excluded from the trial if they were already receiving treatment with lithium. A general physical examination was carried out before trial entry and patients in whom lithium treatment was contra-indicated were excluded, as were any patients with a cyclical pattern to their disorder.

The trial protocol was approved by the ethical committee of each participating centre. The nature of the trial and the procedures involved were explained to each patient (at an appropriate level) and to a relative or responsible guardian. Their consent was required before the patient could be included in the trial.

The trial was preceded by a 4-week run-in period during which all patients received treatment with two placebo tablets once daily. Patients were then allocated to two parallel groups to receive either lithium carbonate or placebo for a period of 12 weeks. Allocation to either the active or placebo group was made by minimisation, a sophisticated form of randomisation which provides for optimum balancing of patient groups in respect of factors which might affect the response to treatment (Taves, 1974). The minimisation procedure was carried out using a microprocessor, into which details of each patient were entered.

During the run-in period and the 12 weeks of the trial, the level of aggression was assessed daily by the nursing staff on duty, who differed during the study, but who all used the five-point scale devised by Dale (1980): 1 = well behaved; 2 = mood uncertain; 3 = overt aggression or attempted aggression; 4 = additional medication required to control patient; 5 = seclusion required. Patients who did not exhibit at least two episodes of overt aggression in two separate weeks of the run-in period were not entered into the trial.

The medical officer assessed each patient at the start of the run-in period, 2 weeks later, at trial entry and after 1, 2, 3, 6, 9 and 12 weeks of the trial. Before trial entry a blood sample was taken for estimation of blood urea, serum creatinine and either protein-bound iodine or serum thyroxine. At each medical assessment blood was taken for the estimation of serum lithium concentration and serum creatinine. The occurrence of possible side-effects of lithium treatment and of enuresis or epileptic fits was recorded.

The starting dose of trial medication was a single daily dose of two 400 mg tablets of a controlled-release formulation of lithium carbonate ('Priadel') or matching placebo. Dosage was subsequently adjusted to maintain serum lithium levels in the recommended therapeutic range

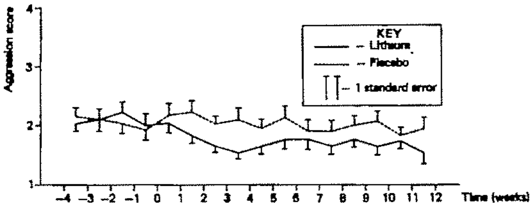

FIG. 1 Group means and standard errors of weekly mean aggression scores.

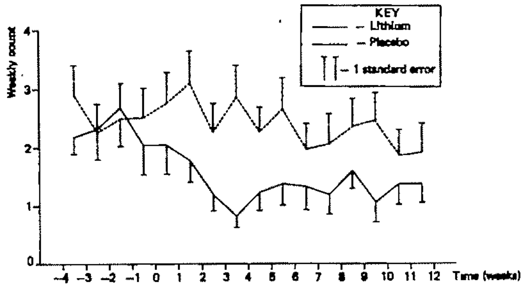

FIG. 3 Group means and standard errors of weekly counts of aggression score = 3 or more.

(0.7–1.0 mmol/litre 12 hours post-dose). The pathologist or another doctor at each centre provided dummy results for serum lithium concentrations for placebo patients in order to retain blindness. Other medication currently being given (e.g. tranquillisers, anti-convulsants) was continued as required but, as far as possible, no new treatment was started during the trial. Any additional medication needed was recorded. Patients could be withdrawn from the trial in the event of severe symptoms requiring other treatment or severe side effects causing concern.

In the statistical analysis of mean aggression scores and counts, the repeated measures nature of the data was taken into account, and repeated measures analysis was carried out using the BMDP 2V repeated measures program. The difference between the treatment groups in terms of response to treatment was assessed using the χ^2 test.

Results

Table I shows the background data for patients in the two treatment groups, which are seen to be comparable for all the factors listed, most of which were taken into account in the process of minimisation.

Since the level of aggression varied greatly from one day to the next, weekly mean aggression scores were calculated for each patient by adding his daily aggression scores for each week and dividing by seven. Figure 1 shows the means of these weekly mean aggression scores for the two groups. Whereas the weekly mean aggression scores are comparable during the run-in period, from the start of active treatment

the weekly mean aggression scores for the lithium group start to fall, and remain below the weekly mean aggression scores for the placebo group for the duration of the trial (i.e. the average level of aggression is lower in the lithium group than in the placebo group during the trial period). Repeated measures analysis, using the mean aggression score over the run-in period as a covariate for each patient, demonstrated a significance difference, almost at the 1% level ($P = 0.012$) between the global treatment means. The covariate correlated highly with the subsequent patient responses $P < 0.001$ and was therefore worth including in the analysis.

Figure 2 shows the mean of weekly counts of aggression scores of 1; that is, the mean number of days in each week that the patients in each group were well behaved, showing no aggression. The groups show comparable counts during the run-in period, but during the trial period the weekly counts of 1 are higher in the lithium group than in the placebo group (i.e. patients on lithium were well behaved on more days of each week of the trial period than patients on placebo). On repeated measures analysis the group means are not significantly different at the 5% level ($P = 0.082$), although the covariate correlates well with subsequent patient records ($P < 0.001$).

Figure 3 shows the mean of weekly counts of an aggression score of 3 or more for each treatment group (i.e. the mean number of days in each week that a score of 3 or more, indicating overt aggression, was recorded in each patient group). During the run-in period the two groups do not differ greatly, and indeed the counts cross over, but during the trial proper they separate and there are fewer counts of 3 or more occurring in the lithium group than in the placebo group. (Clinically, this means that in patients on lithium, aggressive outbursts were recorded less frequently than in patients on placebo.) Repeated measures analysis revealed a significant difference between the group means at the 1% level ($P = 0.002$), with the covariate correlating well with subsequent patient records ($P < 0.001$).

The tendency for patients in the placebo group to show a gradual improvement (in terms of lower mean weekly aggression counts of 3, and higher mean weekly aggression counts of 1) during the trial, may have been due to the inevitable lapses in daily recording as time went on, with progressive under-reporting of aggressive episodes. This would have tended to favour the placebo group, in which aggression was more prevalent during the treatment period, rather than the lithium group.

Individual evaluation was made of the daily aggression scores during the study. In the lithium group 16 patients showed reduced aggression during treatment (73%), two patients showed increased aggression (9%) and four patients showed no change (18%). In the placebo group six patients (30%) showed some reduction in the level of aggression during the trial period compared with the run-in period (50%) showed no change. This difference in response, four patients showed increased aggression (20%) and ten patients between the two treatment groups is shown to be significant on applying the χ^2 test to the resulting contingency table ($P = 0.03$).

Side-effects (thirst, polyuria, inco-ordination, tremor, drowsiness, and vomiting) were reported in eight patients on lithium (36%) but were transitory apart from one case of a patient who developed a persistent tremor, with serum lithium levels of 0.76–1.25 mmol/litre, for whom concurrent procyclidine was prescribed. In one patient lithium treatment was discontinued on account of vomiting, but was subsequently recommenced without problems and the vomiting was attributed to intercurrent infection. 'Lithium side-effects' were also reported in four patients in the placebo group (20%). There were no episodes of toxicity and no patients were withdrawn from the study.

Of the four patients with enuresis in the lithium group, two showed increased frequency of enuresis during lithium treatment, one showed a reduction in frequency and in one patient (whose aggression was dramatically controlled by lithium) enuresis ceased completely. In the placebo group one patient with enuresis was reported to be better during the trial and one was worse.

The only patient subject to fits was in the lithium group, and showed no change in the frequency of seizures during the trial period.

The initial daily dose of 800 mg lithium carbonate was not sufficient, in most cases, to bring the serum lithium concentration above 0.7 mmol/litre, and subsequent dosage adjustments were needed. A serum lithium concentration of 0.7–1.0 mmol/litre seemed necessary for clinical effect. Higher levels than this tended to be associated with tremors or inco-ordination. The highest serum lithium concentration recorded during the trial was 1.25 mmol/litre.

Where serum lithium levels were adequate, a response to treatment was sometimes seen within the first 2 weeks, but in other cases improvement was not apparent for 6–8 weeks. There was a tendency towards lower serum lithium levels at the end of the trial, reflecting either dosage reduction or possibly lack of compliance, which may explain the slight increase in aggression noted in some lithium patients towards the conclusion of the study.

The administration of additional medication to control aggression was recorded in three patients in the lithium group and six patients in the placebo group.

It is probably misleading in a trial of this size to draw conclusions regarding the response to lithium therapy of any particular patient subgroup. However, it was noted that all the patients in the lithium group with high scores for aggression during the run-in period responded particularly well to treatment.

Discussion

In this double-blind trial there was a reduction in aggressiveness in 73% of mentally handicapped patients treated with lithium. There was a statistically significant difference between the treatment groups in terms of the weekly mean aggression scores, and the weekly counts of aggressive episodes during the trial period. It is worth noting that these were difficult patients, many of whom had not responded to other therapies.

This confirms the observations and conclusions of previous investigators who have studied the effects of lithium in aggressive mentally handicapped patients (see the introduction to this paper) and have reported a beneficial effect in 50–88% of such patients.

Obviously the benefits of lithium therapy in the mentally handicapped have to be weighed against the risks, but as in-patients they can be carefully supervised so that the danger of lithium intoxication should be minimal. In this series, classical side-effects were noted in 36% of the patients in the lithium group, but these were mainly short-lived and in no case necessitated the discontinuation of lithium. The reporting of side-effects normally associated with lithium therapy in 20% of the patients in the placebo group was interesting as it showed that blindness was maintained, although it is sometimes claimed that this is not possible in trials with lithium. The side-effects occurring in placebo-treated patients were probably due to other drug therapy on which they were currently maintained.

The effect of lithium treatment on pre-existing enuresis was variable, two patients becoming worse during lithium treatment and two showing improvement. In this respect our series of patients did not reflect the problems of excessive thirst and bed-wetting described by Dostal and Zvolsky (1970), but confirmed the observation by Dale (1980) that lithium treatment may be associated with cessation of enuresis in a patient whose aggression is successfully controlled.

One patient with fits showed no exacerbation during lithium treatment.

From this study, and from previous work (Dostal & Zvolsky, 1970; Sheard, 1975; Goetzl *et al*, 1977; Sovner & Hurley, 1981) a 12-hour serum lithium concentration of 0.7–1.0 mmol/litre should be aimed at for clinical effect. Higher levels were associated with tremor and inco-ordination in our patients, and with neurotoxicity in an earlier trial by Worrall *et al* (1975), although these authors attributed the signs in their two patients to the combination of lithium and underlying brain damage. Most aggressive patients (perhaps because they tend to be hyperactive) need more than 800 mg/day lithium carbonate as a single daily dose to achieve therapeutic levels, and may require as much as 3000 mg/day (Dale, 1980). Once such levels are reached, a clinical response may become evident in 2–8 weeks. A controlled release formulation suitable for once-daily dosage (e.g. Priadel) is obviously easier to administer to difficult patients, and in long-term use is less likely to cause side-effects or renal changes (Plenge *et al*, 1982).

In a cross-over trial in 25 mentally handicapped patients, Tyrer *et al* (1984) used multiple correlation of placebo–lithium factor scores on background variables in an attempt to identify factors associated with a good response to lithium. They concluded that improvement was less likely to occur in socially withdrawn male patients with frequent aggressive outbursts. The identification of subgroups of responders or non-responders seems to have been a particular fascination of workers involved in trials of lithium. Manipulation of the data at the end of a trial invariably yields such subgroups, which may be meaningful but are frequently spurious findings, particularly in small trials. There is a danger that such findings become accepted dogma, and patients who might respond to lithium may therefore not be considered for such treatment. As if to illustrate this, our patients with high initial aggression scores responded particularly well to lithium, and both male and female patients were well represented among the responders. Lithium therapy is therefore worth a 2-month trial in any patient whose repeated aggression or self-mutilation is proving difficult to control.

This double-blind trial, together with the now considerable experience of earlier workers in this field, should serve to establish the place of lithium as a potentially useful agent in the management of those mentally handicapped patients whose uncontrollable aggressiveness makes long-term stays in hospital necessary.

Brief Reports

Mania Following Head Injury

A case of mania subsequent to head injury is presented. The literature reporting cases of mania after head injury is reviewed. It is suggested that the concept of Secondary Mania be broadened to include cases occurring after head injury. It is also suggested that a true bipolar illness can be secondary.

Manic-Depressive Disorder is usually regarded as a 'functional' disorder, of unknown aetiology. However, depression occurring secondary to medical illness has long been described and Feighner *et al* (1972) gave the concept nosological status in their classification of the affective disorders. Krauthammer & Klerman (1978) introduced the concept of Secondary Mania. They described mania resulting from drugs, infection, neoplasm, epilepsy and metabolic disturbances. They distinguished such a syndrome from mania which occurs as a phase of idiopathic manic-depressive disorder. They argue that 'mania is best considered a clinical syndrome of multiple aetiology'. A case of mania resulting from head injury which fits their criteria for secondary mania is described. A search of the literature provided 20 other cases of a manic psychosis following head injury.

Case report

A 48-year-old female entertainer fell from a trapeze and received multiple injuries in July 1985. In addition to fractured ribs, vertebra and iliac crest she also injured her head and lost consciousness for approximately 10 minutes. Skull X-rays showed no fracture. However, she had post-traumatic amnesia of approximately 3 days and developed bilateral fourth cranial nerve palsies with diplopia. On recovery from her physical injuries she was confused and disorientated but CT brain scan was normal. Over the next few days she became overactive and grandiose and was transferred to the psychiatric department. This was 3 weeks after her fall. On admission here she was fully orientated but displayed marked pressure of speech and flight of ideas. Although she was noted to laugh and cry alternatively she reported feeling 'very happy', 'super' and 'very strong', and told us that she was writing a book about her experiences which was sure to be a best-seller. After admission she did not sleep for long at night and insisted on doing 'exercises', requiring restraint on a few occasions. She had no previous psychiatric history and family history was likewise negative. She had suffered a fall 2 years previously and had fractured her pelvis but had no psychiatric problems.

She was treated with chlorpromazine and haloperidol and gradually settled over the following 8 weeks. However, she then developed a depressive episode with sadness, tearfullness and insomnia. This episode responded well to mianserin. However, her diplopia persisted. Prior to discharge an EEG was performed which was normal. Psychological testing showed her to have an IQ of 85 (Mill Hill Vocabulary Test/Ravens Progressive Matrices). Test results on the Wechsler Memory Scale suggested "possible residual deficits in the areas of visual memory and retention of new unfamiliar verbal material". Also, her result on the Benton Visual Retention Test showed some residual deficit in the visual spatial area.

She was quite well by October 1985 and was discharged to return to the UK. She was lost to follow up.

Literature review

A series of 44 post-head-injury patients described by Tennent (1937) included two with a definite diagnosis of mania. Hillbom (1951) and Achte *et al* (1969) reporting the long-term follow-up of a very large number of brain-injured Finnish war veterans identified seven cases of manic depressive disorder. Hoheisel & Walch (1952) described five cases of post-traumatic manic-depressive psychosis. Four of these patients had a positive family history. Parker (1957) described a patient who developed a manic depressive psychosis subsequent to head injury at the age of 41. He had no previous psychiatric history and no family history. However, Parker points out that there were 'emotional factors' in this case which could have been at least partly responsible for his psychiatric disorder. The autopsy of a 49-year-old man who developed a manic-depressive illness after head injury at the age of 41 was described by Deshimaru *et al* (1977). They speculated that his manic-depressive disorder was due to bruising of the bilateral orbital surfaces of the frontal lobes. Cohn *et al* (1977) described a 12-year-old boy who developed 'agitated hypomanic behaviour' after he sustained a closed head injury. He was treated successfully with lithium. A 39-year-old man who developed a bipolar disorder after injury to his right hemisphere was described by Gregersen & Hagen (1983). Lithium had a stabilising effect on his mood. A 23-year-old woman who developed a manic-depressive illness responsive to chemotherapy was described by Sinanan (1984). Khanna & Srinath (1985) described a 17-day episode of mania occurring in a 13-year-old girl with no previous psychiatric history and no family history of affective illness.

Discussion

Whilst the patient described here had no abnormality identified on CT brain scan the fact that she had residual bilateral fourth nerve palsies and some residual cognitive deficits indicates some degree of organic impairment. She was also rendered unconscious by the injury which implies some disruption of the deep structures of the brain (Cairns, 1952). If her affective illness was associated with this impairment it must be regarded as a secondary affective illness in the same way that affective illness occurring due to neoplastic structural damage is secondary. It is unlikely that a 'latent' affective illness was merely precipitated by the head injury as she was aged 48 at the time of the injury and had no previous psychiatric illness and no family history of affective illness. (The cases described above of Parker, Deshimaru, Cohn, Gregersen, Sinanan and Khanna were similar. In most of the others no information on past history or family history is available.) The fact that her psychiatric illness occurred directly after her head injury with no lucid normothymic period intervening also indicates that the head injury was directly causative. It is generally accepted that the shorter the interval between a head injury and the development of a psychosis the stronger is the likelihood of the two conditions being linked (Weller, 1985). This case fulfils the criteria for Secondary Mania as outlined by Krauthammer & Klerman (1978) and thus supports Khanna & Srinath (1985) when they argue that head injury should be included as an aetiological category for Secondary Mania. The patient described here suffered from a depressive episode following the manic phase. Most of the post-traumatic patients described in the literature also developed a bipolar disorder. This would indicate that not only unipolar depression and unipolar mania can sometimes be subsequent to physical illness but that this is also true of a bipolar state. This is supported by Jampala & Abrams (1983) who report the case of a man who developed a bipolar illness after a right-sided cerebral infarction. Oyewumi & Lapierre (1981) report a case of bipolar disorder secondary to brain stem injury and Forrest (1982) described bipolar illness after a right hemispherectomy. This is further evidence against what Krauthammer & Klerman (1978) call the 'one agent-one syndrome' model of causation and supports the idea that unipolar and bipolar affective disorder may be caused by differing pathophysiological pathways.

Further research is needed to clarify whether bipolar disorder subsequent to head injury follows the same course as idiopathic manic-depressive disorder. However, the impression from the literature is that such is the case and that secondary bipolar disorder can be chronic and episodic. Prophylaxis with lithium has generally been shown to be successful in cases of affective disorder secondary to structural lesions (Oyewumi & Lapierre, 1981); Rosenbaum & Barry, 1975; Cohen *et al*, 1980). However, Jampala & Abrams (1983) suggest that carbamazepine may be the 'rational choice' for the treatment of Secondary Mania.

The prognosis for a patient who develops mania secondary to head injury must remain guarded and possibly lithium or carbamazepine prophylaxis should be routinely considered.

Acknowledgements

I would like to thank Dr I. Aherne and Dr R. Galvin for permission to describe their patient.

Compensation Psychosis

Kennedy (1946) stated that "A compensation neurosis is a state of mind, born out of fear, kept alive by avarice, stimulated by lawyers and cured by a verdict". This theme, supported by Miller's influential paper in 1961, has ensured that generations of patients have been regarded with suspicion if they dared to present with psychological symptoms following an accident. The view remained unchallenged for over a decade and is still often presented to, and accepted by, our Courts, despite the fact that Miller reached his conclusions after examining patients who presented for legal reports in whose cases it was not surprising that he found a relationship between compensation and psychological sequelae. The psychological effects of proceeding litigation on the victim of an accident remain a matter of current debate. McKinley *et al* (1983), reported differences between those patients suffering a severe blunt head injury claiming compensation and those not claiming compensation. The reports given by relatives of changes in both patients were very similar. However, reports given by patients themselves differed with claimants reporting slightly more symptoms than non-claimants. In a study by White in 1981, the author followed up 163 victims of accidents admitted to the Birmingham Accident Hospital (76 burns and 87 general accidents). One year after their accident, psychological sequelae were found in approximately two-thirds of the group, one-third being moderately-to-severely psychologically affected. There was no statistical difference between those victims in whom the accident had given rise to litigation and in whom the case was still proceeding and those victims where compensation was not an issue.

Miller also reported that symptoms disappeared following compensation, but again recent studies disagree with this finding (Merksey & Woodforde, 1972; Kelly & Smith, 1981). Merksey & Woodforde (1972) report that neuronal loss and axonal damage has been documented even after mild head injury suggesting therefore, that, when a head injury results from the accident, some symptoms might be understood in organic terms allowing further room for misunderstanding and disagreement.

Case history

Mr H.T. was aged 51 at the time of his accident in 1982. Whilst working at a building site a 35 lb thermolite block was thrown from a first floor window down towards a skip on the ground below. On route it struck him a glancing blow on the back of his head, pushing his head forward towards the skip. It is uncertain whether or not he was rendered unconscious, he had a pre-traumatic amnesia of only a few minutes and the length of his post-traumatic amnesia is uncertain. His skull was not fractured and, although he was taken to hospital after the accident, he was not admitted.

The workman who threw the thermolite block accepted full responsibility, explaining that he had not seen Mr H.T. when he threw it. The blame was also accepted by the company. Our patient bore no resentment towards his fellow-worker, though he did feel that his employers had been perhaps less than sympathetic.

In the weeks that followed the accident, he experienced feelings of unreality, during which he would touch various objects to ensure that they really did exist. According to his wife he needed constant help and guidance, behaving rather like a child. On occasions, she would even have to do up his shoelaces. He was irritable, argumentative and easily upset. He complained that his memory was impaired, and also of being depressed, saying that he felt a sense of frustration and despair due to his memory impairment. He retained a good appetite and he did not describe sleep disturbance or diurnal variation. Whereas previously he had suffered no disturbance of sexual function, following the accident he was unable to sustain an erection.

Our patient had suffered no previous psychiatric illness and there was no history of any such illness in the family. Prior to his accident he was described as a hardworker, conscientious, and enjoying a good sense of humour.

He is the third of eight children and enjoyed a happy, normal childhood. He attended school until the age of 14 and became an apprentice carpenter and joiner, receiving further education at technical college (day release and evening classes). He later became a foreman carpenter and then a site manager, the latter being his employment for 25 years. At the time of the accident he had been working for that particular building contractor for only a few months.

He married at the age of 24 and has one adult son with whom he gets on well. Both he and his wife stated that they had enjoyed an excellent relationship prior to the accident. The change in his behaviour subsequently did, however, affect it adversely. He has never drunk to excess and was not taking medication at the time of the accident.

Assessment and progress

Mr H.T. was initially referred by his general practitioner for treatment and only later did his solicitor request a legal report. It was felt that many of his symptoms could be understood in terms of a traumatic neurosis but that it was appropriate to investigate further. Both EEG and CT scan proved normal and there was no evidence of intellectual deterioration. His memory quotient, however, was significantly impaired. These tests were carried out on four occasions between 1982 and 1985. His full scale IQ (WAIS) varied between 118 and 121 with the memory quotient varying between 90 and 106. There was no evidence of progressive deterioration. EEG and CT scan repeated in 1985 again proved normal.

Following his accident in February, 1982, he was off work for approximately 5 months. After returning to work for 2 weeks he was unable to continue, becoming markedly upset because he could not recall giving or receiving instructions or whether he had completed various tasks. Following a fortnight at home he again returned to work, then once more found himself unable to cope with his duties, remaining at home for a further 6 weeks. He returned to work again, but in August 1983, became markedly anxious and depressed and was admitted to a psychiatric hospital. He returned to work in November 1983, and remained there until January 1984, at which time he was again admitted to hospital and has not worked since that time. Whilst at home, he was able to exercise some of his skills in the form of carpentry but would require his wife to help him as otherwise he could not remember where he had placed his tools and would constantly mislay them.

In October 1985, he became increasingly agitated and refused to leave his home as he felt convinced that neighbours were spying upon him and that the police were about to raid his house in order to look for evidence to use against him. He was admitted to hospital as an emergency. He freely and spontaneously stated that he felt people would spy upon him in order to interfere with his claim for compensation. He described how, during a previous hospital admission, he came to realise that a fellow patient, a solicitor by profession, had been planted by his former company's solicitors in order to spy upon him and obtain evidence to use against him in court. He believed that a neighbour, a director of a security firm had tricked him into helping him mend a car in order to prove that he was not ill. He suspected that his neighbours were reporting his actions back to the insurance company and was convinced that hidden cameras and microphones were recording his every move and utterance.

He was commenced on Trifluoperazine and within 7 days his paranoid symptomatology was much less evident and a few weeks later he was able to admit that all his previous beliefs must have been erroneous and were "more like a nightmare than reality". During his admission he ate and slept well, mixed with other patients and at no time appeared depressed or tearful. His compensation psychosis has not recurred but his memory deficit and symptoms of anxiety and depression remain some months following receipt of a £50 000 settlement.

Discussion

Following a head injury, this patient initially presented with three problems; (1) a post-traumatic neurosis, (2) a post-traumatic personality change as described by Brooks & McKinlay (1983) and (3) a stable impairment of memory with preservation of global intellectual function. Nearly 4 years after the injury he developed features of a paranoid psychosis, describing delusions whose content reflected his preoccupation with the current compensation claim and legal proceedings. His memory impairment could be explained as follows:

(a) that his memory loss was in essence a deliberate disability produced either to gain compensation in monetary terms or to achieve psychological advantage;

(b) the memory impairment was due to an hysterical amnesia i.e. was produced by unconscious dynamic mechanisms which served to protect the victim of this accident from certain fears which had been caused or resurrected by the accident;

(c) memory impairment resulted from cerebral damage.

The first possibility would seem to the authors to be unlikely. Individuals who deliberately produce poor results from psychometric testing tend either to do badly on all the tests or to produce erratic results. In this case tests of intellectual function were similar on each occasion. Initially, verbal scales were slightly higher than performance scales (initial two tests) later becoming virtually identical. Memory quotient remained abnormal when tested on four occasions over 5 years. An organic explanation is most likely and it is supported by the direction of the discrepancy between verbal and performance scales at the initial assessments. It would be hard to accept that a lay person could fake his responses across a wide battery of subtests in order to produce an organic looking pattern. The above tests cannot unequivocally distinguish between organic and hysterical amensia, but again the pattern of results would make the former most likely.

Hysterical amnesia is usually of short duration. The hallmark of hysteria is said to be the absence of psychological distress i.e. 'belle indifference' with the hysterical symptoms protecting the patient against the cause of his distress. In this case the memory loss lasted for 4 years. It remains despite the settlement of his compensation case: the memory difficulties have themselves been the greatest cause of distress to him.

The aetiology of his compensation psychosis occurring as described some 4 years after the accident might also be open to debate.

As a result of differing medical opinions and the failure of the insurance company to agree to early settlement of the case, our patient eventually saw six consultants and two psychologists. He became increasingly preoccupied and anxious over the legal proceedings and particularly upset when he felt there was any implication (by those acting for the insurance company) that he was choosing not to work. It could therefore be argued that the development of his psychosis was due to a natural progression of dynamic processes.

The second possibility is that he coincidentally suffered a psychotic illness and, because of his preoccupation, his delusions naturally took the form described.

A third explanation, the most controversial but perhaps the most interesting, postulates that the organic process which causes memory impairment has eventually led to the development of his psychosis. This accepts the effects of dynamic stresses but suggests an underlying organic abnormality. In this case the process would have caused functional abnormality (both memory impairment and psychosis) without evidence of structural damage as demonstrable by an EEG or CT scan. Such a process is described in the model hypothesised by Wexler (1986) who suggests processes which are intermediary constructs between anatomy and cellular physiology on the one hand, and subjective experience and behaviour on the other.

Whatever the explanation, this patient, like many who have the misfortune to suffer an accident, has experienced great distress. Perhaps in 1986 Kennedy's aphorism could be amended so that psychiatric illness following accidents could be said "to be born out of trauma, kept alive by lack of understanding, complicated by litigation, but requiring appropriate treatment".

Oxygen Saturation during Electroconvulsive Therapy

Oxygen saturation was measured during anaesthesia and electroconvulsive therapy (ECT) using ear oximetry. Significant hypoxia occurred during some treatments; desaturation related to the number of ventilations performed after muscle relaxation and prior to the shock. Desaturation did not correlate significantly with seizure duration. These findings highlight the need for adequate oxygenation during ECT.

The major goal of anaesthesia for ECT is prevention of complications such as discomfort, fractures, aspiration of gastric contents, bradycardia and hypoxia. Monitoring of oxygenation is important during anaesthesia and, as clinical signs are often unreliable, ear oximetry is recommended as a more precise method of detecting hypoxia. The present study measured haemoglobin saturation during routine anaesthesia and ECT to assess the incidence of hypoxia under normal circumstances.

Method

Local Ethical Committee approval was obtained for the study and only patients unable or unwilling to consent were excluded. Four separate ECT sessions were studied, involving 40 patients who were grouped according to which anaesthetist was responsible for them. Anaesthetists were asked not to deviate from their usual practice and did not know what was being recorded; they were not allowed to see the oxygen saturations during the study. The apparatus was unobtrusive and did not interfere with the routine of the list. All patients were anaesthetised using methohexitone and suxamethonium without atropine. A flow of 6–10 litres per minute of 100% oxygen was invariably administered, using a Mapleson C circuit, without a carbon dioxide absorber. Positive pressure ventilation was performed following the administration of the muscle relaxant, both before and after the seizure. The number of positive pressure ventilations given prior to the shock and the time at which oxygen was administered after the seizure were recorded. The seizure duration was measured using the isolated arm technique (Fink & Johnson, 1982).

Oxygen saturation was measured using a Hewlett-Packard ear oximeter, which measures saturations in the range of 65–100%. The patient's ear was 'arterialised' by brisk rubbing for 15–30 seconds, and the probe was applied to the pinna. A potentiometric recorder made a continuous trace of the oxygen saturation during anaesthesia and ECT. The change in oxygen saturation was calculated by subtracting the lowest saturation reached after seizure and before the administration of oxygen from the baseline value.

Data were analysed using Pearson's Product Moment Correlation Coefficient and analysis of variance, followed by the Tukey test, where appropriate.

Results

Four anaesthetists were responsible for 10 patients each; 33 patients were female and 7 were male; the median age was 49 and the age range 21–78 years. The doses of methohexitone and suxamethonium used by each anaesthetist did not differ significantly (Table I).

TABLE I
The doses of anaesthetic drugs used in the four groups of patients

	Anaesthetist 1	2	3	4
Methohexitone: mg				
Mean	66	64	51	74
SD	24	22	17	28
Suxamethonium: mg				
Mean	45	30	35	35
SD	10	8	6	6

The range of oxygen saturations recorded during ECT was 79–100%. 16 subjects demonstrated a fall in oxygen saturation of more than 5% from the baseline value, lasting from 15–75 seconds. Prior to anaesthesia there were no significant differences in oxygen saturation between the four groups, and the degree of hypoxia was unrelated to initial oxygen saturation (Table II). Patients in group 1 remained better oxygenated than those in groups 2 ($P<0.01$), 3 ($P<0.01$) and 4 ($P<0.05$) (Table II). The only difference in anaesthetic technique between the groups was the number of ventilations performed after the suxamethonium, but prior to the shock; anaesthetist 1 ventilated more than the others ($P<0.01$, Table II). The change in oxygen saturation correlated with the number of ventilations given prior to ECT ($r=0.65$, $P<0.001$). All anaesthetists commenced oxygenation within 60 seconds after the seizure had finished, and the oxygen saturation invariably returned to baseline levels or higher.

The seizure duration was significantly less in group 2 compared with group 1 ($P<0.05$, Table II). The duration of seizure did not correlate significantly with the change in oxygen saturation ($r=0.21$).

TABLE II

Baseline and change in oxygen saturation, number of ventilations given and seizure duration in the four groups of patients

	Anaesthetist			
	1	2	3	4
Baseline O_2 saturation: %

Mean	34.9	15.6†	31.1	24.7
SD	17.4	4.9	19.5	14.4
Range	15–65	6–23	8–80	15–60

*Group 1 significantly less hypoxic than groups 2 ($P<0.01$), 3 ($P<0.01$) and 4 ($P<0.05$). **Group 1 significantly more ventilations given than groups 2, 3 and 4 ($P<0.01$). †Group 2 significantly shorter seizure duration than group 1 ($P<0.05$).

Discussion

Death during ECT has been ascribed to cardiac problems involving both vagal and ectopic mechanisms (Bankhead *et al*, 1950). The ECT seizure causes widespread physiological changes due to autonomic stimulation. Bradycardia followed by tachycardia usually occurs, with hypotension followed by hypertension, therefore cardiac output falls initially, exacerbating tissue hypoxia, before rising. Low oxygen saturation occurring as heart rate and blood pressure increase predisposes to myocardial ischaemia and arrhythmias. Atropine was recommended to reduce vagal problems, however, its routine use has been challenged as it does not contribute to cardiac stability during ECT (Wyant & Macdonald, 1980).

As early as 1950, Bankhead and colleagues suggested that cardiac ectopic phenomena occur during the 'deepest cyanosis following the convulsion', but the use of oxygen during ECT did not then become routine. In a description of ECT in 1968 the shock was delivered 50 seconds after the relaxant and, following the clonic phase, three hand ventilations were delivered using, 'room air . . . and never oxygen' (Pitts *et al*, 1968). As recently as 1979 it has been claimed that oxygenation during ECT is unnecessary (Joshi, 1979), although apnoea after the shock can last for a few minutes, and will cause significant hypoxia if untreated. The present study was designed to monitor oxygenation in the clinical situation during routine anaesthesia and ECT. Significant hypoxia was demonstrated and desaturation correlated with the number of ventilations performed prior to the shock, a simple variable in anaesthetic practice.

The present study supports the concept that hyperventilation before ECT may prolong the seizure, as the patients who received fewest ventilations (group 2) had the shortest seizure duration, perhaps reflecting hypercapnia. Hyperventilation with oxygen therefore prevents hypoxia, and may also enhance therapy. As hypoxia was not related to the duration of the seizure, it may be that carbon dioxide is a more important determinant of seizure activity.

The occurrence of hypoxia is demonstrated in the present study, but not shown to be detrimental. In normal circumstances transient hypoxia should be of little consequence, but if accompanied by other problems, for example cardiovascular changes or vomiting, may be more serious. A survey of anaesthetic practice in 1980 showed that most patients are now kept well oxygenated, but a few clinics still did not routinely administer oxygen (Pippard & Ellam, 1981). As the same study showed that over 50% of the anaesthesia for ECT is performed by anaesthetists in training, teaching should emphasise the need for adequate oxygenation.

Acknowledgements

The authors thank Dr R. P. Snaith, Consultant Psychiatrist, for his advice during the planning of the study and preparation of the paper. We are also very grateful to the anaesthetists involved and the staff of the ECT Unit at St James's University Hospital for their cooperation and support.

Anorexia Nervosa and Gastric Rugal Hyperplasia

A case of anorexia nervosa associated with gastric rugal hyperplasia in a 36-year-old male is reported and some speculations are made about the relationship between these two conditions.

Although anorexia nervosa in the male is an uncommon condition, recent studies have shown that males account for 5–10% of all cases (Hogan *et al* 1974; Anderson & Mickalide, 1983). Anorexia nervosa has been associated with a range of medical conditions, including hypothalamic tumour (Heron & Johnson, 1976), pancreatitis (Schoettle, 1979), Gaucher's Disease (Erman & Murray, 1980), Superior-mesenteric-artery syndrome (Froese *et al*, 1978) and pneumoperitoneum (Al-Mufty & Bevan, 1977). Several authors have pointed out that in cases where anorexia-like symptoms co-exist with a physical condition, it is not always easy to decide whether the weight loss is a primary or secondary symptom (Schoettle, 1979). Others have indicated the importance of excluding organic conditions in anorexia nervosa (Heron & Johnson, 1976). The latter authors also comment that even when anorexia nervosa-like symptoms are of organic origin there may be some response to psychological treatment alone, thus highlighting the importance of correct diagnosis before treatment.

Case history

A 29-year-old male wholesale butcher was admitted in an emaciated state measuring 1.765 m but weighing only 55.10 kg. Although overweight as a child, he had weighed 73.00 kg for many years. He gave a 2-year history of gradual weight loss and had lost 25% of his original body weight by the time he was first seen. A previously fit man, during the month prior to admission he had complained of satiety following small meals together with feeling light-headed. He had a 2-week history of being short of energy and, just prior to admission, had collapsed at work whilst carrying a meat carcass on his back. The patient's wife reported that he had always been a loving husband and father who had been quite involved in bringing up their three children. He had often become anxious about his health when developing minor physical illnesses but rapidly returned to his cheerful self on recovery. She had first noticed a problem 2 years previously following the birth of their last child. The patient had again become anxious about his health and, being concerned that his hair might be falling out, had arranged to have a hair transplant. Shortly after that he became concerned about his weight and refused food that she had cooked insisting on providing only high protein meals for himself. He also began to count the calorie content of his meals with the aid of slimming magazines which he hid from the family. By the time of referral he had excluded nearly all carbohydrates from his diet and had begun to abuse laxatives. Although not previously an athletic man, he had recently taken up weight-lifting to the exclusion of all other leisuretime activities. Over the same period he had lost all sexual interest in his wife in spite of their having had a previously satisfactory sexual relationship.

Examination showed marked weight loss, muscle wasting, dry skin and hair and cold cyanosed extremities. His pulse was 60/minute, blood pressure 115/80 mmHg and oral temperature 36.5 °C. The abdomen was scaphoid with no abnormal palpable masses. Even when shown his scaphoid abdomen on video tape he insisted that it protruded. He could not accept that his admission weight was below that expected for a man of his height and build but agreed that he should gain weight though felt that this could only be achieved through muscle development by weight training with reduced food intake.

Investigations revealed a lowered total protein of 53 g/litre with serum albumin of 37 g/litre, raised blood urea of 100 mmol/litre, and raised serum free cortisol of 745 mmol/litre. A barium meal, undertaken because of his complaints of early satiety, demonstrated prominent gastric folds in the body and fundus of the stomach. Although the radiology suggested malignancy, endoscopy and biopsy showed hypertrophic gastropathy with gastric foveolar hyperplasia. There was no evidence of increased gastric secretion even following pentogastric stimulation.

Pending investigation the patient was placed on a regime of bed rest and gradual refeeding which initially resulted in some weight gain. He continued to request laxatives and slimming magazines and, after his wife had refused to co-operate in this, purchased large quantities of a particular brand of mints from the mobile hospital shop which were eventually shown to carry a warning about their laxative qualities. Following this episode his weight fell to 54.00 kg. The patient was treated as a case of Ménètrièr's disease and was prescribed Ranitidine. This resulted in weight gain and eventual disappearance of his enlarged gastric rugae. He was discharged home having regained his admission weight of 55.10 kg and when followed up 6 weeks later had gained a further 5.00 kg. Three months later he was seen again weighing 49.60 kg, having failed to return to work, instead spending most of his time running or weight training. He admitted to excessive exercise and laxative abuse expressing a wish to look like 'Mr Universe'. He was readmitted when a repeat endoscopy showed no evidence of recurrence of his gastric condition. He responded slowly to a refeeding programme and was eventually discharged to day care. He continued to be preoccupied by his weight and physique. He lost his job, was divorced by his wife, and lost most of his friends since they were unable to tolerate his somatic preoccupations. His weight-lifting continued and resulted in the development of tiny muscles contrasting with the emaciation of the rest of his body. More recently he has benefitted from out-patient group psychotherapy and, at the time of writing, has gained part-time employment as a butcher. His weight fluctuates at around 65.10 kg.

Discussion

This patient's intense fear of becoming fat which did not abate as weight loss progressed, persistent disturbance of body image, weight loss of over 25% of his original body weight, and refusal to maintain his body weight over a minimal norm for his age and height, would fulfil diagnostic criteria for anorexia nervosa as defined by DSM-III (American Psychiatric Association, 1980), apart from the requirement for absence of physical illness which would account for the weight loss. With reference to Feighner's more stringent criteria for the diagnosis of this condition (Feighner *et al*, 1972), the requirement for weight loss to be at least 25% of original body weight is clearly met as is that for a distorted implacable attitude towards the eating of food, this being a persistent feature. There was no evidence of any other major psychiatric disorder, although the patient had clearly suffered from anxiety prior to the onset of the eating disorder. With regard to the presence of anorexia, this patient would admit that he was hungry if asked, but stated it was inappropriate for him to eat because this would mean becoming fat. The Feighner criteria includes anorexia as a diagnostic feature but it has recently been suggested that this term should be modified to that of self starvation (Vanderyckan & Meerman, 1984). The same authors point out that an age of onset of under 25 years is illogical, and others have reported cases in the male who meet all other criteria but this one (Andersen & Mickalide, 1983). With these reservations, therefore, the patient would also fit Feighner's criteria apart from the necessity for the absence of any medical disorder which might explain the weight loss.

Since enlargement of the gastric folds associated with low blood protein levels was first described by Ménètrièr in 1888 there have been several reports in the literature describing benign enlargement of the gastric rugae, together with cystic dialation of the glandular mucosa (Butz, 1960). These features were all present in this case, although Searcy & Malagelada (1984) have recently suggested that such patients should be considered as two groups: those with enlarged gastric folds, hypoproteinaemia and oedema constituting Ménètrièr's disease and a separate group with enlarged gastric folds but lacking the other features. They suggest that this idiopathic hypertrophic gastropathy group has a different aetiology, prognosis and response to treatment. This patient had a total protein level within the range suggested by Searcy & Malagelada for patients with Ménètrièr's disease but there was no oedema, his serum albumin being within the normal range. It would, therefore, be more appropriate to place him into Searcy's idiopathic hypertrophic gastropathy group. Although spontaneous remission has been reported (Frank & Kern, 1967), benign gastric rugal hyperplasia is usually a chronic condition which has previously been treated by gastrectomy in those cases complicated by significant protein loss. Recently Vendelboe (1981) has advocated the use of beta intestinal H_2 antagonists since these reduce protein loss and promote regression of the hypertrophic rugae thus avoiding the necessity for surgery. Such an effect was demonstrated by this patient who, when gastroscoped following 4 months treatment with Ranitidine, exhibited no further evidence of gastric pathology.

It is interesting to speculate on the relationship of the enlarged gastric folds to anorexia nervosa. Benign gastric rugal hyperplasia is considerably more common in men (Fieber & Rickert, 1981), and occasionally presents in the 20s and early 30s as does anorexia nervosa in the male (Butz, 1960). In this patient, discomfort on eating, with early satiety and marked weight loss were prominent features which occur commonly in gastric rugal hyperplasia (Searcy & Malagelada, 1984). The patient clearly meets diagnostic criteria for both anorexia nervosa and benign gastric rugal hyperplasia, but the former condition persisted after endoscopic examination confirmed successful treatment of the latter. The patient continued to complain of similar symptoms, in particular early satiety, long after all signs of enlarged gastric rugae had disappeared. Although initially gaining weight in hospital and for a period following discharge he eventually deteriorated and was readmitted at a lower weight than that at which he originally presented.

The causes of benign gastric rugal hyperplasia are unknown but there is no evidence to suggest that anorexia nervosa might be one of them. Although isolated reports of gastro-intestinal complications of anorexia nervosa have been reported (Froese *et al*, 1978), an association with gastric rugal hyperplasia has not. If the relationship between these two conditions were causal one would expect to see them together more often. There is, however, some suggestion that the presentation by this patient of these two conditions together is not entirely coincidental. He had long been anxious about coping with his expanding family exemplified by his concern about hair loss following the birth of his last child. To him losing his hair meant that he was getting too old to care for the family properly and he felt that a hair transplant would enable him to cope again. It had always been important to him to be fit and well so that when he first felt epigastric discomfort he became anxious that there might be something seriously physically wrong with him and he had not wanted to talk to anybody about it. At this point he reached a crisis when, unable to face the prospect of supporting his family whilst sick, he sought a way of becoming fit again without first seeking a diagnosis of his condition. He decided to diet because he thought that this would make him look and thus feel more fit. As he lost weight his anxiety was reduced as the weight loss due to physical illness became masked by that induced intentionally. Anorexia nervosa arising during adolescence often follows a similar crisis in coping with adult responsibilities with weight loss alleviating the associated anxiety and thus becoming self-perpetrating (Crisp, 1980). Vanderyckan & Meerman (1984) suggest a multifactorial aetiology of eating disorders and point out factors which can precipitate anorexia nervosa in predisposed individuals in both the pre-pubertal and post-adolescent age groups. Predisposing factors in this patient would include his failure to successfully complete the tasks of adolescence, leaving him with doubts about his ability to be a husband and father, and his longstanding somatic preoccupations. The physical symptoms of Ménètrièr's disease leading to a fear of serious illness could be regarded as the main precipitating factors.

This sort of relationship between two conditions is one of precipitation of the psychiatric illness in a predisposed individual at the onset of the physical one rather than of a causal link. This case, therefore, demonstrates the importance of considering a co-existent physical condition whenever a diagnosis of anorexia nervosa is made after adolescence, especially in the male with no previous symptoms of an eating disorder.

Acknowledgements

I would like to thank Dr M. R. Morton of Burton Road Hospital, Dudley, and Dr A. N. Hamlyn of Wordsley Hospital, Stourbridge, for allowing me to report on their patient and for their advice and encouragement. Thanks are also due to Mrs P. Smith of the Institute of Family Psychiatry for secretarial assistance.

A Case of Mosaicism with Fragile-X and XXY Components

The case of a 63-year-old severely mentally handicapped man is reported with chromosomal mosaicism. His karyotype was established as mosaic 46XY/47XXY with the fragile site present in a proportion of cells of both cell-lines. He showed phenotypic features which could be related both to the fragile-X and Klinefelter's syndromes.

A 63-year-old man with severe mental handicap was discovered to have an abnormality both in number and morphology of the X chromosomes. His chromosomes were examined when his sister's granddaughter's child died and the diagnosis of Reye's syndrome and spastic cerebral palsy was made at the Hospital for Sick Children, Great Ormond Street. He was found to be a chromosomal mosaic. Two per cent of cells showed the XXY karyotype. A fragile-X chromosome was found in 34% of the cells examined, including XXY cells. In the affected XXY cells, only one of the X chromosomes showed the fragile site.

Case history

He is the youngest of four sibs. His mother's first two pregnancies resulted in the birth of healthy normal daughters. Her third pregnancy ended in miscarriage. At the end of her fourth pregnancy she gave birth to a normal daughter who, however, died at 6 months. Her fifth pregnancy led to the birth of a blind male child with a hare lip who lived only 3 days. Her sixth, seventh and ninth pregnancies ended in miscarriage. In her eighth pregnancy she gave birth to a daughter who was feeble-minded and epileptic. Her tenth and last pregnancy led to the birth of the propositus.

He was admitted to a hospital for the mentally handicapped at the age of 18 years under Section 15 of the Mental Deficiency Act of 1913 having been found to be neglecting himself. His early milestones are reported to have been delayed. He attended elementary school for 4½ years but failed to progress. When he was 9 years of age he was thought to be mentally defective and was sent for a trial period at a special school. He appeared not to benefit from this and was deemed to be an idiot and attended occupation and craft centres. He is reported to have suffered a road traffic accident as a child, but no details of this are available. Apart from a prostatectomy, his medical history is uneventful and he is not currently on any regular medication.

He has a pleasant personality and is friendly but is shy in a group or with strangers. His speech is limited; mostly it is monosyllabic. Occasionally he utters a full sentence. His voice is of normal male pitch. He can dress and undress himself, feed himself and take himself to the toilet. He helps the ward staff with small domestic tasks and can even cook simple items. He enjoys taking the responsibility of looking after other residents in the ward. Occasionally he is aggressive when disturbed or annoyed by others.

On physical examination he is obviously mentally retarded, 170 cm in height, moderately obese and weighs 70 kilos. He is of eunuchoid habitus with wide hips and relatively narrow shoulders. His pubis-sole measurement is 83 cm and pubis-vertex measurement is 87 cm. He has a pronounced dorsal kyphoscoliosis. He has a long face with a high forehead and relatively large ears. He is edentulous with a slightly protruding lower jaw, high arched palate and a slight strabismus of the left eye. There is moderate gynaecomastia but distribution of body hair is of normal male type. The penis is of normal size with both testes descended and the right testis is slightly smaller in size. The hands and feet are of normal size with moderate pes planus. He walks with short shuffling gait but there is no other obvious abnormality in the central nervous system. X-ray of skull and elbows are normal and X-ray of spine showed slight scoliosis. His serum testosterone level is within normal limits, being 15 mmol/litre (normal range of male 10 mmol/litre–38 mmol/litre).

Discussion

Considering the relatively high frequency of Klinefelter's syndrome and the fragile X syndrome, patients with occasional coincidence of both syndromes is to be expected. To our knowledge there have been four case reports in the literature with the concurrence of both conditions in the same patient. These could show variability with respect to phenotypic manifestation which is not altogether surprising as the relative strength of expression of the two syndromes is likely to vary in individuals in which they are concurrent.

Wilmot *et al* (1980) observed a case with less severe mental retardation and less characteristic facial

TABLE I

Comparison of clinical features in different case reports with both XXY and fragile-X

	Case of Wilmot et al (1980)	*Case of Froster–Iskenius et al* (1982)	*Case of* Fryns *et al* (1983)	*Case of* Fryns *et al* (1984)	Present case

Karyotype and % cells with fragile-X	47 XXY 2% Fragile-X	47 XXY 27.9% Fragile-X (3.6% in inactivated X)	XY/XXY (50% XXY) 2% of 47 XXY Showed Fragile-X	47 XXY 51% Fragile-X (20% in both active and non-active X)	XY/XXY (2% XXY) 34% Fragile-X in both XY and XXY

expression than are usually found in patients with fragile X syndrome. His patients had small testes and these findings were thought to be due to the effect of the second X chromosome. On the other hand Froster-Iskenius *et al* (1982) reported a case with mental retardation which was more severe than usually observed in Klinefelter's syndrome while testicular hypotrophy, gynaecomastia and hormonal levels were more characteristic of the 47 XXY condition. In the same case facial appearance with large ears was probably the expression of the fragile X chromosome (see Table I). In the case reported by Fryns *et al* (1983) the face was less typical of the fragile X syndrome, being rounded, and without obvious prognathism. The genital development was compatible with mosaic Klinefelter's syndrome: both testes were small and soft, but testosterone levels and penile size were normal. In their study only 2% of the cells with 47, XXY showed the fragility at Xq27–28 but no fragile site could be found in 46, XY cells. In another report Fryns *et al* (1984) reported a moderately mentally retarded male with a long face and relative prognathism, gynecoid pelvis and small soft testes. His secondary sexual characteristics were poorly developed with scanty axillary and pubic hair. In some cells, fragile sites could be found on both X chromosomes.

In the present case, the facial appearance and severe mental retardation is consistent with the fragile X syndrome. The presence of XXY cells could well be responsible for the gynaecomastia and the reduced size of the right testis. Unfortunately the occurrence of fragile X chromosome in other members of the family could not be determined as permission for further investigations was refused. The recurrent foetal loss suffered by the mother of our case may have been associated with chromosomal imbalance. The possibility of maternal syphilis was considered as a potential cause of recurrent foetal loss—obviously the mother was not available for investigation, but serological tests for syphilis were carried out in the case of the propositus and were found to be negative. In the small number of cases described,

be negative. In the small number of cases described,

there appears to be a tendency of the fragile X to show characteristic facies and a degree of mental retardation, while the remaining features tend to be those of Klinefelter phenotype. It may be of particular significance that the testicular pathology of Klinefelter's syndrome prevents the expression of the fragile X macro-orchidism.

Acknowledgements

We thank Dr Coorez, in whose care this patient is at Leavesden Hospital, and Dr M. A. C. Ridler for his comments on the text. We are grateful to Dr D. Chavda for carrying out the serological tests.

Epilepsy and Psychosis – Ask The Family

Psychotic episodes and epilepsy can occur without mental retardation in tuberous sclerosis. The diagnosis may depend on elucidating the family history since physical signs may not be obvious. Establishing the diagnosis makes genetic counselling possible.

Tuberous sclerosis is a cause both of epilepsy (Rakoff, 1981) and of psychotic episodes resembling schizophrenia (Herkert *et al*, 1972). It is inherited by autosomal dominant transmission although a spontaneous mutation rate as high as 80% has been suggested (Bundey & Evans, 1969). About two-thirds of patients are mentally retarded (Nevin & Pearce, 1968). Even within a family, the clinical features of tuberous sclerosis may show great variability and a family history of epilepsy or of psychiatric illness may be lacking. Members of the family may not be aware that their differing abnormalities are due to the same underlying inherited disorder.

Case report

A 19-year-old epileptic man was referred by the police surgeon. He had been arrested as he had attempted to draw public attention to his stated mission from God "to send the earth back into the sun" by damaging a car. For the previous 2 years he had a history of increasing social isolation and apathy, staying at home and making no attempts to gain friends or employment. For 3 months before admission he had become increasingly aggressive and had begun to express bizarre ideas, particularly in the postictal state.

On admission the patient was withdrawn and reluctant to communicate. He answered questions briefly, though frequently not to the point, and offered no spontaneous conversation. His affect was flat and he was preoccupied with the megalomanic delusional system that he was "Father of all the people of the world", having a mission "to turn the world back into the sun and thus make people believe in Jesus Christ". He also expressed a delusion that the world would end in 1 week. He made no further attempt to act on his delusions in the ward setting. He suffered from thought broadcasting and passivity feelings and had auditory hallucinations of God talking to him. He showed marked concrete thinking in interpreting proverbs. His concentration was poor, mainly because of his preoccupation with the delusions and hallucinations. Though perplexed, his memory and orientation were normal.

Physical examination revealed three small depigmented areas on his back, which were dismissed at the time as being of no consequence. Routine biochemical and haematological investigations were within normal limits. A series of EEGs all showed continuous irregular delta activity with occasional spike discharges localised to the left anterior temporal region.

The patient's father, with whom he had lived following his parents' divorce some years previously, reported that his son had been epileptic from the age of 10 with generalised tonic-clonic seizures. Some 4 years later, his previously good seizure control deteriorated and post-ictal episodes of wandering and confusion began. He had been treated with carbamazepine. In the years leading up to his admission, the frequency of his generalised seizures increased to as many as ten per day and he had once been admitted to hospital in status epilepticus.

A diagnosis of an organic psychosis was made and, in addition to carbamazepine, treatment was started with haloperidol and later flupenthixol decanoate with a good response. Psychometric testing performed when the acute psychotic symptoms had abated showed a Wechsler Adult Intelligence Scale IQ of 99 (verbal scale 97, performance scale 102).

His father had no knowledge of any family history of psychiatric illness, epilepsy or serious physical illness. However, when the patient's mother was interviewed 2 weeks after his admission, subungual fibromata were noted on her fingernails. These were also found on her toenails and were apparently also possessed by her own mother. In view of this, tuberous sclerosis was suspected. Re-examination of the patient showed that the previously discounted areas of depigmented skin were recognisable as ash-leaf patches. Computed tomography of brain confirmed the diagnosis, demonstrating several calcific opacities, two lying in a subependymal position lateral to the bodies of the lateral ventricles. Bilateral temporal lobe atrophy was also noted.

Having established the diagnosis it became possible to initiate a suitable rehabilitation programme for the patient, to offer genetic counselling to his mother and her family and to give a more accurate prognosis.

Discussion

Tuberous sclerosis may present in a variety of ways and with a plethora of clinical features other than the classical triad of adenoma sebaceum, epilepsy and mental retardation (Person & Perry, 1979). Bundey & Evans (1969) investigated patients in whom adenoma sebaceum appeared after the age of 20. Of patients with an affected parent only 20% were epileptic. This finding is the more striking because of the preponderance of severe childhood cases in their study.

Psychosis presenting in affected individuals with no history of epilepsy has also been described (Herkert *et al*, 1972). Schizophrenic-like psychosis and epilepsy, particularly temporal lobe epilepsy, are well known to co-exist (Beard & Slater, 1962). Psychotic phenomena akin to those found in schizophrenia may occur during a temporal lobe seizure and Perez *et al* (1985), from their study of 24 patients with epilepsy and psychosis, concur with the hypothesis that discharges in the dominant temporal lobe are associated with a diagnosis of schizophrenia. The anatomical lesions of the temporal lobes in our patient are of interest in this respect.

Our case demonstrates that tuberous sclerosis may present as a psychotic illness and that physical signs may be overlooked or dismissed as within normal limits. The diagnosis should be considered particularly in patients presenting with psychosis combined with epilepsy. It illustrates the importance of obtaining a detailed family history to aid the differential diagnosis of possible inherited organic disorders. Family members may not be aware of, or may not reveal, significant information. It is necessary to interview more than one relative, particularly if members of the patient's immediate family are divorced or separated.

An Epidemic of Suicide Attempts by Burning in a Psychiatric Hospital

Three patients attempted suicide by burning in one ward of a psychiatric hospital in a period of less than 1 month. No such attempts had occurred there in the previous 9 years. The three patients were schizophrenics with depressive features who occupied the same room in the ward. It seems reasonable to suggest that at least the choice of method and the timing of these suicide attempts were influenced by imitation. Hospital staff should be especially aware of the influence of imitation in suicide in order to avert such undesired epidemics.

Different views have been expressed on the role of imitation in suicide. William Farr (1841) wrote: "No fact is better established in science than that suicide is often committed from imitation". Suicide rates increase briefly following publicity given to the suicide of famous people (Hewitt & Milner, 1974; Phillips, 1974). A statistical association has been shown between reports of suicide inquests in a local paper and the subsequent suicide of men under 45 years (Barraclough *et al*, 1977). These authors are convinced that suicide is contagious.

Durkheim (1897) adopted a different point of view and wrote that suicide "exposes a state which is the true generating cause of the act and which probably would have produced its effect even had imitation not intervened".

An epidemic of suicide by burning was reported in England and Wales in 1978–1979 (Ashton & Donnan, 1979). Between October 1978 and March 1979, there were 42 deaths caused by burning with suicidal intent, while the average in the previous 15 years was only 19 cases/year. The epidemic started following wide publicity in the press given to the suicides of two women who burned themselves in public on 2 and 4 October 1978. It seems reasonable to suggest that at least the choice of the method of suicide was influenced by the publicity surrounding those two cases.

In our closed psychiatric ward, there were no suicide attempts by burning in the last 9 years. The occurrence of three such attempts in a period of less than 1 month drew our attention to the phenomenon of imitation in a psychiatric hospital and to the possible influence of the first suicide attempt on the timing and choice of method in the other two patients.

Case reports

Case A

This single woman, aged 23, born in Israel to parents of European origin, had a schizophrenic illness starting at the age of 16 years when she was first admitted to hospital. Since then she had been admitted several times in acute psychotic states. There were partial remissions but her social and occupational functioning were markedly affected. She never took her medications regularly. Her present admission was because of an exacerbation of her schizophrenic illness expressed by disturbance of thinking, blunted affect, auditory hallucinations and negativistic behaviour. The patient had a striking appearance—tall, blonde with blue eyes and with a ready smile. She played the piano well and, in spite of the severe course of her illness, had a special status among the patients in the department. Treatment with trifluoperazine (Stelazine) 60 mg/day brought about an improvement in her condition.

Three months after her admission, she learnt that her parents were about to separate and that she would have to reside with her father, and she attempted suicide by pressing a burning towel against her body. As a result she suffered split and full thickness burns over about 9% of her body surface. In the course of the attempt, she smiled and expressed a blunted affect, claiming that she had reacted to voices she had heard. These voices had hinted that in this way her suffering would cease. Subsequently, she continued to express suicidal ideation and 2 weeks after the suicide attempt, she was moved to another room.

Case B

This woman, aged 22, who shared the new room of Case A, was born in Israel to a father of oriental origin (Lebanon) and an Israeli-born mother. The patient, married, without children, had suffered from schizophrenia that started at the age of 15 in the form of affective outbursts. During a previous depressive state, she had attempted suicide by cutting her wrists. This time she was admitted to hospital with depressed mood, formal thought disorder, delusions, auditory and visual hallucinations. Four days after her admission, she attempted suicide by tying a nylon cord around her neck. Because there was a possibility that the patient was pregnant, she started receiving ECT which brought about a slight improvement in her condition. However, she continued to lie in bed, with marked evidence of delusions and hallucinations. When it became clear that the patient was not pregnant, the treatment was changed to trifluoperazine (Stelazine) 40 mg/day.

When her condition did not improve significantly after 3 months, she became worried that she might be transferred to another institution for chronic patients. As a protest she attempted suicide by setting fire to a shirt and pressing it against her chest, thus suffering burns over about 2% of the body surface. She later reported that she got the idea and the method from conversations with patient A, who had committed a similar attempt 3 weeks earlier, and who now was in the bed next to hers.

Case C

A female patient, aged 47, born in Iraq, married and the mother of three children, shared the same room with patients A and B. She was admitted to hospital in a state that seemed, at first, as agitated depression following a suicide attempt by swallowing insecticide, in an open ward of another hospital. In our ward, she attempted suicide by trying to strangle herself with a sheet.

Her clinical condition was characterised by detachment, agitation, insomnia, thinking disorders, auditory hallucinations (that gave her orders) and suicidal thoughts. Treatment with neuroleptics, tricyclic antidepressants and ECT did not change her condition. In the course of her extended stay in hospital, the deterioration in her affect and function became prominent and, based on the symptoms, she was diagnosed as schizophrenic. It is noteworthy that the patient's daughter suffered from depression and had also attempted suicide. A number of second degree relatives suffer from schizophrenia or depression.

On the same morning that patient B, who shared the room with her, tried to burn herself, patient C had come to her rescue and summoned help. Half an hour later she shut herself in the restroom, wrapped toilet paper around her body and set fire to it. This caused burns over 3% of the body surface. This attempt was not the last one. After her discharge from hospital she jumped from the third floor of her apartment and was severely hurt.

Discussion

Suicide by burning is unusual in Western countries. In England and Wales it accounted for less than 1% of suicides in 1963–1977. Burning as a method of suicide or attempted suicide is rare also in the United States (Weissman, 1974). In contrast, this method is considered more common in Israel. The last survey that was conducted on this subject in Israel (Modan *et al*, 1970) found that 27.7% of female suicides and 2.9% of male suicides were by burning. This method was found especially prominent among women of Asian and African origin among whom 77.1% of completed suicides were by burning.

The population of completed suicides usually differs in its characteristics from that of attempted suicides (Weissman, 1974), but when suicide by burning is considered, these differences are not clear. In a series from an Australian burns unit (Persley & Pegg, 1981), 47% of suicide attempts by burning died in the hospital. Thus, in about half of the cases the attempted suicide becomes completed suicide. For this reason, it seems to us correct to compare our three cases of attempted suicide with other reports of epidemics of completed suicides.

Although suicide or attempted suicide by burning is supposed to be common in Israel, we feel that data from the 1960s (Modan *et al*, 1970) are not adequate in the 1980s and that methods of suicide in this country have changed and are now closer to those of other Western countries.

Three suicide attempts by burning in a closed psychiatric department is an exception that has not been recorded before. The Geha Psychiatric Hospital is a main district hospital that serves half a million population. Sixty per cent of the inpatients are diagnosed as schizophrenics and most of them return to their community. A small number of patients are transferred to other hospitals on a chronic basis.

Our three patients were considered as high-risk patients for suicide. All of them suffered from schizophrenia accompanied by depressive features. Patients B and C had already attempted suicide more than once, using different techniques. After patient B's suicide attempt, she admitted that she had been influenced by patient A, her new room mate. Also in patient C, who attempted suicide 30 min after her room mate, it seems obvious that imitation played an important role. The tendency to suicide attempts existed in all three patients, but it seems reasonable to suggest that the choice of method and timing were influenced by imitation.

It is worthwhile mentioning that a fourth schizophrenic patient with paranoid delusions toward her neighbours, who shared a room with patient A at the time of the burning, tried to set fire to the neighbours' apartment after discharge from the hospital and as a consequence was severely scalded in her lower extremities. This patient had not until then, made any attempts to harm her neighbours and so we assume that there was some influence related to the suicide attempt of patient A.

In three other reported epidemics of suicide in psychiatric hospitals (Kobler & Stotland, 1964; Kaline, 1968; Anonymous, 1977), the authors blame the epidemics on weakness of professional leadership, faulty supervision and staff demoralisation. Although the contribution of these factors cannot be denied completely, it seems that no attention has been paid to the role of imitation which existed in relation to timing and choice of method. The Crest Hospital epidemic reported by Kobler & Stotland in 1964, started with a patient who killed himself by cutting his wrists, which happened 1 week after another patient was found in his room, bleeding profusely from deep cuts in his throat and wrists. This patient had been rescued and therefore was not included in the suicide epidemic. However, his influence on starting the epidemic seems very significant. In another epidemic (1977), the first two out of three patients who committed suicide were found hanging in their hospital room.

In the current epidemic the staff can be criticised and blamed for not being sufficiently alert to the phenomenon of imitation. It was a mistake to transfer patient A, who had a special status among the patients, to a room together with two other patients known as high-risk cases for suicide. Had these two patients not been exposed to the influence of patient A, their present suicide attempts might have been averted.

It may be concluded that more attention should be paid to the role of imitation in suicide, especially in psychiatric hospitals where patients are more exposed to the influence of other patients. Every act of suicide or attempted suicide necessitates a response on the part of the staff so that this act does not become a subject for imitation. One possibility is to gather the patients for a group session after a suicidal case in order to neutralise the identification with the act by suggestible patients. It also seems appropriate to bring up this subject in individual sessions, especially with high-risk patients. By taking these precautions, such epidemics may perhaps be prevented and thus the distress they cause to the staff and the patients alike may be spared.

Point of View

Depression in the General Population: Comparability of Survey Results

T. K. J. CRAIG, G. W. BROWN and T. O. HARRIS

Bebbington (1986) draws attention to a possible cause for concern regarding the comparability of recent epidemiological research utilising the PSE-ID-CATEGO system of psychiatric caseness determination. In taking issue with our observation that cases in our recent community survey (Brown *et al*, 1985) were broadly similar in terms of severity to those reported in a recent series of out-patients (Sashidharan, 1985), he makes the point that such conclusions are only justifiable when it can be confidently assumed that thresholds for symptom inclusion are applied uniformly between research centres. He argues that this assumption may well be invalid and marshalls two arguments to suggest that the Bedford team may have adopted less stringent rating thresholds. Firstly, he draws attention to the very different population prevalences of disorder reported in recent surveys, contrasting one-year prevalence figures for the Bedford College survey in Islington (Brown *et al*, 1985) with the lower rates reported for other investigations in Edinburgh (Dean *et al*, 1983) and Camberwell (Bebbington *et al*, 1981). Secondly, he reminds us of the body of evidence which suggests that psychiatrists operate stricter criteria for PSE symptoms than their lay colleagues (Wing *et al*, 1977*a*; Sturt *et al*, 1981).

Before taking these arguments and their implicit conclusion too seriously, however, a number of qualifications are in order. Regarding the first argument, we would wish to add that before attempting a comparison of *overall* prevalence rates, attention ought to be directed at ensuring that like is compared with like, in terms of both the general characteristics of the populations concerned and the period over which symptoms have been collected in order to determine caseness. The composition of the Islington survey was deliberately weighted in favour of a specific subgroup of the general population (working-class women with children living at home) who were expected to manifest a particularly high prevalence of psychiatric disorder, and consequently any attempt to compare rates of disorder between this and other surveys must begin by identifying and extracting data for similar groups of women (in terms of class position and parenthood). Each centre, having utilised the PSE, has available a measure of symptoms present in the month prior to interview (i.e. that are generated by the use of the PSE in its most simple form), and we would argue that it is this data which should be used as the starting point when comparing rates between centres, as it is less open to the effects of problems of recall, or those which might result from local modifications. The Bedford College caseness rating based on symptoms measured for the peak of the disorder in the whole preceding year is clearly different from either the episode-based approach used by the Edinburgh researchers, or the 'back-weighted' prevalence estimate calculated for the Camberwell study for approximately a two-month period. Finally, as we are concerned with determining whether differences in prevalence rates between centres might be attributable to differences in thresholds for rating individual symptoms, it would seem logical to use a method of determining caseness which is guaranteed to be applied uniformly by all centres. The ID-CATEGO computer programme, being entirely free from the vagaries of potentially biased researchers, provides the ideal such technique. Dr P. Surtees and Dr P. Bebbington have kindly supplied the necessary material to do this. If all these steps are followed, and ID level 5 is taken to discriminate between cases and non-cases for working-class women with a child at home, the disparity in reported prevalence rates between centres is largely eliminated: the rate for Edinburgh is 18.2% (Surtees, P. G., personal communication); that for Islington is 23.1% and that for Camberwell is 25.0% (Bebbington, P., personal communication). The fact that the two London surveys are so similar suggests that in so far as there are other differences in rates reported by the three centres, they cannot be greatly explained by differences in the rating of constituent symptoms and are likely to reflect real population differences.

Regarding Bebbington's second point, we would concur that there is a risk that lay interviewers overrate on the PSE relative to psychiatrists. However, this is not uniformly borne out in available evidence. Firstly, the studies quoted by Bebbington refer to the proclivities of naïve raters. The study of Wing *et al* (1977*a*), for example, compared PSE ratings made by a psychologist, a social worker, and a psychiatrist who had received *no* formal PSE training, and the results are hardly generalisable to a team which has been trained in the use of the instrument. (One undertakes training precisely because naïve raters are likely to make inaccurate judgements about thresholds). The other study quoted (Sturt *et al*, 1981) seems to suggest that such biases persist even after training, but closer examination of the details of this report show that the raters involved were very different from those employed in the Islington study. For a start, although they were professional interviewers, none had had prior experience with the PSE and all received "a shortened (3-day) version of the usual training course" (Sturt *et al*, 1981). The interviewers were employed as a first-level screen to identify possible cases whose disorder was then formally ascertained by a second interview. Leaving aside the difficulties of interpretation which arise because of recovery or fluctuation of symptoms between interviews, it is our contention that the performance of these semi-trained interviewers cannot be fairly compared with that of a clinical team who received full training and ongoing corrective supervision. Perhaps Bebbington might have referred to the considerable evidence that *after adequate training*, lay interviewers are capable of accurately and reliably administering the PSE, some learning to modify their threshold criteria upwards and others to acquire a tougher perspective (e.g. Cooper *et al*, 1977; Wing *et al*, 1977*b*).

In conclusion, we believe that the issues raised by Bebbington must be considered seriously. It behoves all researchers in this field to co-operate throughout the collection of data. Perhaps, in future, joint rating meetings and mutual monitoring would serve to strengthen confidence in technique.

Book Reconsidered

Sociobiology, the New Synthesis: Edward O. Wilson*

Sociobiology was published in 1975. Four years earlier its author had published "an enormous and definitive book" on social insects, a work which established him as the world authority on that subject. In *Sociobiology,* Wilson set out to apply evolutionary theory to social behaviour not only in insects but throughout the animal kingdom. As a biologist he naturally included man among the animals, but it was this which caused the uproar. Had he omitted his last 33 pages – the chapter on "Man: from sociobiology to sociology" – his book would probably have led a quiet life as a well-written semi-popular textbook on social animals.

Sociobiology was praised as opening a new field in social study, a biological basis for a science of sociology. It was dismissed as the popularisation of a subject outside its author's field of competence, the term sociobiology being "merely a grand word for one branch of evolutionary ethology". And it was attacked with a surprising degree of virulence, not only by creationists and left-wingers but by a host of respectable academics as well (e.g. Sahlins, 1976; Rose *et al,* 1984). To a psychiatrist concerned with the vagaries of human nature, it is the virulence which is interesting; for as Oliver Wendell Holmes said of the indignation aroused by his remark about the pharmacopoeia and the fishes, "a loud outcry at a slight touch reveals the weak spot in a profession as well as in a patient".

The most acrimonious criticism of *Sociobiology* was that it used spurious biological analogy to give pseudo-scientific respectability to sexism and the capitalist ethic of the middle classes. Wilson had argued: that there was strong evidence of genetic factors in the social behaviour of animals (the social behaviour of chimpanzees, for example, is everywhere very similar, even among widely separated groups); that the social behaviour of apes and of present-day hunter-gatherer societies had much in common – including aggressive dominance-seeking males and docile females; and that, as these features most probably had a genetic basis, it was reasonable to presume similar genetic traits in civilised mankind, even if these were now largely overlaid by culture. But, said the critics, animals are not human, and to suppose their behaviour had anything in common with human behaviour was to be guilty of naive anthropomorphism. So *Sociobiology* was derided as mere myth-making, as a just-so story, as a piece of bourgeois thought; and its author's suggestion that his new synthesis might provide "an enduring set of first principles of sociology" (page 579) was considered absurd or offensive, not only by orthodox sociologists but also by philosophers who held ethics to be outside the scope of science.

What these criticisms imply, I think, is that Wilson stirred up the never-ending conflict between science and religion (or the secular counterparts of religion). The stability of most societies depends on the general acceptance of a moral code, whose authority derives from myths enshrined in holy writ. Ideas or discoveries which might undermine the credibility of these myths will threaten social stability; and the rulers of society, who derive their power from its stability, will naturally wish to suppress such dangerous knowledge – and have done so down history with a violence exemplified by the fate of Prometheus, Galileo, the Christian heretics, and the Russian dissidents. In 1690 the physician and philosopher John Locke argued that since civilised behaviour depended on a belief in God, the protection of the State should be withdrawn from atheists; and in the early 19th century the progress of geology was retarded by the fear that if God's special intervention in the course of nature were denied, it would lead to free-thinking and so to revolution (Gillespie, 1951). Wilson's contribution to dangerous knowledge was to support the idea that human social behaviour is partly under genetic control. The idea is dangerous (to those in power) because it implies a person cannot be held entirely responsible for his behaviour. If that were so, then society would be without a moral sanction against those who broke its rules. This explains why the Church disapproved of astrology, why Stalin disapproved of genetics (as shown by his support for Lysenko), and why the predestination of Calvin was of a kind "not to be enquired into".

The dominance of nurture over nature has been upheld not only by those wielding religious power

*Cambridge, Mass. and London: The Belknap Press of Harvard University Press (1975); first reviewed in this *Journal* in 1976 (**129**, 282).

but also by philosophers and sociologists fiercely opposed to religion. Hume, who defined a clergyman as "a person appropriated to teach hypocricy and inculcate vice" (Brady, 1984), and who, on his deathbed, told Boswell that "when he heard a man was religious he concluded he was a rascal", nevertheless believed the mind is a *tabula rasa* at birth and that a person's character and behaviour are formed entirely from what happens to him thereafter. John Stuart Mill (1873), whose father taught him that religion was not merely a mental delusion but a moral evil opposed to the progress of the human mind, deplored "the prevailing tendency to regard all marked distinctions of human nature as innate". He held this idea to be "one of the chief hinderances to the rational treatment of great social questions", and believed there were "irresistable proofs" that "by far the greater part" of natural differences between men were produced by "differences in circumstances". Darwin on the other hand, although also a freethinker, concluded that the greater part of human attributes were inborn (Barlow, 1958); and Galton (1883), who had found that both the physical and mental attributes of identical twins were strikingly similar even when they had been reared apart, considered this clear evidence of "the vastly preponderating effects of nature over nurture". Maudsley (1919), always biologically minded, took the same view: "civilised nature doesn't mean the vital (brutish) nature is any less".

There was still another criticism of *Sociobiology*. This was directed against its reductionist view that human attributes are all understandable in biological terms and therefore, ultimately, in terms of physics and chemistry. Maudsley was a reductionist, defending himself on the general ground that matter is more wonderful than you think (Maudsley, 1913). In recent years reductionism has been made respectable by the support of eminent physicists and biologists (Jaynes, 1976; Atkins, 1981; Smith, 1985; Dawkins, 1986). But this opinion, which would have been considered blasphemous in a religious age, is still emotionally or intellectually unacceptable to many. Even Alfred Wallace, Darwin's co-discoverer of the origin of species, never believed that evolution applied to Man. Evolutionary reductionism, first attacked by Samuel Butler in his *Luck or Cunning?*, has been criticised on the general ground that evolution is not a passive process but implies at every stage the presence of individual learning and purposive exploration (Popper, 1974; Granit, 1977), and on the particular ground that human mental powers are so much greater than other creatures' as no longer to be comparable, the influence of culture now quite outweighing that of genetics (Crook, 1980).

These multifarious criticisms of *Sociobiology*, and particularly the virulence of some of them, surely indicate the importance of the subject raised in its final chapter. Wilson did not deny the large part played by culture in shaping human society: he simply pointed out that there were probably some genetic factors too, and that it would be useful to enquire further into the nature and strength of such factors since, in so far as they were present, they would exert a constraint on the range of cultural possibilities: "the genes hold culture on a lease" (Wilson, 1978). The gain to sociology from accepting a more biological basis might be that this would involve taking a long-term evolutionary view of human nature in addition to the short-term cultural view. Darwin noted that there are animal species (e.g. the emu and the cassowary) where the usual sexual patterns of courtship and care of offspring are reversed – a phenomenon that might remind one, for instance, of that German tribe noted (and deplored) by Tacitus – and an interesting parallel has been drawn between the genetic variations of behaviour in animal species and the cultural variations of behaviour in human societies. But Darwin also believed in capitalism, in the innate superiority of men's minds over women's (his opinion was similar to that of Mill) (Darwin, 1871) and of the white races over the black (Dawkins, 1986); and Maudsley (1919) held that "democracy is in no wise lovely". The fact that we now tend to think differently illustrates the rapidity with which cultural values may change, and this suggests there is a risk in basing sociological theory on what may prove to be transient aspects of human thought and behaviour. "All sensible biologists", said Bonner (1975, see also Andreski, 1972), "are apprehensive of human sociology" because it seems such a "murky mixture of the obvious and the obscure". Wilson's book reinforced what is perhaps a growing opinion that if sociology is to become a science it must be based on biology (Pugh, 1978; Symons, 1979; Berghe, 1979). My own hope is that the furore over *Sociobiology* will represent an instance of today's outrageous idea becoming the commonplace of tomorrow.

Dementia in 2001

SIR: In his review of the various studies of the prevalence of dementia in the elderly (*Journal,* February 1987, **150,** 193–200) Ineichen mentioned the effect of sample size on the results, but did not sufficiently emphasise its importance. The prevalence of a disorder in a sample is only an estimate of the prevalence in the target population, and the reliability of that estimate depends on the size of the sample. The most extreme findings (large and small) tend to be found in those surveys with the smallest samples, as is shown by the studies of severe dementia in those aged 65 and over quoted by Ineichen, where the sample size is inversely correlated with the deviation of the sample prevalences from the mean ($r = -0.78$; $P < 0.01$). The effect of sample size can be quantified by calculating the standard error or confidence interval of the finding, and where the sample is small these will be large in proportion to the estimated prevalence (Clarke *et al,* 1986).

This is particularly true for the very old, where influential prevalence figures for dementia have been derived from small sub-groups of the elderly within samples of those aged 65 and over. In view of the predicted expansion of this particular age group and the implications of this for medical and social services, it is surprising that our working estimates of the prevalence of dementia are still so vague. Ineichen's rule of thumb (1% of 65–74s and 10% of over 75s) may be correct, but in the present state of epidemiological knowledge it remains something of a guess.

Khat Psychosis

SIR: I echo the call by Critchlow & Seifert (*Journal,* February 1987, **150,** 247–249) for greater awareness of khat consumption in the UK and its psychotropic effects.

Case Report: A 22-year-old Ethiopian male was brought to Accident and Emergency by his brother, with a one-year history of progressively odd behaviour. He had left college and had stopped claiming DHSS benefit. He had drawn strange patterns on the walls of his flat. On direct questioning he denied illicit drug use. On admission he was unkempt, restless, emotionally labile, and experiencing third person auditory hallucinations. He was normotensive with a heart rate of 85 per minute and small pupils. Urine drug screen was negative. He was treated with chlorpromazine (200 mg t.d.s.), and his positive symptoms disappeared after 72 hours. He remained lethargic and withdrawn. Four days later he again became restless, hallucinated, and was unable to sleep. He settled after 48 hours of continued medication. He later stated that prior to his exacerbation he had chewed khat leaves. He had been a habitual chewer from 10 years of age, and prior to admission he had chewed twice weekly.

The level of sympathetic arousal may be helpful in distinguishing the rare cases of khat intoxication producing manic-like psychosis (as described by Giannini & Costellani (1982)), from khat-induced exacerbation of psychosis. Halbach (1972) comments on the rarity of khat-induced psychosis in areas where chewing is endemic and suggests that most reports of associations are of exacerbation of psychosis in predisposed individuals. This may be explained by the bulky nature of the preparation only permitting low plasma levels of the amphetamine-like agent to be attained by chewing.

Khat leaves are chewed fresh for the best effect. The patient informed us that leaves were flown in twice weekly from Ethiopia and sold at a retail outlet in East London. A packet wrapped in banana leaves costs £5 and provides enough for an evening. There are no legal restrictions on the sale or use of this substance in the UK. The regular importation suggests there must be considerable demand for this substance in London. As yet there is no evidence that use of this substance has spread beyond the East African immigrant population. Khat use should be enquired after in patients from this region presenting with psychotic illness.

I would like to thank Dr H. F. Oakeley for his advice and permission to discuss his patient.

Electroconvulsive Therapy in the Elderly

SIR: O'Shea *et al* (*Journal*, February 1987, **150**, 255–257) present the case of a 91-year-old patient who responded well to ECT. The oldest documented patient to receive ECT was a 94-year-old woman (Bernstein, 1972). We describe the successful use of ECT in a woman aged 103 years.

Case Report: The patient, who was born on 6 December 1883, was referred to us by her GP with a history of worsening depression over the preceding weeks. On admission she appeared very depressed and expressed the idea that God no longer wanted her. She felt that she was evil and that she belonged to the devil. She also said that she felt "dirty and rotten" inside. She was preoccupied with religious ideas and spoke of little else. Her family reported that her interest in outside events had diminished prior to admission and her appetite had deteriorated. She was diagnosed as suffering from a psychotic depression.

She told us that her first episode of depression had been 40 years previously, when she lived in England. This had recurred from time to time over the years and her first admission to this hospital was in 1977. That episode was similar in its presentation to the current one. At that time she was treated with ECT but relapsed soon after. Altogether, in 1977 she received three courses of ECT, each of approximately four treatments. There was no definite family history of affective illness. Physical examination during this recent admission revealed that she was suffering from mild congestive cardiac failure and atrial fibrillation. She was receiving digoxin and frusemide for this. She was treated initially with a course of mianserin and later of doxepin. These produced no change, and after eight weeks of in-patient care she was still depressed and miserable. We discussed ECT with her and her family and she agreed to receive a course. The anaesthetist had some reservations, but in view of her persistent depression and previous response to ECT he agreed that it was an acceptable risk to give her a general anaesthetic. She received two treatments in all and was remarkably improved after the second. She was somewhat confused after the treatment, but this disappeared within 24 hours. As she was by now well, it was decided not to proceed to a full course of ECT. It is now two months since the patient's discharge and she remains well.

We think that this report demonstrates the effectiveness of ECT as a treatment for psychotic depression even in the very elderly age-group. We agree with Weiner (1982) that ECT is a relatively safe treatment in the elderly if performed with due precautions.

Delusional Parasitosis

SIR: Macaskill's report (*Journal*, February 1987, **150**, 261–263) of a patient's delusional infestation which responded to non-pharmacological treatment was optimistic, but probably describes a mild form of disorder – as might be expected when clear precipitants are present. However, the potential dangerousness of these patients must be emphasised.

Case report: After the death of his wife and 22 years of police service in Antigua this 70-year-old man emigrated to England, where he has lived alone and worked as a security officer for 18 years (until his retirement in 1982). His complaints about insects started in 1980 when he was rehoused in council property following compulsory purchase of his flat: since then his life has been dominated by delusions of infestation. He has persuaded the council to rehouse him three times, despite having set one flat on fire and been convicted of criminal damage for flooding another. He has also persuaded Environmental Health officers to fumigate his property eight times, although they have never seen any insects in his flats. He was detained under Section 3 of the Mental Health Act in 1983, following a fire, but he was discharged by a tribunal.

In November 1986 he was readmitted under Section 136 following two fires. Mental state on admission revealed a dishevelled, smoke-stained, angry man who shouted loudly and aggressively about his detention and complained that "insects swarm all over me". He was cognitively intact and had a normal computerised tomography scan. During the month of observation while detained under Section 2 this mental state persisted. A Section 3 order was made, and treatment with haloperidol syrup (Andrews *et al*, 1986), up to 30 mg/day, was started. There was a general improvement: he was able to conduct a normal conversation and he became calmer and even friendly. However, his delusions of infestation have persisted and he continues to buy large quantities of fly sprays. He has recently been treated with fluphenazine decanoate as a long-term treatment and because compliance was doubtful at times.

Suicide has previously been reported (Bebbington, 1976), but we are not aware of a report of fire setting associated with this condition, thus indicating that this may be a rare occurrence. However, fumigation is often used by these patients and it seems essential to explore any attempts or intentions by them to use fire or smoke to combat the infestation, and to consider admission in order to protect both the patient and neighbours. Many such patients relapse when treatment is stopped, which raises legal and ethical difficulties when long-term treatment is attempted.

Is there a Lithium Withdrawal Syndrome?

Sir: The letter from Hawkins & Shepherd (*Journal*, February 1987, **150**, 273) contained a number of inaccuracies and misconceptions.

Firstly, they state that the words 'withdrawal' and 'relapse' are not interchangeable. I make it clear in my opening sentence that the paper is concerned with "the possibility of relapse being caused by drug withdrawal". Their criticism would seem to be an unnecessary exercise in semantics.

Secondly, they state that to show a withdrawal effect it is necessary for there to be a "fall in the relapse rate lower than expected for a period after the withdrawal syndrome has ended". This is clearly wrong. The question is whether there is an *increased* risk of relapse in the withdrawal period in addition to that which would be expected taking into consideration the natural history of the disease process. This is not the same thing.

Thirdly, they state that the theoretical relapse rate "can never be known", and ask "How can one distinguish a withdrawal state causing relapse and relapse alone?" Perhaps they are not aware that this is why control groups are used in order to estimate the theoretical relapse rate. In the control group only 8% of patients relapsed in the first three months, compared with 28% in the experimental group. This difference cannot be explained by the experimental group being at higher risk, because after three months the relapse rates are identical.

Finally, no firm conclusions can be drawn from a retrospective study, hence the title poses a question. Correspondence in the same issue (*Journal*, February 1987, **150**, 264–265) has highlighted the fact that despite increasing use of lithium there has been an increasing readmission rate for mania at a number of different centres. There has been no satisfactory explanation for this. One possibility is that repeated lithium withdrawal increases the number of relapses, and I think this topic deserves further consideration.

BITE: Self-rating Scale for Bulimia

Sir: The paper by Henderson & Freeman (*Journal*, January 1987, **150**, 18–24) is a useful and timely development in the scientific study of eating disorders. However, four points require further consideration.

Firstly, the authors need to clarify whether they regard the BITE as a screening test or as a diagnostic instrument. The statement that "subjects achieving a high score have a high probability of meeting... criteria for bulimia" indicates clearly that it is a screening test. However, the observations that the BITE "can be used to *identify* binge-eaters in a given population" (our emphasis), and that it provides the information necessary to make a DSM–III diagnosis of bulimia, suggest that the authors also consider it to be a diagnostic instrument.

Secondly, the criterion for caseness is unclear. In study 1, the only criterion given for the patient group is that they were binge-eaters at "various stages of treatment". This is too imprecise – an operational definition is a central requirement for work of this nature. The absence of such a definition from study 1 is all the more mysterious since one was used in study 2. Where diagnostic criteria are considered, it is not always clear which are meant. DSM–III criteria were used in studies 2, 3, and 4, while the authors conclude, in their instructions for administration, that high scorers have a high probability of meeting "DSM–III criteria for bulimia *and* Russell's (1979) criteria for bulimia nervosa" (our emphasis). There is a crucial difference between the two: DSM–III criteria are relatively broad, in contrast to Russell's criteria which require evidence of a morbid fear of fatness. By which criteria does the BITE identify cases?

Thirdly, the authors adopted a case-control strategy. This method gives rise to over-optimistic estimates of the validity coefficients. As Williams *et al* (1980) noted:

> "a group of symptoms selected on the basis of the ability to discriminate between two distinct populations, i.e. 'known ill' and 'known well', may be effective in classifying respondents who happen to come from one of those groups. However, in epidemiology we are not presented with individuals who clearly belong to one of these two groups: we are presented with individuals whose probabilities of illness are distributed along a continuum. Instruments which can distinguish clearly between distinct caseness groups, i.e. well-separated locations on the continuum, need not necessarily perform well in classifying individuals from various and intermediate probabilities of illness."

Another problem with the case-control approach is that since the prevalence of caseness in the study population is set at 50%, the resulting positive predictive value will be considerably higher than that appropriate to the use of the same test in a population where the prevalence is much lower than 50% (Williams *et al*, 1982), as is invariably the case with eating disorders.

Fourthly, there are several methodological points which require clarification. For example, why did the control group in study 1 contain both men and women, whereas the patient group consisted only of women? How were the sub-scales derived? How were the cut-off points decided upon? Where does the proposed lower cut-off (10), which appears in the discussion but not the results, come from? This cut-off is claimed to be relevant in the identification of sub-clinical groups: how can this be so, when no such patients were studied?

The authors are premature in their claim that the BITE is "a tested, valid questionnaire". For example, they say that "the modified BITE produces neither false positives nor false negatives". This is much too sweeping a claim, based as it is on one relatively small validation study. While this questionnaire may fulfil an important need, more development work is required.

Predictions of Outcome in Depressive Illness

SIR: Carney *et al* (*Journal*, January 1987, **150**, 43–48) claim that their study supports the dualist theory of classification of depressive illness. They reach this conclusion on the basis of the finding that their sample of depressive in-patients was not normally distributed on the Newcastle scale and the finding that outcome after two weeks differed between the endogenous and the neurotic groups. Their conclusions about both of these findings are open to different interpretations.

Firstly, depressed patients who are admitted to hospital are extremely unlikely to be a representative sample of all depressed patients: they have generally failed to respond to general practice or out-patient treatment with antidepressant medication. These non-responders will contain disproportionate numbers of patients with severe neurotic and severe endogenous features, the first group being relatively immune to physical treatments, the second group requiring more vigorous physical treatments. Thus, it is hardly surprising that depressed patients admitted "on clinical grounds" do not show a normal distribution of scores on the Newcastle scale.

Secondly, their conclusions about differing outcome between the two groups derives from a comparison of measures before and after fourteen days of a trial of antidepressant medication. Outcome is thus confused with treatment response. As the authors state, albeit in a different context: "the wisdom of attempting to base conclusions about diagnosis and classification on the response to a particular treatment is basically unsound".

Thus, these findings provide no convincing evidence for the dualist theory of the classification of depressive illness.

The Impact of a Liaison Psychiatric Service on Patterns of Referral in a General Hospital

SIR: It is interesting to read of a change in referral rate associated with the organisation of a liaison psychiatric service (Brown & Cooper, *Journal*, January 1987, **150**, 83–87). However, it would be misleading if the discovery of such a link were to remain as a conclusion in itself.

The real question to be addressed is whether such a change in referral rate represents an increase in work done with patients and their families. If general hospitals were a virgin soil for such work then there would be grounds for thinking this to be so, but this is not the case. Social work departments have been developing liaison work for the past 90 years, and many of the problems encountered by liaison psychiatrists are familiar to us.

Despite the reluctance of some medical and surgical specialists to refer patients, it has been possible for the social worker to offer not only a practical service where appropriate but a skilled therapeutic service to patients suffering from mild affective and neurotic disorders, and preventive work with patients at high risk of such disorders.

For example, at St Charles Hospital, London, the Social Work Department offers counselling to surgical patients and patients with life-threatening medical conditions such as cancer, to all women seeking terminations of pregnancy, and to elderly patients and their relatives. They had also developed a system of assessment of patients admitted following deliberate self-harm in advance of the 1984 DHSS recommendations and in consultation with the psychiatrists at Springfield Hospital.

Because of the social worker's perspective it is often possible to offer a systematic approach which includes and takes account of family and network processes. It is frequently a failure to attend to these that leads to slow discharge or high re-admission rates. It would be unfortunate if an increase in the level of liaison psychiatry with a medical psychiatric model were to undermine this work.

Although much of this is written up in the social work journals it is likely that these are read even less frequently by doctors than the medical journals are read by social workers. Perhaps more collaboration and research is needed in this area.

A Patient with Resistant Schizophrenia

SIR: We read with interest, but some surprise, the recent report by Roberts *et al* (*Journal*, December 1986, **149**, 789–793). The case highlights many of the difficulties of managing schizophrenia resistant to treatment. However, we were puzzled because the authors presented this as "clearly an unusual case". The tenor of the paper suggested that one is unlikely to find other such patients.

Watt *et al* (1983), in a prospective study, followed 121 patients presenting to the mental health service of a discrete geographical area for five years: 50% failed to become symptom-free in that time, and for over 40% each acute exacerbation of the disorder resulted in progressively less recovery. Among patients with a first episode of schizophrenia referred from nine medical centres in London and its surrounds 17 (nearly 7%) never left hospital throughout the first 20 months of follow-up. (Macmillan *et al*, 1986). On the Denis Hill (Secure) Unit, another ward at the Bethlem & Maudsley Joint Hospital, there are currently 16 out of a total of 27 patients with psychotic illnesses, mostly schizophrenic in type. Five of these have been floridly ill with positive symptoms, probably unremittingly so, for a time approaching that described by Roberts *et al* and have been continuously in hospital with well documented, vigorous treatment with the full range of medication appropriate to psychosis. Some have had ECT too. Another patient who first presented with psychosis and was first admitted only 18 months ago has similarly failed to show any significant reduction of his psychotic features. The other secure units in the South East Thames Region could report a similar situation and the Special Hospitals, in particular Broadmoor and Park Lane, could report many such patients. Even the open forensic unit at the Maudsley Hospital usually has one or two such patients.

How can it be that psychiatrists working together in the same institution can have such different experiences? We would speculate along the following lines. First, psychiatry is becoming increasingly compartmentalised, and with the very considerable clinical demands made on all of us there is insufficient time to explore the interesting byways of other people's wards and practice. Secondly, forensic psychiatric units have been encouraged by general psychiatrists to take aggressive patients off their hands and do so. In our experience treatment resistant schizophrenic patients are frequently aggressive. Thirdly, the policy of dismantling NHS asylums has forced a number of treatment resistant schizophrenic patients into non-medical settings, such as prisons, doss houses, and the streets.

One comment on the treatment resistance itself may be pertinent. Most schizophrenic patients who do not respond to medication (in the sense that their hallucinations and delusions do not go away) do, in fact, derive some benefits from medication, either in terms of sedation, in mood improvement, or in improvement of other neurotic symptoms. Furthermore, our current work shows that although our treatment-resistant psychotic patients almost invariably have unusual cognitive patterns on neuropsychological testing, most can be helped a great deal by the provision of a stress-free milieu (advocated by Murray), together with the careful provision of suitable occupations and recreations. Above all, they need appropriate supportive psychotherapy.

WATT, D. C., KATZ, K. & SHEPHERD, M. (1983) The natural history of schizophrenia: a 5 year prospective follow-up of a representative sample of schizophrenics by means of a standardised clinical and social assessment. *Psychological Medicine*, **13**, 663–670.

SIR: I was astonished to read the Maudsley Grand Rounds case report (Roberts *et al*, *Journal*, December 1986, **149**, 789–793). Where is the data to support the view that all "acute symptoms of schizophrenia can be controlled pharmacologically"? Existing data suggests that a substantial proportion of cases show unremitting psychotic symptoms. The landmark Camberwell study of Brown *et al* (1972) included 29 patients who left hospital with persistent symptoms in the 101 consecutive admissions who were discharged to family households. The five patients who remained in hospital probably suffered persistent symptoms. Thus, it seems reasonable to conclude that at that time excellent treatment at the Maudsley Hospital was unable to induce a remission in one-third of cases.

Despite considerable recent advances in our understanding of the pharmacology of schizophrenia there is little evidence to suggest major advances in the efficacy of drug treatment. However, there have been developments in psychological interventions that appear to add to the efficacy achieved by drugs alone. These include a broad range of behavioural psychotherapy interventions (Hagen, 1975; Paul & Lentz, 1977; Falloon, 1985). Before advocating the low stress social environments offered by the long-stay asylum I would recommend pharmacologists to seek the assistance of a skilled behavioural psychotherapist in the comprehensive management of schizophrenia.

Psychological Disorders in Obstetrics and Gynaecology

SIR: In her review of *Psychological Disorders in Obstetrics and Gynaecology*, Jequier (*Journal*, December 1986, **149**, 807) applauds the comprehensive coverage assembled by the editor of the book, R. G. Priest.

About one-fifth of all pregnancies end in spontaneous abortion or miscarriage, although estimates range from 10 to 43% (Miller *et al*, 1980; Llewellyn-Jones, 1982). This is comparable in frequency of occurrence to that of induced abortion, which Olley (1985) puts at about three in ten. Yet a complete chapter is given to the latter and the bare mention of the former is in a brief coverage of psychogenic factors in repeated abortion.

It is now being recognised in some of the literature (Raphael, 1984) that spontaneous abortion frequently has profound psychological effects and that these reactions are often missed or mishandled, partly because the event is dismissed as 'routine'. What a pity, then, that this "splendid contribution to the literature" has failed, like the reviewer, to give recognition to such a common and distressing, but often ignored, problem in obstetrics and gynaecology.

Comprehensive Psychiatric Community Services for the Severely Disabled

Sir: I was interested in Wing & Furlong's plans for a "haven community" to serve the future needs of West Haringey's chronically mentally ill (*Journal*, October 1986, **149**, 449–457), as their proposals have much in common with the developments which have taken place within Oxford's Department of Rehabilitation and Community Care. They rightly stress that disability in one aspect of life does not necessarily imply an equal disability in all areas; any one patient should be able to obtain a unique combination of residential, occupational, and recreational services (Gan & Pullen, 1984).

In 1980 a service was started at Littlemore Hospital to meet the needs of Oxfordshire's 'new long-stay', although patients are accepted on the basis of clinical criteria rather than length of previous admission. This has evolved into the Young Adult Unit, based on a 24-bedded ward, The Eric Burden Community (EBC), on the edge of the Littlemore site (Pullen, 1986). The same building also houses the Unit's out-patient department and is the administrative centre of a developing network of hostels and group homes specifically for the young adult chronically mentally ill. Day care for this group includes a centre, based in an Oxford church, run by the Oxford branch of MIND (Hope & Pullen, 1985).

Our experiences confirm the necessity of providing continuity of care for the severely 'socially disabled' by a single team. A sense of 'haven' can also be created by the knowledge that wherever one happens to be living at the time one still 'belongs' (once accepted, patients remain on the case register of the department indefinitely).

One anxiety I have after reading about the Friern plans concerns the capacity of the proposed 12-bedded mother house to re-admit patients during their inevitable relapses. We have retained the EBC as a hospital ward (albeit one run as a therapeutic community in which, for example, the residents are responsible for the provision of most meals) because we feel that it is at times of crisis that long-term patients most need the care of those who know them well. The psychiatric hospital bed is an essential component of community care.

The Friern Haven appears to be an exciting and imaginative response to the present needs of some of the hospital's existing long-stay patients and to the future needs of Haringey. Elsewhere, other patterns of service will be more appropriate, but in every case there will need to be an integrated network of varied services. I join Wing & Furlong, however, in arguing "that responsibility for the most severely disabled and disturbed group... should be given high priority rather than left as a residual group to be provided for only when all other services are in place".

Delineating Social Phobia

Sir: Solyom *et al* (*Journal*, October 1986, **149**, 464–470) state that "the problem of overlap may also arise because both agoraphobia and social phobia may be based on fear of having a panic attack, i.e. both may suffer from panic disorder."

DSM–III and DSM–III–R (8/1/86 draft) attempt to distinguish social phobia from panic disorder and agoraphobia. Social phobics in DSM–III and DSM–III–R are defined by the occurrence of intense anxiety specifically in response to feeling scrutinised or evaluated by other people (or in anticipation of this). This differs from the panic attack associated with Panic Disorder or Agoraphobia. To meet the DSM–III–R definition of Panic Disorder, an individual has to experience intense anxiety episodes occurring at times when the patient is not the focus of others' attention.

Soylom *et al* appear to be questioning this diagnostic convention. The reasonable question to ask is: does the convention make sense? Specifically, is there a meaningful basis to distinguish between the anxiety experience of Social Phobia and the panic attacks associated with Panic Disorder or Agoraphobia with Panic Attacks?

Several lines of evidence suggest qualitative differences between the anxiety experience of social phobic and panic disorder or agoraphobic patients. Aimes *et al* (1983) noted differences in the symptom pattern.

Social phobics reported more blushing and muscle twitching, and less limb weakness, breathing difficulty, dizziness or faintness, actual fainting, and buzzing or ringing in the ears than did agoraphobics.

Analogue studies and open clinical trial suggest greater beta-blocker efficacy in social phobia than agoraphobia (Gorman *et al*, 1985). Tricyclics are quite helpful for blocking panic attacks. Clinically they seem less useful in social phobia. Controlled trials to confirm these impressions, however, are needed. MAO inhibitors appear useful in both conditions.

Plasma epinephrine does not appear to be elevated during *in vivo* or lactate induced panic attacks (Liebowitz *et al*, 1985). A study in progress is demonstrating that at least a subset of social phobics (perhaps 50%) demonstrate plasma epinephrine elevations of 50% or more during performance challenge. Studies in medical house officers suggest two to three-fold epinephrine rise during more stressful real life public speaking (Dimsdale & Moss, 1980). Social phobics are significantly less likely to panic with sodium lactate infusion than are agoraphobics (Liebowitz *et al*, 1985).

Onset and offset seem to differ as well. Social or performance anxiety is triggered only when the individual is faced with interpersonal evaluation or scrutiny, and is probably induced by cognitions that one will perform badly, look foolish, etc. Panic attacks related to panic disorder often occur unexpectedly, especially early on, without obvious cognitive precursors. When feeling anxious, social phobics prefer to be alone to recover their equilibrium; agoraphobics are less likely to panic, and more readily recover, in the presence of a trusted person.

Both agoraphobics and social phobics do fear the onset of severe anxiety experience. Available evidence, however, suggests important differences in pathophysiology, which Solyom's statement obscures.

Clinical Tests of Memory as Sensitive and Specific Signs of Dementia

SIR: Psychogeriatricians could make greater use of Kopelman's evaluation of clinical tests of memory (*Journal*, October 1986, **148**, 517–525) if his organic and non-organic groups are sub-divided to allow the analysis of Alzheimer and depressed groups. This would extend the validity of several tests of memory, comprehension, and orientation as contributors to the common and problematic differential diagnosis of depressed versus Alzheimer patients. Using the number of subjects failing to score at cut-off point for each test (his Table III), the relative discrimination between these groups was assessed with the two-tail Fisher exact probability test (Armsen, 1955). The Gresham memory and orientation questionnaire, Wechsler logical memory, paired associates, name and address, and anomalous sentences tests all show significant discrimination beyond the 0.05 level of probability. Although test cut-off points were chosen to maximise the discrimination between organic (Korsakoff and Alzheimer) and non-organic (healthy controls and depressed), some show sensitivity exceeding 80% to Alzheimer's disease and specificity exceeding 80% relative to depression and healthy controls: logical memory with 45 minute retention below 50% of immediate retention; paired associates total score less than 14: name and address learnt in more than two trials. This is sufficiently promising to be worth cross-validating. A table of discrimination, sensitivity, and specificity is available from the author.

The publication of revised cut-off points chosen to maximise the discrimination of Alzheimer's disease from depression and normal controls, taking into account the base-rates for these pathologies, would greatly assist the selection and monitoring of cases in clinical trials. The availability of sensitivity, specificity, and misclassification rates as a function of test score (Anthony *et al*, 1982) would permit the selection of a cut-off point with high sensitivity for a screening study and a cut-off point with high specificity in a study of unambiguous groups of normal, depressed, and Alzheimer patients.

Caffeine and Panic Attacks

SIR: It has not been clearly shown that caffeine alone can cause panic attacks in normal subjects. I report an adverse reaction which occurred during a normal volunteer study in which caffeine was compared against placebo and rolipram (a CNS phosphodiesterase inhibitor).

Case report: A 21-year-old healthy male volunteer with neither a history of panic attacks nor severe anxiety was given 500 mg of caffeine – equivalent to 5 – 8 cups of coffee – in the form of 1 gm of caffeine citrate in an orange drink. After approximately 20 minutes the subject started to feel an intense dread, which was quickly followed by the somatic symptoms of severe anxiety, including sweating, palpitations, and physical restlessness. He was unable to tolerate staying in the experimental room, and he had fears of impending death. Diazepam (15 mg) was given intravenously, which quelled both the physical and the cognitive changes, but did not remove them entirely. After around 1½ hours the anxiety symptoms returned and further diazepam was required.

This adverse reaction has implications both in theory and in clinical practice. Firstly, the interaction between the benzodiazepines and caffeine is not yet fully understood (File *et al*, 1982); Ghoneim *et al*, 1986). It is known that caffeine is an adenosine receptor antagonist at concentrations found in plasma (Daly *et al*, 1981) and not, as had previously been thought, a phosphodiesterase inhibitor. Diazepam interacts at the benzodiazepine receptor, yet this experiment shows that a benzodiazepine will attenuate the symptoms of anxiety induced by caffeine. This is shown by the return of the anxiety after around 1½ hours, when the diazepam is unbound from the receptor; the plasma half-life of caffeine is of the order of 3–6 hours (or longer) in healthy non-smoking men (Axelrod & Reichenthal, 1953). This would imply that the causation of anxiety might in some way be related to adenosine receptor antagonism. Secondly, it shows that large doses of caffeine can cause severe anxiety in normal people, and therefore an estimation of caffeine intake needs to be part of the assessment of panic attacks. Although this may seem a large dose of caffeine it is not uncommon, as Graham (1978) showed, for people in the general population to drink this quantity in a 24-hour period. Finally, this finding also emphasises the importance of caffeine in the generation of anxiety, which does not amount to panic, in the coffee-consuming general population.

Hyponatraemia and Lofepramine

SIR: Hyponatraemia in psychiatric patients has been variously attributed to compulsive water drinking (Ferrier, 1985), to the primary psychiatric disorder (Singh *et al*, 1985), and to the syndrome of inappropriate secretion of anti-diuretic hormone (SIADH) induced by psychotropic drugs (Sandifer, 1983; Streeten *et al*, 1981). SIADH is a recognised complication of tricyclic antidepressants, and has been reported in association with amitriptyline and desipramine (Sandifer, 1983). We wish to report a case of hyponatraemia which was probably due to SIADH in association with lofepramine.

Case report: A 52-year-old married woman with a history of schizoaffective illness was admitted as an emergency into a medical ward with an acute onset of lethargy, anorexia, vomiting, severe weight loss, and confusion. There were no significant findings on physical examination, but she had repeated abnormal biochemical results. The initial report was: Na^+ 110 mmol/litre, K^+ 3.3 mmol/litre, urea 1.9 mmol/litre, and creatinine 64 mmol/litre. Her urine sodium and osmolarity were not determined.

She had been off all neuroleptics for six months, but had been prescribed lofepramine (140 mg daily) four weeks before her presentation. The hyponatraemia persisted until her lofepramine was stopped, and within 36 hours it resolved. It is of interest that she had been on fluphenazine, haloperidol, trifluoperazine, iprindole, and amitriptyline in the past without any undue effect.

It is likely that her condition was precipitated by lofepramine. However, we were unable to confirm this conclusively, since it would have needed a challenge test to do so. However, we hope that this case will draw attention to the possibility of a drug-induced hyponatraemia in psychiatric patients.

Clomipramine and Flupenthixol – Additive Antidepressants?

SIR: The possibility that flupenthixol and tricyclics would have an additive antidepressant effect was first suggested by Reiter (1969), although the combination has never been specifically evaluated. This report shows the effect of manipulating flupenthixol dose when a stable tricyclic regime is being given concurrently.

Case report: A 31-year-old female with a severe, recurrent, unipolar, depressive psychosis met RDC criteria (Spitzer *et al,* 1977) for major depressive disorder, endogenous, psychotic, and retarded sub-types. She was non-delusional, but had suicidal and homicidal hallucinations. She was a DST non-suppressor, and had a Hamilton score of 38. In the first 25 months of her third episode, she was refractory to treatment with tricyclic antidepressants, lithium/tricyclic, tricyclic/antipsychotic, and lithium/tricyclic/antipsychotic combinations, carbamazepine and ECT. Marital therapy, cognitive-behaviour therapy, light-exposure and an exclusion diet were similarly ineffective.

At that time, her medication was changed to clomipramine (300 mg/day), L-tryptophan (1 g b.d.) and thioridazine (100 mg t.i.d.) but, despite four weeks on this regime, her mental state deteriorated and remained refractory to six further ECTs. Her hallucinations were prominent, she was sleeping only two or three hours a night, showed virtually no diurnal variation, and had become increasingly agitated. We decided to add flupenthixol to her regime, the depot form being chosen because of previous non-compliance: 20 mg was given initially and 40 mg three days later. Five days later she began to improve rapidly, with marked attenuation of hallucinations, sleep disturbance, and social withdrawal. Twenty-four hours later she was expressing optimism regarding the future, the first such emotion in over two years. Fortnightly injections were planned. Three days after her next injection she suddenly relapsed, but eight days later she improved. Two further cycles of eight days well and eight ill followed. We attempted to rationalise her medication by replacing thioridazine with flupenthixol, but, despite increasing flupenthixol, we were unable to reduce her thioridazine. Indeed, a pattern of decreased well-being on increased doses of flupenthixol developed, no symptomatic relief being obtained on 80 mg flupenthixol fortnightly.

At this stage further injections were withheld, in the expectation of clinical improvement. Nine days later (23 days after 80 mg flupenthixol had been administered) improvement began. The following day 20 mg was administered. Improvement continued until seven days later, when she claimed to be "as well as I have ever been". A regime of 20 mg fortnightly was adopted. On this regime, withdrawal of thioridazine and L-tryptophan and halving the dosage of clomipramine had no adverse effect on her mental state, and she remained free from affective symptomatology until her discharge six weeks later. Three weeks after discharge she began to deteriorate, hallucinations returning after a further three weeks and re-admission occurring one week later. She admitted not taking her clomipramine after discharge, although she had received flupenthixol injections as planned. Six days after reintroduction of clomipramine (150 mg/day) she began to improve.

Since the patient's medication regime was uncontrolled, it is not possible to draw firm conclusions about her response. However, improvement occurred only when flupenthixol and clomipramine were given in combination, and was maintained only with a dose of flupenthixol not normally considered antipsychotic. Indeed, beneficial effects were lost at higher doses. It is therefore unlikely that improvement was due to either agent alone. The close relationship between her mental state and manipulation of her medication make spontaneous fluctuation unlikely. Johnson & Malik (1975) describe mood elevation in the seven days following flupenthixol injection – our patient did not show this pattern.

It is likely that her response is unrelated to the antipsychotic effects of flupenthixol. It has been assumed that the antidepressant effect of flupenthixol is manifested at lower doses than the anti-psychotic effect – although this has never been proven by case studies or clinical trials. The most likely explanation for her response is an interaction between clomipramine and flupenthixol, not involving the anti-psychotic effects of the latter, the rapidity of the response to the drugs in combination suggesting synergism between the two compounds.

Illness episodes of this chronicity and severity are uncommon and we think that the fact that she responded to the combination is encouraging. More case reports of such efficacy in resistant depression would be necessary to assess the feasibility of this regime being used in a clinical trial in this condition.

Water Intoxication in Congenital Neurosyphilis

SIR: Water intoxication may occur in almost any psychiatric disorder (Ferrier, 1985), but this is the first report of it in congenital neurosyphilis. In about 80% of cases of water intoxication the patients are psychotic (usually schizophrenic). Although this patient was psychotic, mentally retarded, and had some abnormal neurological signs, the precise diagnosis of congenital neurosyphilis was delayed, as by the time she was seen VDRL and TPHA were negative and Hutchinson's teeth had been extracted.

Case report: A 48-year-old mentally retarded woman was admitted to a psychiatric ward after she violently attacked her 75-year-old mother, with whom she still shared a bed at night. Prior to admission she was doing little apart from smoking heavily (80 cigarettes a day) and drinking fluids excessively. Each day she would consume 3 pots of tea, 6 pints of milk, 2.5 litres of orange juice, and an unknown quantity of water directly from the taps. The patient had three previous admissions to the psychiatric unit. The first time, at the age of 45, diagnoses of mental retardation, alcoholism, and depression with obsessional and hypochondriacal features were made. The second admission (aged 46) followed her attempt to set fire to her home. She was still abusing alcohol (8–10 pints of beer per day) and was depressed. While in hospital she drank water to such an extent that she developed hyponatraemia, hypokalaemia, and had *grand mal* seizures. During the third admission (at the age of 47) she was still drinking alcohol and water excessively, and was thought to be depressed. Following discharge she did not abuse alcohol, but continued to drink water as before. On this fourth occasion she presented as a slim, dishevelled, perplexed woman who was incontinent of urine. She was agitated, incoherent at times, mumbled, and drew a cross on my forehead with her finger and prayed, but was unable to explain why. She was disorientated in time and place, described herself as being frightened and everything around her as being larger (macropsia). There were no auditory hallucinations or systematised delusions. Physical examination of cardiovascular and respiratory systems was normal. There was an abdominal scar from a duodenal ulcer operation. Central nervous system examination showed decreased visual acuity and two small aneurysms in the right eye. The right knee jerk was absent and the right plantar response was up; the left plantar response was normal. The ankle jerks were absent. Proprioception was impaired, but more on the right side. Pin prick showed glove and stocking peripheral neuropathy. She had a tremor of both hands. Her gait was slightly ataxic. Musculoskeletal system was normal apart from swelling over right knee and left ankle.

Investigations: FBC, thyroid, liver function tests, serum glucose, midstream urine culture, ECG, and EEG were normal. VDRL, TPHA, FTA were negative. CT scan showed minimal degree of general cerebral atrophy. Urea, calcium, sodium, and potassium were below the lower end of the reference range, in keeping with excessive water intake. Urinary osmolality was 116 mosmol/kg (reference range 40–1400) and plasma osmolality was 277 mosmol/kg (reference range 275–295). Old case notes were obtained from the Rheumatology Department; those stated that at the age of 19 (when she presented with backache) her Hutchinson's teeth were noticed. WR was found to be negative, TPI positive, and CSF gave a typical Lange curve. She was treated with a full course of penicillin and Hutchinson's teeth were extracted.

Progress: following administration of trifluoperazine (15 mg nocte, orally) her fluid intake decreased, she became continent, and her mental state improved, but the serum electrolytes were still abnormal, so demeclocycline (250 mg q.d.s.) was added. Further restrictions on water intake and cigarette smoking were made. On discharge her mental state was normal apart from mental retardation (IQ 63) and slight memory defect. Her fluid intake was 1.9 litres daily, and all electrolytes were normal. Two weeks later she stopped taking her medication and soon had a relapse. The same treatment was attempted on an out-patient basis, and she again improved.

Diabetes insipidus has been reported as a rare manifestation of congenital neurosyphylis, but no previous reports of water intoxication were found in the literature. While in both conditions polydipsia and polyuria occur, in diabetes insipidus urinary osmolality is well below plasma osmolality, and serum urea and sodium tend to be raised. In water intoxication, both plasma and urinary osmolality are low and serum urea and sodium are below reference values. The syndrome of inappropriate antidiuretic hormone secretion in which hyponatraemia occurs can be excluded by the absence of raised urinary osmolality. This patient has been treated with trifluoperazine, and although psychotic symptoms were effectively treated the water intake remained excessive. Dopamine has been shown to inhibit vasoprotein release in man (Lightman & Forsling, 1980) and it is suggested that in this case its antagonism by trifluoperazine could have led to increased ADH. Demeclocycline, an antidiuretic hormone antagonist, was therefore added to the treatment, and this was followed by the return of serum electrolytes to reference values. However, the effects of neuroleptics on ADH secretion are inconsistent and I suggest that the personal habits of the patient such as smoking and tea and alcohol intake were not considered. This patient drank large quantities of tea and smoked heavily prior to this admission. Theophylline increases cAMP and diuresis. The effect of nicotine is to increase ADH and decrease diuresis, while alcohol has the opposite effect (Laurence, 1977). Therefore, smoking and tea intake should be controlled as part of treatment for water intoxication.

I am grateful to Dr D. Hailstone for his permission to report this patient.

Neuroleptic Malignant Syndrome and Compulsive Water Drinking

SIR: The neuroleptic malignant syndrome (NMS) is thought to represent an idiosyncratic reaction to dopamine blockade, probably mediated via basal ganglia and hypothalamic pathways (Szabadi, 1984). Compulsive water drinking has been associated with a variety of organic and psychiatric disorders, particularly psychosis (Ferrier, 1985). Although the biochemical control of thirst remains uncertain, it seems likely to involve dopaminergic pathways in the hypothalamus. Both these conditions carry a significant morbidity and mortality and are probably underdiagnosed. I report a patient who exhibited compulsive drinking while suffering NMS.

Case report: A 27-year-old woman was admitted, mute, with generalised muscle rigidity, coarse Parkinsonian tremor, sialorrhoea, difficulty swallowing, and sweating. She was indiscriminately incontinent of urine, and had episodic attacks of tachycardia and profuse sweating. She was never pyrexial. This condition had developed immediately after starting haloperidol (one week previously), and failed to respond to oral or intravenous anti-cholinergic drugs. A diagnosis of NMS was made, and all neuroleptic drugs were stopped. One week later she was observed to be drinking copious amounts of fluid; drinking from taps, water jugs, undiluted bottles of squash, and continually requesting drinks on top of those provided with her diet. She was still rigid and incontinent. The excessive drinking lasted five days, and proved impossible to quantify. Urea and electrolytes had been normal prior to excessive drinking (blood urea slightly reduced at 2.7 mmol/litre; reference range 3.0–7.0 mmol/litre). Two weeks after discontinuation of neuroleptic drugs her condition had completely recovered and there was no evidence of psychosis.

Although I am not aware of any reported association between excessive drinking and NMS, Wedzicha & Hoffbrand (1984) described a case of recurrent NMS associated with hyponatraemia. The authors suggested that the hyponatraemia may have precipitated NMS, and they noted that the patient was observed to be drinking excessive water on the ward, which raises the possibility that the excessive drinking and hyponatraemia could have been secondary to NMS. The association between neuroleptic drugs and drinking behaviour is unclear. Smith & Clarke (1980) concluded that increased thirst is likely to be related to the hyperdopaminergic state, but speculate that neuroleptic drugs may induce thirst by a mechanism similar to that proposed for tardive dyskinesia, i.e. denervation supersensitivity, occurring at hypothalamic dopamine receptors.

Once recovered, our patient was unable to recall drinking excessively or to explain it. Unfortunately, we do not have the data to comment on whether water intoxication occurred, or if there was any disturbance of antidiuretic hormone production, although this would be of great interest. It is not possible to say whether the two conditions were causally related, but they do have in common a disturbance of hypothalamic dopamine function and at least one reported patient with NMS (Wedzicha & Hoffbrand, 1984) has been observed to drink excessively and to develop hyponatraemia. Given the difficulties in recognising compulsive drinking before serious consequences occur, in awareness of the possibility is essential.

Switch Mechanism in Affective Illness and Oral S-Adenosylmethionine (SAM)

Sir: A mechanism for switching manic-depressives out of depression has been postulated (Bunney *et al*, 1970). The spontaneous switch rate from depression to hypomania or mania in untreated unipolar and bipolar depressives was reported to be 10–14% over a six-month period (Bunney, 1978; Lewis & Winokur, 1982). Drugs acting on brain biogenic-amines, like tricyclic anti-depressants, are known to give rapid switches of mood from depression to mania; increases in these amines are thought to underlie these changes. The possibility of switching retarded, potentially suicidal depressives into a less hazardous euphoric state has long excited speculation (Bunney, 1978; Lewis & Winokur, 1982). There would be advantages if this could be effected by means of a naturally occurring physiological brain metabolite given by a non-intimidating procedure rather than by the use of drugs or ECT.

We have recently reported (Carney *et al*, 1983) switching in three of 12 depressives receiving i.v. SAM. We calculated that the probability of such an event occurring by chance within six days of starting SAM was remote ($P<0.001$) and it was probably associated with SAM. However, there was no certainty that oral SAM, unavailable during the previous study, would have the same effect as i.v. SAM.

At Northwick Park Hospital we gave SAM in daily doses of 500–1600 mg orally for 14–42 days in an open study to six endogenous depressive in-patients (Newcastle score 6 or more (Carney *et al*, 1965)). Three became hypomanic during the trial. Thus, a 26-year-old female teacher whose brother had developed mania after receiving i.v. SAM in the previous study became hypomanic. A 50-year-old female clerk who had become hypomanic when given i.v. SAM in the former study showed a similar reaction. A 70-year-old man with no previous or family history of affective illness, unresponsive to other anti-depressant treatments, including ECT (the other two patients were considered for ECT), developed hypomania. All had been retarded, non-verbal, seclusive, and exhibited nihilistic or intrapunitive delusions. Each went through a brief euthymic period of 1–3 days before suddenly becoming elated, with marked increases in the production of speech and activity, and all developed grandiose ideas. One had heightened libido. Over the trial period the mean plasma SAM level in four of these patients increased from 30.5 to 144.0 ng/ml, i.e. from 2 to 10 times the basal mean value.

We have already demonstrated that SAM can cross the blood-brain barrier and influence monoamine metabolism (Bottiglieri *et al*, 1984). These results with oral SAM support the earlier report of switching (Carney *et al*, 1983) associated with the use of i.v. SAM and again suggest that some apparently endogenous depression is SAM-responsive (Reynolds *et al*, 1984). SAM is the major source of methyl groups in the brain, and intimately connected with brain and amine metabolism and membrane and neuro-transmitter function. Further studies of oral SAM in endogenous depression would be worthwhile. We are currently undertaking double-blind placebo-controlled trials of i.v. and oral SAM in patients with endogenous depression.

A HUNDRED YEARS AGO

Causes of Idiocy

Although Dr Down's patients came from every variety of social rank, he could not draw any safe deductions as to the influence of various occupations of the parents on the causation of idiocy. He had collected 400 cases with fair social antecedents, and had found that 75 per cent were the children of merchants, country gentlemen, officers in the army and navy, gentlemen of independent means and liberal education, and members of the titled aristocracy. No less a proportion than 25 per cent were the children of members of one or other of the three *learned professions*. Of these, 18 per cent were children of members of the clerical profession. Mr Galton finds that the legal profession (which procreates fewest idiots) gives birth to 11 per cent of the foremost men of eminence; that the medical profession (which procreates 1 per cent more of idiots than the legal) gives origin to 9 per cent of scientific men; while the clerical profession, which procreates the maximum amount of idiocy, gives birth to only 6 per cent of men of science. These statistics illustrated the process of natural selection.

Book Reviews

Editor: Sidney Crown

Examination Notes on the Scientific Basis of Psychiatry. By TIMOTHY G. DINAN. Bristol: Wright. 1985. Pp 148. £7.25.

The aim of this book is to provide a revision text for the disparate array of basic sciences knowledge which currently comprises the syllabus for the Part 1 MRCPsych examination. It succeeds in twelve brief chapters. In his disarming preface Dinan, a lecturer at St Bartholomew's Hospital, warns that some readers might find the book "intellectually emaciated". He need not worry: the short notes format renders the text spare, certainly, but there is no lack of intellectual reward.

The opening chapters on neurosciences reflect Dinan's academic background and are excellent. Post-membership clinicians looking for an up-to-date distillation of this fast-moving area will find it here. Chapters on psychopathology, diagnosis and classification, psychopharmacology, epidemiology and statistics, and social psychiatry all achieve a uniformly high standard which should equip any candidate with more than adequate ammunition. The essentials of psychology and neuropsychiatry are all there, although future editions might usefully include a little more about neuropsychology and drop the old epilepsy classification. The single weak section is that on genetics: three pages is hardly enough to encompass the genetics of adult mental illness and, in my experience, the preliminary exam requires more than is here.

This is a good, cheap, compact book which capably fills a long-felt gap in the psychiatric textbook market.

S. W. LEWIS, *Lecturer and Honorary Senior Registrar, Institute of Psychiatry, London*

Psychopathology in Epilepsy: Social Dimensions. Edited by STEVEN WHITMAN and BRUCE P. HERMANN. Oxford: Oxford University Press. 1986. Pp 309. £35.00.

As recently as 1956, 18 American states still had "eugenic sterilisation laws applicable to people with epilepsy". This is just one of the more recent events in a story of prohibition and prejudice. It is hardly surprising that there should be a perceived sense of stigma pertaining to epilepsy and that this social process should have an effect on emotional reactions in people with the disorder.

It may seem self-evident that people with epilepsy should develop emotional problems not only as a direct consequence of the illness but also because of psychosocial issues such as threat of unemployment or perceived discrimination. However, there are less obvious factors; one contributor presents evidence that about two-thirds of his sample reported a fear that they may die with their next seizure.

The declared aim of this multi-author book is to redress the imbalance between biological and social approaches to the study of the psychopathology seen with epilepsy. Each chapter is designed to stand alone and, despite editorial introductions to each section, there is little opportunity to develop an argument through the whole work. The contributions vary in interest. It often seems that too much time is being devoted to a detailed discussion of the contributors' own research, especially when this has already been published. This is a pity, because there are some important messages in the book. One of the two (British) longitudinal studies demonstrates little evidence either of poorer abilities or of discrimination among children with epilepsy. Nonetheless, the subjects seemed to feel stigma; as children they were more prone to develop emotional disturbance, and as adults they were more discontented with their lives. This discrepancy between the subjective and the objective is both an academic puzzle and a therapeutic challenge.

This is a book priced for the library rather than the individual. It is unlikely to have a general appeal, but selective reading would be of interest to those who work in the field and have not read the original reports.

STUART TURNER, *Lecturer in Psychological Medicine, King's College School of Medicine and Dentistry, London*

Controversies in Alcoholism and Substance Abuse. Edited by BARRY STIMMEL. New York: The Haworth Press. 1986. Pp 236. $34.95.

This book contains a collection of papers dealing with various aspects of alcohol and substance abuse, from American workers in the discipline. Whilst the editor is at pains to disclose the 'politicalisation' of the organisations involved in this field, the only contribution I found contentious was a short paper on marijuana. The articles might therefore not be particularly controversial, but in the main they are thorough, well informed, and up-to-date. On the grounds that most of the bad habits, cults, and crazes of the USA, like 'Hurricane Charlie' eventually arrive on our shores, we should be forewarned and forearmed.

I found the contributions covering the abuse of cocaine helpful. Clinical, behavioural, and biochemical aspects are discussed in some depth. The description of, and the information derived from, the notional telephone helpline 800-Cocaine is particularly relevant to what we might be faced with in the future, whether it be the folklore and jargon or the statistics.

There are two articles on AIDS – one dealing with the epidemiology as applicable to the USA, and the association of AIDS with intravenous drug misuse, and the other concerned with diagnosis and early recognition. There are two papers on medicinal approaches to opiate abuse, including narcotic antagonists (naltrexone) and psychotropic drugs, followed by a contribution by the editor advocating caution in the use of psychotropic drugs for individuals with a past history of substance abuse, specifying some special hazards.

The use of narcotics for the relief of pain and the attendant underusage ('Americanised' into 'opiophobia') are dealt with sensibly if one reads beyond the jargon of the abstract which introduces each chapter.

Finally, I would single out (there are some other contributions on social drinking in pregnancy) a paper on the cost-effectiveness of in-patient treatment of alcoholics. This is a timely review and is not confined to transatlantic findings. The development of day units in the UK since the mid-seventies would appear to be vindicated on the grounds of both cost and effectiveness, when reviewed alongside experience in the USA and Canada.

G. SEDMAN, *Consultant Psychiatrist, St Ann's Hospital, Poole*

Research in Community and Mental Health, Vol 5. Edited by JAMES R. GRANTLY. London: Jai Press. 1985. Pp 319. £45.70.

This is the fifth volume in an annual series of collections of research in the epidemiology of mental health. It consists of eleven papers loosely grouped in four sections, although there is little of a common theme within, let alone between, the sections.

The concept of a volume which is in essence a hardback annual journal (albeit with papers which are somewhat extended compared with those in the average journal) seems a rather clumsy one, and I am not sure what it achieves. As one would imagine, the papers are variable in quality; some, e.g. Aneshensel's exposition of a model of the natural history of depressive symptoms, being of real interest. She postulates that the majority of the community consists of 'stayers' – defined in respect of depression either as constantly symptom-free (the majority) or constantly symptomatic (the minority) – and a significant minority consists of 'movers'. 'Movers' are sometimes symptomatic and sometimes asymptomatic, depending on other variables which she goes on to explain. This paper has a real relevance to daily clinical practice, but I found many of the other papers too remote from either the clinical practice or theoretical understanding. They concentrate on the relationship between psychiatric disorders and the social and cultural framework within which the disorders arise, and since the culture is a foreign one and is of little day-to-day relevance to a psychiatrist practising in the UK these are less easy to evaluate.

I do not think the book is worth the price for most private purchases.

GILLIAN WALDRON, *Consultant Psychiatrist, Tower Hamlets Health Authority, London*

Transsexualism and Sex Reassignment. Edited by WILLIAM A. W. WALTERS and MICHAEL W. ROSS. Oxford: Oxford University Press. 1986. Pp 191. £17.50.

This is a much better book than the last one on this topic I reviewed in this Journal (*Female-to-Male Transsexualism. Historical, Clinical and Theoretical Issues*, by Leslie Martin Lothsteing), and is a very interesting and useful book which should be read by people interested in the field. It is designed to be, and succeeds in being, appropriate for patients as well as clinicians. The book is from Australia, and includes contributions from physicians, surgeons, psychiatrists, and others concerned with the treatment of transsexual individuals in Melbourne. There is also a chapter written by a patient.

In a multi-author book on this topic there is inevitably some repetition in the chapters on gender identity, causes, and diagnosis, but I found this tolerable. I thought the more practical parts of the book, including details of gender reassignment surgery, welfare services, endocrine aspects, and voice, speech, and language considerations, to be best. The discussion of clinical aspects seemed a little incomplete and the consideration of the causes of transsexualism bedevilled by our profound ignorance in this field. On the whole these authors appear to favour a postnatal origin of transsexualism, but I found their presentation unconvincing. The problem is not with people who have multiple personality difficulties and perhaps other sexual problems as well as transsexual inclinations, for whom the sexual anomaly can be construed as part of a more general personality disturbance; the real difficulty is with transsexuals who I think in this book are said to have primary gender dysphoria who are frequently brought up in what, in ordinary terms, are normal families, have siblings without major personality problems, and are entirely without substantial psychosocial difficulties. It is difficult to see how an early family constellation so subtle as to be unnoticed on ordinary examination should serve to produce such a fundamental disturbance as gender dysphoria, unassociated with any other problem and not affecting other siblings exposed to the same parents.

This book seemed a bit muddled about homosexuality and about sexual object relations in transsexual people, but refreshingly sensible in relation to psychodynamic, feminist, and other current excesses.

I was unable to find any clear statement about the authors' indications for surgical intervention. This omission may have been deliberate in a book designed to be presentable to patients as well as to staff, but in many ways it is the crux of the matter. I applaud the courage of these Australian colleagues in taking seriously the need of a significant number of transsexual people for surgical intervention as part of a treatment programme, and note that the opportunities for the treatment of people with this problem in the UK are exceedingly limited and not as satisfactory as would be expected in a civilised country.

J. P. WATSON, *Professor of Psychiatry, United Medical and Dental Schools, Guy's Hospital, London*

Recovering From Rape. By LINDA E. LEDRAY. New York: Henry Holt. 1986. Pp 258. $9.95.

This is a readable, relatively short handbook for rape victims and their friends and family. The first and largest part takes the victim and the 'significant other' (by this is meant the victim's boyfriend or other family member) through the stages, both emotional and administrative, which will be experienced after rape. It covers dealing with the police and doctors, the stages of the emotional trauma, and advice on how to recuperate. Each chapter contains separate sections for the victim and the other and looks at the experience from both points of view.

The second part of the book, and in my opinion the least successful, looks very briefly at explanations for rape and ways in which rape might be prevented.

The first part contains no advice with which one would argue. It is clear, and well-illustrated with case histories. The major drawback is that it relates very much to the situation in the USA, and all the supplementary information at the back about Rape Crisis Centres is American. The brevity with which the issues in part two are covered contrasts with the leisurely and usefully repetitive style of the first part, and in my view sits rather uncomfortably alongside it.

With these minor reservations I would recommend this book to my patients.

JULIE A. HOLLYMAN, *Consultant Psychiatrist, Springfield Hospital, London*

The Overactive Child (Clinics in Developmental Medicine No. 97). Edited by ERIC A. TAYLOR. Oxford: Blackwell Scientific Publications. 1986. Pp 269. £16.00.

The idea that a particular child's problematic behaviour can be briefly described as hyperactive is remarkably tenacious. High levels of motor activity, apparent inattention, and a disorganised or unfocused quality of behaviour are prone to elicit the use of the term from clinicians. The extent to which hyperactivity (or similar labels) is an heuristic, reliable or valid term is assessed by this book, and suggestions as to management are made.

The five contributors have helped to create the mass of information which the book explains, and the results of their joint enterprises at the Institute of Psychiatry are quoted in detail in some chapters. Such data, taken with the recent findings of others, point towards various conclusions: a broad concept of hyperactivity has little or no scientific support, and relabelling the problem as attention deficit is unhelpful. The distinction between situation-specific and pervasive overactivity is important: a narrowly defined hyperkinetic syndrome with pervasive overactivity can be identified and multiple causation is the rule, and so assessment and interventions should be broadly based. Drugs are demonstrably powerful treatments.

Perhaps there is little that is new in this, but the value of the book is the way in which it examines habits of thought and assumptions made in conceptualisations. The scholarly approach leads to some sections being over-referenced, and there is some fence-sitting. This is a book which is mainly about being thoughtful. It cannot be definitive, given the state of things, but it is certainly important. Given the good reputation of the *Clinics in Developmental Medicine* series, it will be generally available in paediatric libraries; it ought to be in every psychiatric library, and the wise child psychiatrist will obtain his or her own copy.

PETER HILL, *Senior Lecturer in Child and Adolescent Psychiatry, St George's Hospital Medical School, London*

Differential Therapy of Depression: Possibilities and Limitations. Edited by H. HIPPIUS and N. MATUSSEK. Basel: S. Karger. 1986. Pp 248. SFr186, $103.50.

This book consists of the proceedings of a symposium held in 1984 in West Germany. The symposium was opened by the head of the Federal Health Department, a former psychiatrist, who spoke with specialist insight of the problems posed for his department by pressure for non-medical psychotherapy and against pharmacotherapy and ECT.

The clinical section opens with a review by Pichot examining the idea that response to amitriptyline, imipramine, MAOIs, and ECT can be predicted from symptomatology. He rightly concludes that the evidence is weak, but does not discuss the importance of spontaneous remission and placebo response which may have their own clinical predictors. Four papers follow on clinical experience with fluvoxamine in comparison with other antidepressants; none directly address the issue of whether fluvoxamine is an effective antidepressant. In three papers the numbers of patients studied are so low as to preclude any serious conclusion as to efficacy. A large international multi-centre trial has been carried out, but only the briefest reports have appeared in the literature. It is hard to understand why a full description of this trial does not appear in the volume, much of which concerns fluvoxamine. Wagner *et al* discuss the potentially important issue of the influence of concomitant medication on efficacy and side-effects in the multi-centre fluvoxamine trial, but details of the trial design and results are too brief to permit critical evaluation. They state that fluvoxamine was superior to placebo in the American centres but not in the European centres – the European results are then excluded!

Several contributions (those by Beckmann, Holsboer, Berger, and Fahndrich) examine whether MHPG or 5HIAA in biological fluids, the dexamethasone suppression test or sleep parameters predict antidepressant responses to drugs. The conclusions are generally disappointing, and patient numbers are again low. Some of the chapters are useful reviews. The most interesting new material was Berger's study of sleep in 66 patients with depression. Reduced REM latency and early morning wakening, putative markers of endogenous depression, were as frequent in the neurotic group as in the endogenous.

There are two detailed studies of fluvoxamine on heart and liver function in patients with existing cardiac or hepatic disease.

In the pharmacological section, chapters by Sulser and Brunello highlight the puzzling and, one suspects, important interactions between serotonin and noradrenergic synapses. Direct pharmacological actions of antidepressants are many and diverse, yet all share the ability to induce a delayed decrease in noradrenergic beta receptor function which appears to be mediated by 5HT neurones. This 5HT–beta receptor interaction may be involved in the ability of fluvoxamine to decrease beta-receptor numbers, yet other 5HT re-uptake blockers such as citalopram do not affect beta-receptor numbers.

The book concludes with chapters by Asberg on cerebrospinal fluid 5HIAA and by Matussek on attenuated growth hormone responses to clonidine – perhaps the most consistent biological abnormality associated with depression.

This book is very expensive, and is as much concerned with fluvoxamine as with the subject indicated by the title. Unfortunately the book is not informative on whether fluvoxamine is an effective antidepressant with particular indications. The chapters on the biology of depression and antidepressant drugs are the best, and some of the reviews are useful. However, much of this material is more cheaply available elsewhere.

J. F. W. Deakin, *Senior Lecturer in Psychiatry, University Hospital of South Manchester*

An Introduction to Marital Problems. By Jack Dominian. London: Fontana. 1986. Pp 206. £2.50.

Dominian states in his preface that his aim was to provide an introductory text for the caring professions, and in this he has succeeded admirably. The inexpensive paperback format makes it an ideal course text and I have no doubt it will be widely used for this purpose by the various disciplines involved in health care. Most psychiatric libraries will want a copy on their shelves and it is sufficiently inexpensive for trainees to buy their own.

The first two sections review briefly the contributions from sociological and psychological research and examine the 'family cycle' in the light of current social trends and current knowledge of psychosocial processes within the family. The last section briefly introduces current therapeutic models and practice.

It is a readable book, but is slightly marred by some carelessness in preparation – for example, there are some references in the text which are omitted from the reference list. The author relies heavily on stereotypical descriptions which, on occasion, strike an irritatingly naïve note. These are minor criticisms, and it is clear that this book is a valuable addition to the literature.

O. S. Frank, *Consultant Psychiatrist, Westminster Hospital, London*

Eating Disorders: Effective Care and Treatment. By Felix E. F. Larocca, St. Louis: Ishiyaku Euro-America. 1986. Pp 261. $27.50.

Larocca is the Medical Director of the BASH (Bulimia, Anorexia, Self Help Inc.) treatment and research centre for eating and mood disorders in St Louis, and he has aimed this book at students of the various professions involved in the care of patients with eating disorders.

One third of the book's 16 chapters are on bulimia; there is one on obesity and two on anorexia nervosa, and the remainder cover the anorexia–bulimia nervosa spectrum. These proportions probably accurately reflect current interest. The range of the chapters is unusual: there is one describing dissociative states, in which large extracts of therapeutic dialogue are transcribed, and another on "burnout and eating disorder therapists". The chapter on the oral manifestations of the eating disorders is excellent, with good illustrations and a text which clearly defines dental terminology. Several chapters address the diagnostic difficulties which presently perplex those working in this field; Munoz authoritatively advocates the 'British School' of diagnosis of the eating disorders, as proposed by Fairburn and Russell, and the European influence is continued in two further chapters.

Several aspects of the production of this book were disappointing: my review copy had the last two chapters superimposed on the ghosted print of earlier chapters; the tables and figures in Lacey's chapter were all bunched together at the end; and the absence of illustration in the chapter on the management of obesity resulted in this otherwise interesting chapter becoming incomprehensible when the surgical techniques were described. Throughout the book several references were incomplete.

Despite these caveats this book is of interest to those working within the field of eating disorders and for those in other fields wishing to keep abreast of the recent developments within this rapidly expanding field.

JANET TREASURE, *Research Worker, Institute of Psychiatry, London*

The Psychosomatic Approach: Contemporary Practice of Whole-person Care. Edited by MARGARET J. CHRISTIE and PETER G. MELLETT. Chichester: John Wiley & Sons. 1986. Pp 447. £32.50.

The practice of psychosomatic medicine forms a large part of the workload of a general hospital psychiatrist, and has developed into a sub-speciality of its own – liaison psychiatry – with its own group in the Royal College of Psychiatrists. It is an acceptable area for research both by physicians and psychiatrists, and books, journals, and papers abound in this field. It is against this background that this book has been published.

There are eight sections. The first, 'Contemporary psychosomatics', consists of two chapters: Christie introduces the other chapters in the book while giving a brief overview of the field, and Lipowski clarifies some of the concepts and terminology in this area. He traces the historical development of psychosomatic medicine and discusses semantic issues.

Section two, 'The beginnings of life', covers a number of areas of obstetric and paediatric care. There are chapters dealing with genetic counselling, attitudes to care in labour, and the admission of children to hospital. This is followed by a section on eating behaviour, with a presentation of a multifactorial model of obesity marrying behavioural, physiological, and neurochemical elements and a review of abnormal eating behaviour giving the current state of knowledge about anorexia nervosa and bulimia.

The section on cardiovascular disorders includes chapters on the management of hypertension and the alteration of type A behaviour in patients with coronary artery disease. This is followed by another section on the management of practical clinical areas, namely the treatment of chronic pain and the use of benzodiazepines in the relief of anxiety.

Section six concentrates on non-hospital medicine, with chapters on community medicine, training for primary health care, clinical psychology in general practice, and occupational health. This last chapter covers a number of important areas, including work stress, the relationship between alcohol and occupational factors, and accidents at work. The final chapter in this section deals with the treatment of the home environment of the schizophrenic patient.

The penultimate section deals with the psychosocial aspect of surgery and cancer, and the book ends with a discussion about terminal care.

The editors and authors have produced an excellent book which is clearly laid out, well-written, comprehensively referenced, and is informative and interesting. I would strongly recommend this book to all those involved in the field of health care, especially as it appertains to the interface between medicine and psychiatry.

JEREMY M. PFEFFER, *Consultant Psychiatrist, The London Hospital*

Forensic Psychiatry and Psychology. Edited by WILLIAM J. CURRAN, A. LOUIS MCGARRY and SALEEM A. SHAH. Beckenham: Quest Meridien. 1986. Pp 549. $61.25.

This book is in six parts and comprises 22 individual chapters. The authors are experts in various aspects of the interdisciplinary fields of forensic psychiatry and psychology. The main objective of the book is to improve the quality of forensic expertise within the two disciplines in the American judicial and correctional systems. The intention is to provide a comprehensive review of the current problems and issues in the field, ranging from knowledge about training programmes to increasing the effectiveness of testimonial, consultative, and treatment services.

Each of the six parts deal with a particular aspect of the subject matter. Part 1 focuses on professional training and ethical standards. Major training programmes in various parts of America are extensively discussed, and it is emphasised that these tend to lag behind increased clinical and research activities. An appreciation is made of the important roles of social workers and nursing staff in the forensic field. Part 2, the most detailed section of the book, deals with techniques and procedures for assessment and treatment. Part 3 covers family violence and child abuse, child custody issues, matrimonial problems, and juvenile delinquency. Part 4 contains four chapters on sexually related offences, and Part 5 deals with personality disorder and its legal implications. The final part covers some of the roles of mental health professionals in court proceedings and in prisons.

This book covers a range of topics related to the interface between psychology, psychiatry, and the law. The chapters are of consistently high quality, and although predominantly related to the American judicial system, this is undoubtedly a valuable contribution to forensic psychiatry and psychology literature. The combination of recent research findings, developments in clinical assessment and treatment techniques, and related professional issues are well presented and discussed. The major limitation is the absence of information on the role of the forensic expert in the sentencing stage in court proceedings. For the British psychiatrist and psychologist this seriously limits the value of this otherwise excellent book.

GISLI H. GUDJONSSON, *Senior Lecturer, Institute of Psychiatry, London*

The Penguin Dictionary of Psychology. By ARTHUR S. REBER. London: Penguin Books. 1985. Pp 848. £5.95, $7.95.

This is a remarkable achievement: a dictionary written by one man. It is nearly 1000 pages long and covers 17 000 terms, mainly from psychology and psychiatry but with considerable representation from medicine, philosophy, sociology, linguistics, pharmacology, anatomy, physiology, and an extraordinarily large collection of 'miscellaneous' terms, e.g. peg-word system, a mneumonic technique – the example was chosen by opening the book at random! One author has an advantage over many authors in being less dry and more interesting. On the other hand, as with Dr Johnson, the reader has to live with prejudices, such as a remarkably one-eyed view of parapsychology.

Dictionary and encyclopaedia reading has an intellectually and emotionally compulsive quality to it. Highly recommended both for libraries and the individual reader.

SIDNEY CROWN, *Consultant Psychiatrist, The London Hospital*

Inquiring Man: The Psychology of Personal Constructs (3rd edition). By D. BANNISTER and F. FRANSELLA. Beckenham, Kent: Croom Helm. 1986. Pp 194. £16.95 (hb), £7.95 (pb).

In the Preface the authors say that the third edition of this book, which first appeared in 1971, comes 30 years after Kelly's seminal work *The Psychology of Personal Constructs;* in those 30 years the theory has acquired proven status as a practical tool and as a rich source of new thinking. Over the same period they see that traditional psychology has undergone vital, if cautious, change.

The book retains its original character in that it is a highly readable exposition of the essential theoretical and philosophical bases of Personal Construct Theory. The distinctive Personal Construct approaches to such issues as personality, assessment, development, interpersonal relationships, therapy, and psychological abnormality are all clearly outlined. The coverage of the relevant literature is usefully updated.

As with earlier editions, the presentation relies heavily on a 'compare and contrast' method with other psychological models: behavioural, psychodynamic, psychometric, and cognitive. Unfortunately, in propounding the virtues of Personal Construct Theory the authors are unnecessarily disparaging of these different frameworks. They make no attempt to disguise their disdain for the limitations of these schools of thought.

It must be admitted that Bannister (now sadly deceased) and Fransella have done much by their own efforts to make Kelly's ideas as well known and widely used in this country as they are today. They have been for many years the standard bearers for the radical 'alternative' Personal Construct creed. Despite its at times irritatingly polemical style, the third edition of *Inquiring Man* is still a good, brief, and readable account of the main elements of Personal Construct Theory and can be recommended as such.

TOM TRAUER, *Top Grade Clinical Psychologist, King's College Hospital, London*

Movement Disorders. Edited by NANDKUMAR S. SHAH and ALEXANDER G. DONALD. New York: Plenum. 1986. Pp 406. £49.50.

This is a multi-author book of twenty chapters in five sections, dealing with Parkinson's disease, tardive dyskinesia, Tourette's syndrome, Huntington's disease, and drug-induced disorders. Although the emphasis is on biochemical aspects of each condition, clinical features are discussed in most of the chapters – sometimes in some detail.

The introduction by Stahl is a reasonably clear and up-to-date overview of movement disorders discussed in terms of the neurotransmitter inbalance hypothesis, with useful definitions of clinical terms and a comprehensive list of references to recent literature. The diagrams in this chapter, although somewhat overdone, are helpful in elucidating a difficult field. This chapter can be recommended to clinical neurologists and psychiatrists, as well as to the reader with a specialist interest in brain biochemistry.

The rest of the book is very disappointing. It has all the disadvantages of a multi-author volume without any of its advantages. With one or two exceptions, the chapters in each section are irritatingly repetitive, usually covering the same ground as the previous chapter without offering any new viewpoints. However, some excellent reviews stand out: for example, the chapter on Parkinson's disease by Lieberman & Goldstein is a good review of the biochemical background to the treatment of the illness, and the chapter on drug-induced disorders by Pearce & Clough is another good review from a clinical viewpoint.

The time is ripe for a book on movement disorders, that spans the overlapping interests of psychiatrists, neurologists, and biochemists, perhaps written from one or other point of view. Unfortunately, this book does not quite make it. As it stands, it may have some use as a source of references for specialist readers but is not really viable as a general book on movement disorders, nor as a volume that gives "a more complete understanding" of movement disorders in relation to one another – an aim identified by one of the editors in the preface to the book. It is hardly value for money at its present price.

SUMAN J. M. FERNANDO, *Consultant Psychiatrist, Chase Farm Hospital, Middlesex*

Body and Mind in Old Age and Decay (Sinai Papers number 3). By A. SUNIER. The Netherlands: Van Gorcum. 1986. Pp 307. Dfl. 49.50.

This book is part of a series of three; Sunier is part author of the preceeding works on the Holocaust and problem patients. The title itself is chilling. Before we reach the list of contents, we are offered "guidance": the need becomes increasingly apparent with each page.

Despite the obviously diligent research and effort involved in producing this book, it reads like an inadequate translation of an over-inclusive work. There are frequent irritating spelling errors, and an awkward use of language which at times verges on incoherence. The style is idiosyncratic, dogmatic, and occasionally impenetrable.

What of the contents? The book is divided into two parts. The first two-thirds comprises an unhappy mixture of philosophy and the past findings in dementia. These are loosely woven together. In the second part, the author turns to a group of 70 of his own patients and presents a series of data with an attempt to relate the preceeding discussion with his results, setting himself the immense task of studying "the roots of our knowledge about the body of human subjects", including "molecular biology, cognitive psychology, sociology, and psychoanalysis", to examine the possible causation of dementia. "Our knowledge of the living system" should, he says, be expressed in "a homologous language of growth and decay of structures". There must be a simpler way...

The pathological process of dementia and the resulting adaptation will find expression in a multitude of patterns: so much is evident. Sadly, Sunier, despite his altruistic objectives, takes us little further.

D. KINGHAM, *Senior Psychiatric Registrar, Barrow Hospital, Bristol*

Psychotherapy and the Paranoid Process. By W. W. MEISSNER. New Jersey: Jason Aronson. 1986. Pp 433. $40.00.

The significance of Meissner's contribution lies in his grasp of the underlying structure of paranoid states. Here he explores the therapeutic aspects of the process that he first described in his earlier book, published in 1978. His model of paranoia rests fundamentally on what he describes as the introjective structure, consisting of two polar configurations of both aggression and narcissism. The aggression polarity involves a weak, *victim* introject and a strong, controlling, *victimiser* introject. The narcissistic configuration involves an inadequate, inferior pole, associated with feelings of shame and humiliation, and a grandiose, superior pole. These internalised objects can at different times be felt to be part of the self or part of the object. They are derived from actual early interactions with the parents, and incorporate aspects of the parents' own personality organisation – in Meissner's experience, parents of the paranoid person have often been themselves caught up in pathological aggressor-versus-victim and superior-versus-inferior patterns. He finds that paranoid patients are often very threatened by any attempt to confront them with their rage towards their parents; by projecting negative aspects onto other figures the patient attempts to preserve a good relationship with the primary object, the parent. Usually the paranoid patient is more subjectively in touch with the inferior victim poles, but the opposite poles are always active in repressed or projected form. Depressive patients may also show similar patterns of identifying with the victim introject, but show less projection than the paranoid patient.

Meissner discusses in detail the structure of the therapeutic process. Stage one is to establish the therapeutic alliance through sensitive listening, being particularly attentive to the patient's individuality rather than preoccupied with the therapist's theory. The next stage involves defining the projective system *before* challenging it – this is done through listening to the patient's account of his experience of himself and the world in which he lives, getting as much detail as possible about perceptions and feelings. Then the projective system can be challenged, first by tagging feelings – by adding remarks like "that seems to be how you feel" in order to help distinguish between feelings and reality; initially the patient will offer explanations and conclusions as if they were accepted fact. At this point there can be the crucial shift in focus from the projective system to the introjects. While initially the patient will more easily be in touch with the inferior victim introject, he must gradually be made aware of the superior, destructive, aggressive pole. The derivation of the introjects from actual early interactions can then be clarified. However, the introjective configuration is not easily given up, because it provides the essential core around which the sense of self and other are organised. This motivation must be explored, and the patient then needs to mourn the loss of the internal attachments, which then ushers in a phase of increased transference dependence.

Meissner explores the paranoid process in psychotic, borderline, and narcissistic states, and its role in adolescence, in addiction, in suicide, and in the ageing process. His discussion is scholarly and comprehensive. My one criticism is that in his efforts to be thorough he does not always sufficiently highlight foreground against background. The book is likely to be valuable to all dynamically-oriented psychiatrists and therapists.

PHILIP MOLLON, *Psychotherapist, Dryden Road Hospital, Tyne and Wear*

Current Psychiatric Therapies 1986, Vol. 23. Edited by JULES H. MASSERMAN. Orlando, Florida: Grune & Stratton. 1986. Pp 308. $63.00.

Jules Masserman is a name to be reckoned with in American psychiatry. He is now 79, and this book is the last in the *Current Psychiatric Therapy* series that he intends to edit. I am not familiar with previous volumes in the series, but the last one was described in this journal as making "no scientific case for progress" but as having "some curiosity value". The same could be said of this volume. Seven past Presidents (including the editor himself) and the current President of the American Psychiatric Association have contributed reviews of various fields, but they are conspicuously lacking in new findings or new research. The chapter by Freedman, on the psychopharmacology and psychotherapy of anxiety, is unusual in the number of papers cited, but none are more recent than 1979.

With the exception of a brief chapter by Kolb on the treatment of chronic post-traumatic stress disorders, the contributions about current psychiatric practice of potential application in this country are more concerned with their American practitioners than the treatment. Topics covered include proposals to fix treatment charges according to diagnostic category (discussed by both Talbott and Beigel), women's issues (Nadelson & Notman), and the ever-widening horizons of the malpractice lawyer (two chilling chapters, one by Slawson demonstrating the increasing legal responsibility of the American clinician for the actions of his or her patient, and the other, by Charles, documenting the distress caused to the clinician by a malpractice suit).

A large section of the book is given over to short accounts of their work by psychiatrists from the Bekhterev Psychoneurological Institute, Leningrad. The editor states that "Soviet psychiatrists are as scientifically progressive, ethical, and humanitarian as we try to be in our country", but the impression from this book is that they have become excessively preoccupied by social conformity. The spectre of political schizophrenia haunts the chapters and it is a shock to read that Ponomareff considers that the Institute of Clinical Psychiatry in Moscow is even more over-inclusive in its use of this abused diagnosis.

The remainder of the book is mainly concerned with spiritual matters, although there is one lively description of the ceremony preceding the May and Baker Plenary Address to the World Congress of Community Psychiatry, which involved a Swami and "lovely sari-clad maidens" whom the editor was required to symbolically deflower (his association, not mine).

Potential readers should bear in mind that the editor has interpreted his title, *Current Psychiatric Therapies*, as the Russians interpret schizophrenia and the World Congress of Community Psychiatry interprets inaugural ceremonies: rather loosely.

DIGBY TANTAM, *Senior Lecturer and Honorary Consultant Psychiatrist, The University Hospital of South Manchester*

Psychology and Medical Care (2nd ed). By GERRY KENT and MARY DALGLIESH. Eastbourne: Ballière Tindall. 1986. Pp 342. £7.50.

This book has thirteen main chapters divided into three sections: psychological processes, human development, and doctor-patient communication. The authors are to be congratulated, because they have produced a book which is both factually rich and readable. I liked the presentation of psychotherapeutic theories in the first part, which also contains chapters on memory, intelligence, and the sensory apparatus. Human development is covered in the biological life cycle framework.

There is more than enough here for the undergraduate, and it provides a useful revision for the general professional trainee. The references and suggested further reading give up-to-date information for more detailed research into the literature.

WILLIAM HUGHES, *Consultant Psychiatrist, United Norwich Hospitals*

The Twenty-Minute Hour: A Guide to Brief Psychotherapy for the Physician. By PIETRO CASTELNUOVO-TEDESCO. Washington, DC: American Psychiatric Press. 1986. Pp 172. $12.00.

This is a sensible book which tries to persuade the general physician to listen to his patient and to offer what the author calls "supportive psychotherapy". What the author tries to do is show the physician (by which he means an American general practitioner in private practice) that the work of psychotherapy can easily be fitted into the framework of the usual routine. The level of undertaking is really counselling (Cawley's level 2). He concentrates on the limitations of what can reasonably be achieved by a "non-expert", at consultation and in a subsequent series of ten 20-minute interviews. This may seem luxurious besides the 6 minutes suggested by Balint & Norrell, although hardly enough for most out-patients. Castelnuovo-Tedesco is clear about whom it is reasonable to attempt to help within this time span, what should definitely not be attempted, and on interventive strategies. He is helpful about how to limit the focus to what he calls the present and the future and how to appropriately blinker oneself to the past and the transference.

I think that what is offered is probably less sophisticated than what is available to general practitioners in this country now. It does seem appropriate, however, for physicians and surgeons who might be interested in helping their patients with the emotional conflicts that may manifest themselves as physical disease. (It is heartening to read of a man being positively investigated for the emotional disturbance that might have lead to the perforation of his peptic ulcer!). It would be nice to think of it also in the hands of psychiatrists whose training seems to make it so hard for them to hear any meaning in what their patients say.

I doubt that this book will satisfy the 'converted' or that it will find its way into the hands of the 'unconverted'. I think it might be helpful, however, as a teaching adjunct to those involved in liaison work with physicians, surgeons, and psychiatrists.

R. R. N. CARVALHO, *Consultant Psychotherapist, St Mary's Hospital, London*

Suicide and Depression Among Adolescents and Young Adults. Edited by GERALD L. KLERMAN. New York: American Psychiatric Press. 1986. Pp 383. $24.95.

This book is based on a conference held in 1982 on preventive aspects of suicide and depression among adolescents and young adults. Epidemiological and aetiological factors of suicide are identified and different means of intervention considered, and the possibilities for the prevention of mental illness in this age group discussed. It is sometimes difficult to see any clear order in the sequence of chapters, with different subjects side by side. One chapter is not specifically concerned with adolescence, but with the statistical techniques that can be used to investigate the heritability of major depressive disorders. In contrast is a painful insight into the inner world of Vivienne, an unfortunate victim of suicide at the age of 13, who had written her troubled thoughts in letters and a diary.

Several chapters report on current research. However, the lack of data make them unsatisfactory. There are some useful literature reviews, in particular a clear account of research on personality and psychosocial factors in suicide and depression in adolescence.

The book forms an interesting and thought-provoking collection for anyone having contact with adolescents.

JOYCE ALMEIDA, *Registrar in Child Psychiatry, The London Hospital*

Intensive Family Therapy: Theoretical and Practical Aspects. Edited by IVAN BOSZORMENYI-NAGY and JAMES L. FRAMO. New York: Brunner/Mazel. 1985. Pp 507. $35.00.

In common with most child psychiatrists I practice, and indeed enjoy practicing, family therapy. Unlike many, however, I do not read a great deal of the family therapy literature. I find that too often I become bogged down in a mass of neologisms, or completely unreadable accounts of theoretical models. I have always felt guilty about this, and have wondered whether I might become a better therapist if I read more! I was therefore pleased to receive this book and decided to make an effort to read it through, mainly as an exercise in self-education with a review as a secondary goal. I threw myself into the first chapter and began reading. As I read on I became puzzled by the need of several authors to justify why they practice family therapy at all, as opposed to individual psychoanalytic therapy. I noticed with growing puzzlement that none of the references were more recent than 1963. At that point I turned to the publication details and discovered that this is a reprint of a book originally published in 1965. No reason is given by the publishers or the editors as to why they thought a reprint would be useful 21 years later.

I assume that this is regarded as a seminal work in the development of psychoanalytically-based family therapy. In 1965 it may well have been a most important book, helping those who were treating patients with schizophrenia or other serious psychiatric illnesses through individual psychotherapy to look at the social environment of their patients. With all the developments in family therapy since then and with the growing body of knowledge of the effects of family interactions on the course of psychiatric illnesses, this book can only be regarded as a historical curiosity. I cannot see how this reprint will be of any use other than as an indication of the thinking in the 1950s and 60s of certain analysts who were beginning to transfer their interests from the inner representation of the family to its existence in the real world.

STEPHEN N. WOLKIND, *Consultant Psychiatrist, Maudsley Hospital, London*

Essential Papers on Narcissism. Edited by ANDREW P. MORRISON. New York: New York University Press. 1986. Pp 491. $50.00 (hb), $22.50 (pb).

Why is narcissism important? Kernberg provides an answer: he states that there exists a group of patients whom we might consider as a pure culture of the pathological development of narcissism. These patients on the surface do not present serious disturbed behaviour. He goes on to outline the features of these patients, concluding that they are a subgroup of the borderline group of personality disorders. The importance of identifying this particular group is that they may regress to a psychotic level of functioning, which can come as a surprise if the professionals working with them are not alert to the constellation of symptoms and their significance.

This book draws together various views on narcissism, starting with Freud's classic paper 'On narcissism'.

This is perhaps the most difficult, because of what was for Freud an unusual lack of clarity. But perhaps it is this confusion that enabled subsequent workers to take ideas from it and develop them in the light of their clinical experience. It is a pity the papers are not dated; one assumes they are in chronological order, but this may not be so. Pulver's chapter contains a clear explanation of the concept and the problems of the use of the same word to convey different meanings.

Cooper discusses recent developments, and Kohut's paper is of interest, particularly where he suggests that healthy narcissism may become transformed into humour, creativity, empathy, and wisdom. Kernberg's 'Factors in the psychoanalytic treatment of narcissistic personalities' is a must, and Alice Miller's paper is of interest to general psychiatrists trying to understand depressed patients. Morrison's paper on shame uses Kohut's formulation of the defects in the early development of the structure of the self leading to narcissism, and suggests that shame reflects self-depletion in such patients, and is a painful experience which needs recognition. It is not sufficient to treat the ensuing depression.

There are three papers on treatment: psychoanalysis, supportive psychotherapy, and general psychiatric management. Ideas vary on how to deal with dependence, manipulative behaviour, paranoia, passive-aggressive behaviour, or antisocial behaviour. What is agreed is that if there is to be a fundamental restructuring of these patients, it is long, slow, difficult work.

Meissner's paper attempts to integrate the theoretical problems of narcissism with the problems encountered in treatment. Bromberg's paper may become a classic. It describes the essence of narcissism as currently understood and the pain of the 'mirror and the mask' for patients and those trying to treat them; however, it concludes by offering some hope.

JUDITH TROWELL, *Consultant Psychiatrist, Tavistock Clinic*

Community Surveys of Psychiatric Disorders. Edited by N. N. WEISSMAN, J. K. MYERS and C. E. ROSS. New Brunswick: Rutgers University Press. 1986. Pp 544. $60.00 (hb), $25.00 (pb).

As MacMahon pointed out, 'No problem of definition in medicine is more baffling than that of defining mental illness". One might add that the validity of this assertion is nowhere more apparent than in studies of psychiatric morbidity conducted in community settings. Moreover, the notion of community raises perplexing questions. The frustrations encountered in the struggle for definition, representative sampling, and the specification of appropriate dependent and independent variables, and the efforts to achieve reliable and valid results since Jarvis first attempted to determine the frequency of idiocy and insanity in the mid-19th century, are thoroughly exposed here in 19 chapters by 30 eminent authors. The Midtown Manhatten, Stirling County, New Haven, and NINH Epidemiologic Catchment Area Program studies are dealt with, along with several European surveys. In addition to the editors, the contributors include Dohrenwend, Dunham, Endicott, Helgason, Hollingshead, Jablensky, Regier, Robins, and Wing. Inevitably, the editors concentrate on work done in the USA; little attention is given to the British experience. For example, only three surveys from a general practice setting are referred to, and these only in a Table.

GREG WILKINSON, *Senior Lecturer, Institute of Psychiatry, London*

A Matter of Interest: Clinical Notes of A Psycho-Analyst in General Practice. (The Roland Harris Trust Library Monograph Series No. 2). By KENNETH SANDERS. Strathtay: Clunie Press. 1986. Pp 109. £6.50.

This compassionate little book lives through its case material. It is in truth a matter of interest for GPs rather than in any sense a textbook. It serves as a reminder of the potential available to bring consultations to life by acknowledging the internal world of the patient via 'restrained investigation'. This, if not actually solving the patient's problem, promotes a feeling of warmth and concern, and certainly a satisfying deepening of interest.

Sanders' practice is affectionately placed historically, and some characters introduced in rather an *Under Milk Wood* sort of way. There is poetry in the case cameos: for instance, the Russian "Lady with the miniatures" and her deathly romance with her impotent, alcoholic rear-gunner, Charlie.

Quite a lot of psychoanalytic theory is taken for granted, and sometimes a surprising interpretation stands out rather starkly, with no obvious lesson to be drawn. However, there are lessons in the chapter on Bion: we are led to the idea of rescue rather than action, and the three-dimensional notion of containment.

Throughout, Sanders wisely reminds us of the importance of projection of anxieties from childhood deprivation. There is the delightful case of Sally and her grandmother, where the original encounter was a request for a sedative. The patient was unaware of the complexity of the problem, and the grandmother bewildered, but with the help of Sally's pictures the doctor interpreted safely and helpfully. Could we GPs do more of this?

Published by
The Royal College of Psychiatrist

ISSN 0007-1250

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal,* great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary.*

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al, British Medical Journal,* 7 May 1983, **286,** 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins,** and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and th reference list are in complete agreement as regards dates an spelling of names. The text reference should be in the forn '(Smith, 1971)' or 'Smith (1971) showed that . . . '

DURKHEIM, E. (1897) Le Suicide. Paris. Translate (1952) as Suicide: A Study in Sociology, by J. A Spaulding & C. Simpson. London: Routledge & Kega Paul.

KENDELL, R. E. (1974) The stability of psychiatri diagnoses. British Journal of Psychiatry, **124,** 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970 Education, Health and Behaviour. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosi and treatment. In Pathology and Treatment of Sexua Deviation (ed. I. Rosen) Oxford: Oxford Universit Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols an Abbreviations: A Guide for Biological and Medical Editor and Authors* (3rd ed. 1977), £2.00, available from th Publications Office of the Royal Society of Medicine. Term or abbreviations which might not be understood by th average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separat sheet, with an adequate heading; table and heading should b self-explanatory without reference to the text. The desire position of the table relative to the text should be indicated i the left margin.

Figures should be individual glossy photographs, or othe camera-ready prints, *not* photocopies, clearly numbered an captioned below. Avoid cluttering figures with explanator text which is better incorporated succinctly in the caption. figure intended to occupy a single column should be draw (or photographed) 80–110 mm wide to allow for a 2/3 reduc tion; a figure requiring the whole width of the page should b 180–210 mm wide. Lettering (film-set or stencil) should b 12pt sans (initial capital for the first word only) to give 8p on the printed page. Labels on graphs should read parallel t the axes. Units must be clearly indicated and should be i brackets (*note*—'litre' should be spelled out in full unles modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the orig inal b/w negative (not, for example, from a colour slide or printed page) and should be glossy and sharply focusse Labels, arrows, etc. should be shown on a duplicate print o overlay. Do not write anything on photographic prints, an do not use staples or paper-clips on them. These procedure apart, all the comments on figures and tables apply equally t photographs.

8. **Proofs** A proof will be sent to the senior author of a article. Reprints, which are prepared at the same time as th *Journal,* should be ordered when the proof is returned to th Editor.

9. **Letters to the Editor** Letters should not exceed tw double-spaced typed pages. They will be edited for clarity an conformity with *Journal* style and may be shortened. Ther should be no more than five references; tables and figure cannot be used.

RESEARCH TO PRACTICE IN CHILD PSYCHIATRY

Topics to include:
- ★Depression in childhood and parents
- ★Modern approaches to autism
- ★Parenting and its breakdown
- ★The efficacy of psychotherapy
- ★Peer relationships and disorder
- ★Social factors in psychopathology

Speakers to include:
- Professor A D Cox
- Dr C Dare
- Professor P J Graham
- Professor R Nicol
- Professor M L Rutter
- Dr D Steinberg
- Dr S Wolkind
- Professor W Yule

MEDICAL DIRECTOR

Centracare Saint John Inc., a fully accredited, 362-bed psychiatric teaching hospital, providing a comprehensive range of mental health services to southern New Brunswick, located in the progressive, picturesque port city of Saint John, New Brunswick, invites applications for the position of Medical Director.

The successful candidate will have complete responsibility for the supervision of all psychiatric and medical services and the coordination of all clinical treatment and research activities.

The hospital is affiliated with Dalhousie Medical School and an academic appointment is possible for a suitable candidate. There is scope for limited private practice.

Preferred applicants should be eligible for licensing to practice in the province of New Brunswick, and have:

(a) Canadian Fellowship in Psychiatry (or equivalent), with some experience in administration

or

(b) A minimum of five years experience in medical administration.

Compensation will include a negotiable, extremely competitive salary, generous relocation program, along with a comprehensive benefits package.

Applications and/or requests for further information should be directed to:

UNIVERSITY OF QUEENSLAND

Equal Opportunity in Employment is University Policy

CHAIR OF CHILD PSYCHIATRY: DIRECTOR OF CHILD PSYCHIATRY

Applications are called for appointment to the newly established combined position of Foundation Professor of Child Psychiatry (Department of Child Health, University of Queensland), and Director of Child Psychiatry (Royal Children's Hospital, Brisbane).

Applicants should possess a distinguished research record and extensive clinical experience at consultant level. They should have a demonstrated ability in teaching at both undergraduate and postgraduate levels. Applicants should have qualifications registrable in the Medical Specialty of Psychiatry with the Medical Board of Queensland and hold the Certificate in Chair Psychiatry (RANZCP), or have had experience equivalent to that required for that Certificate.

The appointee will be expected to have a significant clinical and teaching practice within the Royal Children's Hospital, Brisbane. It would be hoped that the appointee would link with the University Department of Psychiatry situated at Royal Brisbane Hospital for development of the teaching and research interests as is appropriate in a collaborative manner.

Salary per annum: A$58349 plus a clinical loading of A$10433 per annum.

Closing Date: ***30 June 1987*****. Reference No. 16987**

Additional information and application forms are available from the Secretary-General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF.

2-DAY COURSE ON EATING DISORDERS

Institute of Psychiatry London

24th–25th September, 1987

This new multidisciplinary course for both Medical and Non-Medical Professionals will deal with all aspects of the Management of **Anorexia Nervosa** and **Bulimia Nervosa** including in-patient care, treatment of complications, and individual and family psychotherapy. **Lectures** will be given by Professor Crisp, Professor Russell and Professor Wakeling and many other experts in the field. There will be **Video Workshops, Discussion Sessions** and **Visits** to the **In-Patient Unit.**

Course Fees: £50
Overnight accommodation available in local
Hall of Residence

Review Article

Depressive Disorder in Primary Care

C. V. R. BLACKER and A. W. CLARE

Since the pioneering study of psychiatric morbidity in primary care by Shepherd *et al* in 1966, it has become increasingly apparent that a substantial proportion (between 20% and 25%) of patients consulting their GP are suffering from some form of psychiatric disturbance (Goldberg & Blackwell, 1970; Hoeper *et al*, 1979). The composition of this psychiatric morbidity has been shown to be almost wholly affective in nature and largely mild in degree. In their important review Jenkins & Shepherd (1983) recently summarised the now extensive findings relating to overall minor psychiatric morbidity in primary care. However, recent collaborative studies between psychiatrists and GPs have identified that within this dilute pool of minor disorders, lurks a significant but poorly served population of patients suffering from depressive disorders which are by no means minor in degree. A number of crucial issues regarding this depression in primary care emerge which the present paper aims to review. In particular, how common is it, and how severe? How does it present and what, if any, are its special characteristics? What is the precise relationship between depressive symptoms and depressive illness presenting to the GP and what is the relationship between physical illness and depression? And finally, what is the course and outcome of depression in this setting and what are the indications for and effect of treatment?

The extent of the problem

As early as 1947, Watts drew attention to the problem of depression in general practice by showing that 'endogenous depression' was a much commoner condition in that setting than was generally appreciated. Since then numerous studies have attempted to measure and describe this phenomenon but the problems surrounding their definitions of 'caseness' (i.e. at what point a set of complaints becomes serious enough to be considered epidemiologically, sociologically, or clinically significant) have made their interpretation difficult. A popular solution to this problem has been simply to record the actual number of depressive symptoms. Thus Shepherd *et al* (1966) found that, within a range of London practices, 7% of men and 13% of women "usually felt unhappy", 2% and 6% respectively "felt so unhappy that they wished they were dead", 1.8% and 2.5% "always felt miserable and blue", and 2.7% males and 4.4% females "felt that life was entirely hopeless". Other studies of depressive symptoms are summarised in Table I. As can be seen, they demonstrate wide discrepancies between rates for 'depression' so defined, the reasons for which include differences in the way symptoms were elicited, the choice of instrument used to measure them, and in the cut-off scores by which 'caseness' was defined.

As the rates in Table I show, the experience of depression itself is a common one in general practice. Yet examination of such patients shows that only a small proportion of them fulfil diagnostic criteria for depressive disorder, i.e. have a pervasive disturbance of mood, or demonstrable impairment, or any of the constellation of 'associated symptoms' with which the notion of the depressive syndrome is surrounded. The issue of 'caseness' thus moves up from the mere quantification of symptoms to consider their type, severity, and statistical relationship as well as other measures such as degree of associated impairment and help-seeking behaviour as embodied in modern operational diagnostic criteria. In case this is thought to cover unnecessarily familiar territory for readers, it is helpful to recall that GPs are confronted by a

TABLE II
Prevalence of 'depressive illness'

Study	*Sample*	*Diagnostic category*	*Rates*
Barber (1981)	Nine Glasgow GPs 1 month	101 new cases of 'depressive' illness'	Incidence = 3.7 cases per GP per month
Porter (1970)	Single practice 2.5 years	93 cases of 'depressive illness'	Prevalence per consulting patients = 1.7% men = 7.8% women Annual incidence per 1000 at risk = 6.5 men = 29.3 women
Johnson & Mellor (1977)	Five Manchester practices. Consecutive cases. Period of sampling not known.	119 new and 88 'in-treatment' cases of 'depressive illness'. Diagnosis confirmed by psychiatrist interview	Prevalence per consulting patients = 3.7% (both sexes)

bewildering range and variety of continuously distributed emotional states which often defy the neat categorisation laid down by existing systems of diagnosis and classification. Current classifactory distinctions between one affective disorder and the next are largely arbitrary and derived from experience with psychiatric-service populations which (because of the peculiar nature of the referral system) are no longer representative of their disease-population of origin. Thus traditional concepts such as the 'endogeneous/neurotic' dichotomy, used to categorise depressive disorder and acquired by GPs in their medical training, are less helpful than they might be. It is not surprising therefore that many GPs have their own ways of defining caseness and labelling disorder (Clare, 1982). In particular, many GPs resort to the notion of a disorder's 'understandability' in defining caseness. However, this creates its own difficulties, not the least of which is that few depressions in any setting are truly 'endogenous'; the majority appear to have arisen in the context of, if not actually caused by, readily discernable life events, illnesses, or social and relationship difficulties of one kind or another. Moreover, as shown in Jenkin's & Shepherd's review, the role these social factors play in the context of depression is complex and very poorly understood. Therefore, the equation 'understandable = appropriate/normal' commonly used by GPs to define caseness in affective disorder is misleading and may well be responsible for much of the apparent diagnostic and therapeutic inertia which seems to afflict them in the management of depressed patients. From the GPs point of view the importance of these arguments is that a more satisfactory definition of caseness will give greater weight to the *form* and *degree* of the ensuing depressive reaction and less to the circumstances against which it arose. Fortunately the operational criteria by which depressive *disorder* is distinguished from all other manifestations of 'depression' have largely been those chosen for epidemiological studies of depression in primary care, the reliability of which have also been greatly enhanced by the more rigorous handling of 'caseness' provided by structured psychiatric interview and diagnostic instruments such as the Present State Examination (PSE: Wing *et al*, 1974) and the Research Diagnostic Criteria (RDC: Spitzer *et al*, 1978). The efficacy of such instruments in controlling for the vagaries of caseness-definition are demonstrated by the greater concordance between the findings from studies which employ them. Nevertheless, such instruments are not infallible and they fail to account realistically for important axes such as personality or physical illness which exert a powerful influence on a clinician's normal case-making decision. The issue of what constitutes a 'case' of psychiatric disorder in primary care is thus still a matter of debate. We therefore turn to consider the prevalence of depressive *disorder*. Studies drawing their data from a retrospective examination of GP case records generally report low prevalence rates for depressive disorder presumably because many cases fail to be detected by GPs (see below). Furthermore not all identified cases are recorded in casenotes, and even when they are, GPs do not always award the patient a specific diagnostic label, or prefer to use alternative labels (e.g. 'anxiety') to describe them (Clare, 1982). Such studies therefore yield low 1-year period prevalence rates for depressive disorder in the range 0.2%–1.5% (percentage at risk, both sexes, diagnoses matched with ICD and DSM) (Watts *et al*, 1964; Wing *et al*, 1967; Bebbington, 1978). Crombie (1974), reporting on the Second National Morbidity Survey of 1970/71, recorded that 3.1% of consulting patients in the UK were suffering from neurotic depression giving a 1-year consultation rate of 35.5/1000 at risk (a substantial increase on the previous survey). The reasons for this increase are unclear but may include a true increase in prevalence during that time, or a change in public attitudes making it more likely that depressed people will seek help from GPs, or that GPs have greatly increased their diagnostic vigilance and recording skills. Other studies of depression, not dependent upon the retrospective examination of case records are summarised in Table II.

More reliable studies of depressive disorder which bypass the problems of case-detection by GPs include those of Wright *et al* (1980) and Nielsen & Williams (1980). In both studies patients screened for depressive symptoms (see Table I) were subjected to a clinical diagnostic interview with one of several psychiatrists. On the basis of these interviews Wright returned a very high rate for RDC depressive disorder of 17% of consulting patients. However, only 32% of those eligible for diagnostic interview agreed to receive it and only two of these were men. Nielsen found that 10% of consulting patients fulfilled a diagnosis of 'Depressive Neurosis' (DSM-II) whilst on Feighner criteria 6.8% were judged to have primary depression and 4.9% secondary depression.

Using the structured psychiatric interview and diagnostic techniques referred to earlier, Casey *et al* (1984) made a study of 'conspicuous' psychiatric morbidity referred by GPs from a single centre over the course of a year. On the basis of diagnostic interviews using the PSE the authors report that 'nearly half' of the sample (approximately 3.3% of consulting patients) had depressive disorder. Comparison with other studies suggests that this figure is on the low side, the probable reason for which is the well-known problem of non-recognition of psychiatric disorder by GPs. Casey's figure for overall psychiatric morbidity, too, is on the low side (7% of consulting patients compared to the 15% plus reported by Shepherd and others) giving further grounds for suspecting that many patients went unrecognised by the diagnosing GPs.

Hoeper *et al* (1979), using a familiar two-stage design (the GHQ and the Schizophrenia and Affective Disorder Schedule—Lifetime Version, Endicott & Spitzer, 1979), returned point prevalence rates for RDC depressive disorder out of 1972 consulting patients as follows: major depressive disorder (5.6%), intermittent depressive disorder (5%), and minor depressive disorder (3.4%). It should be born in mind that these three categories are not mutually exclusive since patients may have more than one disorder simultaneously. These prevalence rates are, however, adjusted for the 30% of cases which, on interview, the GHQ was found to have failed to detect. In this study patient recruitment was low: 15% declined to complete a GHQ and 30% of GHQ-positive patients declined to be interviewed. The importance of obtaining high recruitment in epidemiological studies of this sort concerns the nature of the patients so missed. It is our experience that primary care patients who are most reluctant to participate in questionnaires and interviews are very likely to be suffering from some form of emotional distress (e.g. bereavement) or psychiatric disorder (typically alcoholism, personality disorder, and major depression). Their non-inclusion would therefore exert a powerful influence upon prevalence rates. Other criticisms of Hoeper's study include the use of social workers to make the diagnostic interviews and the shortness and timing of their 3-month sampling frame (January and March—a time of year notorious for its association with high rates of physical illness and general distress). Short sampling-frame studies fail to account for the well-known seasonal fluctuation in depression, and also produce disproportionately large numbers of chronic cases (and those who, because of the presence of other factors—such as personality, loneliness, or physical illness—tend to consult more frequently). Not surprisingly therefore, 80% of Hoeper's sample were later found to be suffering from chronic disorders.

Thus the definitive study of prevalence of depressive disorder in primary care remains to be done although we hope shortly to publish our own findings in which many of these methodological problems were taken into account (Blacker & Clare, in prep.). In the meantime, one may tentatively conclude that point prevalence rates for RDC Major and Minor depressive disorder of approximately 5% each in consulting patients are not far from the mark. There are suggestions from other investigators that this figure is similar in other centres despite their differences in geographical location. The importance of this finding is that depressive disorder is therefore one of the more common clinical problems encountered by GPs in the course of their work, the severity and characteristics of which we shall now consider.

Severity of depression in general practice

It is frequently stated that primary care depressives are milder, more 'neurotic', more 'reactive', and less 'biological' than those found in psychiatric settings. Certainly such patients are very well represented in primary care but the question remains whether depressions in this setting are always of this type—or whether cases of more severe depressive illness also exist but currently escape referral to psychiatric services? Of course, the proportion of severe-to-mild disorders in a particular practice will probably be influenced by its geographical location because of the effects of demographic and social variables upon prevalence (Shepherd *et al*, 1966). Individual GPs bias and accuracy, therapeutic orientation and referral attitudes will also exert an effect upon the proportion of cases deemed 'severe'. The traditional view of a positive relationship between severity and likelihood of referral to psychiatric services is largely derived from experience with patients suffering from psychotic illnesses. The situation in depression is unclear. A number of authors have reported a marked differential of severity between psychiatric-service and general practice depressives. In comparison with depressed psychiatric in-patients, Davies & Blakshi (1973), Johnson (1973, 1974), and Fahy (1974) found that primary care depressives were milder and borderline in quality. Sireling *et al* (1985*b*) compared 'GP depressives' with psychiatric out-patient depressives selected for inclusion in a drug trial and concluded that 'general practice depressives were considerably less severely ill than psychiatric out-patients, with fewer depressive symptoms and shorter illnesses, as well as less primary and less endogenous depressions'. However, these conclusions are partially forced upon them by their sampling: depressed patients already receiving antidepressants at the time of entry, or who were felt to be so depressed as to require (or have recently required) a psychiatric opinion, were excluded. Thus, in this otherwise valuable study, many of the more severely depressed would have been removed before the essential comparisons were made. In addition, one-fifth of the so-called 'general practice depressives' did not have depression at all but were found to be suffering from anxiety states or other conditions. Exceptionally severe cases of depression are likely to gravitate quickly into psychiatric care but it is important to bear in mind that depressed patients found within psychiatric services represent a distillation or 'creaming off' of cases from a comparatively dilute pool of disorders in the community. Thus, if taken as a whole, these two populations will always demonstrate a differential of severity due more to the effects of sample composition than anything else. After controlling for this, Brown *et al* (1985) found considerable overlap between the severity of depressive disorders in psychiatric out-patients and in the community. What distinguished the two, it seemed, was not the severity of disorder but the way symptoms were expressed. Their findings support the notion that GPs tend to make a decision to refer depressed patients not so much on the basis of the illness severity but on the presence of additional 'complicating' factors such as personality difficulties, alcohol abuse, non-response to treatment, or threatened self-harm. Fahy (1974), too, found that severity of depression was not a major factor in a GPs decision to refer. Studying the question of severity of general practice depression by comparison with psychiatric-service patients may not, therefore, be the best way to proceed. The additional complicating factors, which referred patients appear to have, make independent contributions to the measurement of disorder severity and so confuse the picture. The alternative solution is to obtain a large and representative sample of general practice depressives and make a within-group study of depression severity using a hierarchy of caseness as defined by various diagnostic and classification systems. There are, of course, ways of defining severity other than the type number and statistical relationship of individual symptoms. In clinical practice the degree of associated social impairment or disability is often a decisive factor although this invites confusion with other variables such as personality and social support. In a large sample of over 200 consecutive cases of depressive disorder, Johnson & Mellor (1977) found that half of these general practice patients were unable to continue with their normal lives. They concluded that the traditional view of general practice depression as a mild and self-limiting condition was therefore mistaken.

Only a proportion, probably less than 10%, of depressed patients in primary care are referred to psychiatric services. As will be shown later only a small proportion currently receive what would be regarded as an adequate course of treatment. Quite what happens to the depressed patients who thus escape referral and who therefore remain 'locked' and untreated within the community is not known. The worrying statistics with regard to GPs' contacts with suicidal patients (Barraclough *et al*, 1974), chronicity of disorder (see below), and the emerging association between depression and alcohol and drug dependency in the community (Brown *et al*, 1985) suggest that the current complacency with regard to the severity of GP depression should be resisted.

Sociodemographic factors and depression in general practice

The importance of sociodemographic variables in the study of any disorder lies in the identification of groups of patients who may be considered to be 'at risk'. The impression gained from exposure to general practice is that young, working-class, women are responsible for the lion's share of the community's depression. However, this is largely due to the effects of consultation processes since young women are over-represented in this setting. Tischler *et al* (1975*a,b*) reported that single, unemployed people living on their own over-used GP services when compared with other groups in the general population from which they were drawn.

Previous studies of depressed patients in general practice have reported a variety of often conflicting findings whose interpretation is difficult. Often, little effort is made to define 'caseness' and the usual inclusion of chronic relapsing disorders (which constitute a substantial proportion of cases seen in this setting) may lead to biases in reported sociodemographic findings (e.g. civil status and employment) because of the negative effects such disorders have upon relationships. Studies of single practices or those drawn from similar areas will generally report sociodemographic associations which reflect the composition of the populations they serve; thus studies conducted in inner city areas will report high rates for unemployment or unmarried status. Case-records studies or those using GPs will also be subject to bias because of the known effect that sociodemographic variables exert upon GPs' case-detection abilities; for example Marks *et al* (1979) demonstrated that doctors are more likely to detect psychiatric disorder in women than in men. Studies in which only the patient is interviewed may be biased because of the perceptual distortions which being depressed confers; for example, Henderson (1981) showed that depressed people tended to devalue or underestimate the true nature of their supportive relationships. Lastly, few studies have controlled for other social variables when examining for associations between depression and individual sociodemographic factors an exception to which being that of Hesbacher *et al* (1975).

Because of the uncertain and conflicting nature of the evidence it is not proposed to discuss individual sociodemographic factors and depression in great detail. Two factors, however, do merit attention—sex and age.

Sex

All the studies of depression in general practice quoted so far report a sex distribution in which women far outnumber men. General population studies report a sex-ratio for various depressive disorders of approximately 2:1 (e.g. the recent ECA programme, Robins *et al*, 1984; Myers *et al*, 1984) but in general practice this ratio rises to 3:1 or even 4:1 (Porter, 1970; Dunn & Skuse, 1981 & Sireling *et al*, 1985*a*). The reasons for this sex differential are complex and poorly understood but genetic factors probably make only a small contribution. Jenkins & Shepherd (1983), in their review, suggest that the greater prevalence of minor psychiatric morbidity amongst women may have an environmental basis but illness-behaviour is also an important consideration. Consultation rates are higher in women than men for almost all forms of complaint and women report more symptoms and are more likely to seek help for minor complaints of any kind than men (Shepherd *et al*, 1966). Primary care studies of depressive symptoms shown in Table I are unanimous in finding that women tend to have higher scores on self-report questionnaires than men. Men, on the other hand, are less inclined to identify themselves as psychiatrically ill or to communicate their feelings to others (Horwitz, 1977), a finding confirmed by general population studies showing that men are less likely than women to seek professional help when depressed (Weissman & Klerman, 1977 & Roberts & Vernon, 1982). It is well known that men have higher rates than women for suicide and alcoholism both of which are also well known to be associated with depression. Moreover, family studies of alcoholic men have shown that their non-drinking sisters have a higher than expected incidence of depressive illness (Winokur *et al*, 1971). Thus it may be wrong to identify women as being especially 'at risk' from depression if men express it in different ways (e.g. through violence or substance abuse, so earning an inappropriate label of 'personality dis-order'). In the light of the link between illness behaviour, alcoholism, and depression in men it is worth noting that a recent general population (Robins *et al*, 1984) and primary care (Casey *et al*, 1984) study both reported the usual excess of depression amongst women and alcoholism and personality disorder amongst men but found that the prevalence of *total* psychiatric disorder was the same in both sexes.

Age

Depressive illness has been traditionally thought of as a disorder of middle age and onwards, a concept supported by Dunn & Skuse (1981) who examined patient case-records from a single practice for a 20-year period. They found that women became progressively more prone to depression (or consult for it) as they grew older. However, this positive association between depression and older age may be complicated by other factors such as course and outcome: Dunn & Skuse showed that women were less likely than men to recover once depressed—and so more likely to have chronic disorders. The 'gathering' effect of those with chronic disorders will tend therefore to favour older depressives in cross-sectional studies in which chronicity is not controlled for. Not all primary care studies, however, support the idea of the predominantly older depressive. Mazer (1967) in a five-practice study in Massachusetts, noted that the peak age group for women complaining of disorders which were predominantly 'psychoneurotic' or affective in nature, was 25–34 years. (Men 'peaked' about a decade later). So marked was this finding that 12% of the women in this age range had consulted their GP with a psychiatric complaint at some point during the 3 months of the study. Thereafter the prevalence rates by age fell off rapidly suggesting either that many of these disorders do not persist or that these patients become disillusioned and cease seeking help from the GPs. Other primary care studies also support Mazer's findings showing that younger adults seem to be especially at risk from depression (Porter, 1970; Berndt *et al*, 1983 & Sireling *et al*, 1985*a*). Of course illness-behaviour must be acknowledged since older patients may be reluctant to disclose that they are depressed. Weissman *et al* (1981), in a general population study of depressive disorder, found that younger patients were three times more likely than older age-groups to consult a GP when depressed. Nevertheless illness-behaviour is unlikely to be the only factor behind this association between depression and younger age in primary care. Several studies record that younger adults have more depressive symptoms and symptoms of a greater intensity than older groups e.g. Craig & Van Natta (1979). Recent and reliable general population studies also show that it is predominantly younger adults who are now developing the major depressions. All three sites in the massive NIMH study in the USA (Robins *et al*, 1984) obtained the same unexpected finding that lifetime prevalence rates for major depressive disorder was significantly greater in the younger as opposed to the older respondents. The peak age-group in this case was 25–44. The conclusion from these findings is that younger adults now seem especially likely to develop major depression, and more likely to consult a GP when they do so. On the other hand they are also more likely to recover once depressed than older patients and less likely to experience further episodes over the following decades. The significance could be that depression is a phenomenon which is on the increase, or that general population and primary care studies are now 'unearthing' a previously unknown phenomenon of depression in the young. Older patients who have chronic or recurrent depressions and who are selectively referred to psychiatrists may represent a later, second, prevalence-peak.

Social class and socioeconomic status

These often reflect the characteristics of the practices studied and it is not surprising that studies of psychiatric disorder in different primary care settings are in disagreement as to whether certain classes of patient are more prone to depression than others. Nevertheless several primary care studies are in agreement that patients from lower socioeconomic classes appear to be especially 'at risk' of depression. Wright *et al* (1980) found that the single most important predictor of score on a self report depression questionnaire was socioeconomic status: the higher the status or educational attainment the less likely it was that the person would rate themselves as depressed. This finding was confirmed by Hesbacher *et al* (1975) and Nielsen & Williams (1980) both of whom took the precaution of controlling for other social variables first. Of course studies such as these may be picking up variations between the classes in terms of response-set, not actual depression. Class is a very complex variable and previous efforts to study class in relation to populations which include housewives and the increasing numbers of unemployed or never-employed suffer from the usual difficulties of definition. More detailed and sophisticated analyses of individual variables which are linked with class (such as income, the use of leisure time, and social networks) are now required.

Civil status

Primary care studies reporting associations between civil status and depression are wildly contradictory and no conclusions can be drawn. Thus Porter (1970) found that single women were almost entirely spared from depression whilst married ones were particularly at risk. Berndt *et al* (1983), conversely, found that the highest scores on the Beck Depression Inventory were obtained from the single, divorced, and widowed whilst the never-married had the lowest scores of all. Nielsen & Williams (1980) showed, predictably, that any severing of marital ties was associated with higher depression scores on the BDI, whilst Craig & Van Natta (1979) found that the never-married had the highest rate of depressive symptoms and the married, the lowest.

Civil status, social support, social stresses, life difficulties and life events are all important topics in depression but few or none of the studies of depression in primary care have examined them. They thus fall outside of the scope of this article and readers are referred to the recent reviews by Jenkins & Shepherd (1983) and Paykel *et al* (1984) in which such topics receive extensive coverage. Therefore, we turn now from issues of caseness, prevalence, severity, (i.e. what general practice depression is like) to consider those which directly concern the GP-patient axis; in particular the decision to consult, presenting symptoms, diagnosis by GP, and treatment.

The decision to consult

General population studies show that the majority of people who develop depressive disorders seek help from a GP. Although the situation is somewhat different in the USA where one may bypass the GP and contact a mental health professional directly, Weissman and Myers (1978) still found that 85% of community respondents had in fact turned to their

GP for help. In the UK, 68% of Brown & Harris' (1978) sample of depressed women and 88% of Wing *et al*'s (1981) community sample had sought help from their GP in the previous year. Confirmatory evidence of this help-seeking behaviour in connection with primary care is shown by Widmer & Cadoret (1978) who found that consultation frequencies increased as patients developed depression.

Severity of depression is one factor in leading to a decision to consult. Weissman & Myers (1978) found that the more severely depressed a person was as measured by their score on a self-report questionnaire, the more likely they were to have sought help, and measures of depression and anxiety, found that severity of symptoms or emotional distress gave the best discrimination between patients who had or had not consulted their GP. Only 9% of the non-consulting depressed were as severely depressed as 70% of those who had consulted the GP. In addition those who were classified as 'ill' as well as being emotionally distressed were significantly more likely to have gone to the GP although they claimed that the overlap was small and of little practical significance. The authors posited a link between major life events, a tendency to greater severity of psychological symptoms, and likelihood of consulting a GP.

Not all those who suffer from depression will necessarily choose to consult their GP for help, particularly if the GP in question has been found to be unhelpful in the past. In particular, as already discussed, men and those in older age groups seem to be less inclined to consult a GP when depressed—whether or not out of stoicism is not clear. The importance of the findings with regard to decision to consult is that the burden for delivering care to the majority of society's depressed falls to the GP. It remains to be seen how such patients present and how they might be recognised.

Physical symptoms and the presentation of depressive disorder

Depressed people may consult their GP in one of two ways: either complaining of depression or presenting with other complaints which are more physical in nature. It is frequently reported that general practice depressives are especially likely to present with complaints which are partly or wholly somatic in nature. Watts (1970), reporting on a large series of 773 depressed primary care patients, showed that only "a small number" presented with symptoms that were "clearly depressive in type". The ten symptoms most commonly presented were:

1. tiredness, shortage of energy, feelings of being weak and run-down
2. headache
3. anxiety or tension
4. depressed mood
5. backache
6. insomnia
7. pains in the chest
8. dyspepsia
9. giddiness
10. pains in the trunk, arms and legs.

It is interesting to note that pain was responsible for 35% of the presenting symptoms. Nevertheless, some of these complaints (namely 1, 3, 4, and 6) might be legitimately regarded as part of the depressive syndrome thereby reducing the force of Watts' conclusions. Such somatic symptoms may of course originate from several sources. They might be vegetative symptoms belonging to the depressive syndrome, part of the psychological 'vocabulary' of patients who habitually somatise their feelings, psychogenically determined hypochondriacal symptoms such as 'pain', or the exacerbation of actual physical illness by underlying depression. Examination of the literature shows that the problem in presentation of depression seems not to be that depressive features are absent, or that these disorders are true 'masked depressions', but that the key symptoms are obscured by a great deal of somatic 'noise'.

Thus Goldberg & Blackwell (1970) found that only 7.8% of predominantly affective disorders presented with symptoms which were entirely psychological in nature whilst the majority had a combination of psychological and somatic symptoms. Likewise Widmer & Cadoret (1978) demonstrated that 26% of primary care depressives had somatic symptoms which featured prominently in their presentation (only 9% had purely physical complaints). Widmer divided these somatic complaints into:

1. ill-defined 'functional' complaints
2. pain of undetermined aetiology in a wide variety of sites
3. 'nervous complaints' including mainly tension and feelings of anxiety.

Nevertheless, two-thirds of Widmers' sample of 154 depressives presented non-somatically.

'Caseness' and severity in the context of presentation of depression is likely to be very important but is seldom, or never, properly defined. In addition, there is lack of rigorous care of the definition of what is a 'presenting symptom'—whether it is the first complaint uttered by the patient, the main 'theme' of the consultation, or the complaint which the GP or the investigator considers to be the most important. The definitive study on depression in this setting has yet to be done, although at least three separate studies are now underway and should be appearing in due course. The conclusion to date is, that although a proportion of depressed persons in primary care present somatically, this does not justify an assumption that many do. Experience teaches that the majority of general practice patients with depressive disorders can be quite easily identified providing the usual clinical enquiries about both cognitive and physiological components of the syndrome are made. There is nothing mysterious about general practice depression in this context. The difficulties more often arise when the various symptoms which go to make up a diagnosis of depression are also shared by physical illnesses of one sort or another.

Depression and physical illness

The relationship between depression and physical illness is well established. Not only do chronic, painful, disfiguring or incapacitating illnesses induce low spirits in people who have them, but certain illnesses are also known to be powerful depressors of mood in their own right, most notably the endocrine, metabolic, infective, and neoplastic diseases. Not surprisingly, since a large number of people who go to GPs are suffering from physical disorders, the association between physical and depressive illness in primary care, as on a medical ward, is a frequent and strong one. Nielsen & Williams (1980) reported that 46% of medically ill primary care patients scored over 13 on the Beck Depression Inventory compared to only 9% of those without such illnesses. Wright *et al* (1980), too, found that the risk of depression was increased for GP patients who had co-existing medical illness. However, Sireling *et al* (1985*b*) found, contrary to expectation, that only 36% of their GP depressives had physical illnesses and in only 20% was this judged to be related to the mood disturbance. A converse association between depression and physical illness may be due to the increased vulnerability to physical illness that psychiatric disorder exposes people to. Many psychiatrically ill patients have low incomes, poor diets and hygiene, poor housing, and are obliged to live in crowded hostels where transmittable illnesses are sometimes rife. Shepherd *et al* (1966) showed that psychiatric patients, especially those with chronic conditions, tended to have more general physical morbidity than other primary care consulters. A 'significant associated medical factor' was found in 44% of those with psychotic and 23% of those with neurotic illnesses. In addition some people appear to be specially susceptible to both physical and psychiatric illness. This hypothesis was tested by Eastwood & Trevelyan (1972) who made careful independent assessments of both psychiatric and physical illness in primary care patients using objective data including laboratory investigations. Of those with psychiatric disorders, 17% were also found to have physical disorders (often unknown to the patient) compared with only 2.4% of the non-psychiatrically ill control group. They concluded that both types of disorder tended to 'cluster' in some individuals. In such cases the psychiatric disorder tended to be chronic and to precede the onset of the physical disorder. The older the patient, the greater this tendency was found to be. However, this association between depressive and physical morbidity may not be a direct aetiological one:

(1) Neurotic or depressed patients consult more frequently than non-depressed and have a low threshold for reporting physical complaints when they do, thereby making this association more apparent than real.
(2) There may be third common factors such as age. As has been already discussed, prevalence rates for chronic and recurrent depressive disorder rise with increasing age as do rates for physical morbidity; thus the association between the two could be due to chance.
(3) Another explanation may be that the presence of physical illness may delay recovery from psychiatric disorder. This is supported by Mann *et al* (1981) who found that primary care neurotic patients, still disturbed at follow-up 1 year after entry, were more likely to be suffering from physical illnesses than those who had recovered. From the epidemiologists point of view the importance of this finding is that patients who have both types of illness will tend to be over-represented in samples of consulting patients.

In cases in which symptoms are shared between depression and physical illness and distinguishing between them proves difficult, other, non-core syndromal, symptoms such as anxiety or a previous psychiatric history of depression assume greater importance. However, even with the best of intentions, some patients will defy confident diagnostic allocation and will ultimately require a trial of treatment.

Non-detection of Depressive Disorder by the GP

It has been amply demonstrated in a number of studies that GPs fail to detect between 33% and 50% of cases of psychiatric disorder presenting to them. The same rates for non-detection apply too to depressive disorder as shown by Bebbington (1978); Houpt *et al* (1979); Hoeper *et al* (1980); Nielsen & Williams (1980); Hankin & Locke (1983) and Zung *et al* (1983). One might expect the effect of co-existing physical illness on GPs' case-recognition abilities to be a powerful one and Freeling *et al* (1985) noted that major depressives missed by their GP were more likely to be suffering from physical illnesses to which the depression seemed to be related. Other investigators have concentrated more on the sociodemographic characteristics of unrecognised patients. Hankin & Locke (1983) and Hoeper *et al* (1984) in the USA, Marks *et al* (1979) in the UK, and Chancellor *et al* (1977) in Australia all confirm that GPs tend to under-diagnose psychiatric disorder in males, the young and old, those with higher education, and those who are unmarried. Conversely, females, those from the lower socioeconomic classes, and who are separated, divorced or widowed (and unemployed), are more likely to be correctly identified by the GP when psychiatrically ill. (Probably because of small sample size, Freeling *et al* (1985) failed to demonstrate any sociodemographic differences between recognised (10) and unrecognised (14) patients with depressive disorder). It is likely that the influence that such sociodemographic variables play in affecting case-recognition is mediated through the GPs' notions about what constitutes a 'typical' case which is itself dependent upon previous experience with large numbers of young depressed women. The reasons for GPs failure to recognise cases of psychiatric disorder have been discussed at length by Goldberg and Huxley (1980) who divide them into 'patient factors' (chief of which is the tendency to 'somatise' psychological symptoms (see above)), and 'GP factors' (which include diagnostic 'bias' and 'accuracy'). However, a third source of non-recognition of disorder which is seldom alluded to, concerns the nature of the primary care system itself. The approach to diagnosis and management of patients in primary care is radically different from that in hospital-based settings. The average duration of a consultation in primary care is about 7 minutes, during which time the GP must select which aspects of the patients complaints he regards as important. Primary complaints may have to be pursued at the expense of secondary or tertiary complaints. In addition, GPs often spread diagnostic decisions over several consultations and defer making a firm diagnosis (especially when evidence is uncertain) until a patient has presented with the same symptoms on several occasions. This pragmatic policy probably derives from GPs' previous experiences with large numbers of psychological disturbances which are essentially short-lived and self-limiting. Evidence for the effect of the consultative process upon case-detection, however, is provided by studies showing that GPs are more likely to pick up cases of psychiatric disorder that are chronic, already known to them, or in which the patient is a frequent consulter (Shepherd *et al*, 1966; Locke *et al* 1966; Marks *et al*, 1979; Hankin & Locke, 1983). Thus studies yielding high rates of hidden psychiatric morbidity in which the diagnostic efficiency of GPs are examined on the basis of a *single* index consultation, may not do justice to GPs. A more accurate measure of 'hidden' psychiatric morbidity might therefore be obtained if investigators took *serial* patient consultations and then examined the diagnostic efficiency of GPs at the end of a defined number (e.g. three). It is also important, because of the way GPs proceed to diagnosis, to allow them a degree of flexibility in their response to case-recognition since GPs may fail to award a specific diagnostic label but will often record a psychological observation (if asked) which indicates that they are not completely unaware of patients' mental states. In a WHO collaborative study, Gastpar *et al* (1981) found that GPs had little difficulty in differentiating between depressed and psychologically normal patients but differentiation between depressed patients and those with other psychiatric disorder proved more difficult. Thus, in many studies, failure to recognise a disorder may be confused with failure to award a specific label. As was shown to the case in the decision to consult, there appears to be a relationship between syndrome-severity and the likelihood of a case being detected and correctly identified by the GP. Hankin & Locke (1983) reported that the mean depression score of a group of GP-identified depressives as measured by a self-report questionnaire (the CES-D) was significantly higher than for the non-identified depressives. As part of Sireling's study (see above) Freeling *et al* (1985) found that their small sample of 24 major depressives who were 'missed' by the GPs were 'less obviously depressed' and less likely to complain of depression. They were also more likely to have feelings other than normal sadness, and to report mood changes which were responsive to external cues. Although patient factors are not unimportant, case-recognition is still largely dependent upon the clinical vigilance on the part of the GPs. In the light of this the study by Goldberg *et al* (1980), showing that GPs case-recognition can be improved by giving extra tuition in interviewing skills, has direct relevance.

Treatment of depression in primary care

Watts (1966) suggested that a motivated GP should be able to treat '90%' of his depressed patients at home, emphasising that this was not only less costly than specialist care but far better for the patient since it maintained important ties with the family and community. For the vast majority of persons in the community who, develop depressive disorder 'treatment' will continue to come in the form of interventions from their GP since only a small proportion of those who consult their GP are ever referred to psychiatric services (a situation which is unlikely to change in the future). The treatment options available to the GP fall, broadly speaking, into three groups: psychotropic medication, some form of psychotherapeutic or social intervention, and referral to psychiatric services. The first two alternatives tend to be envisaged at present on an 'either/or' rather than an 'either/and' basis which probably diminishes their overall efficacy. However, for many depressed patients consulting their GP, the decision to treat will often end in a prescription of psychotropic medication. General Practitioners have been criticised in the past for using antidepressants and anxiolytics in an inappropriate and cavalier manner (Weissmann & Klerman, 1977; Weissman *et al*, 1981) and in doses which are low or which psychiatrists consider to be 'subtherapeutic' (Johnson, 1974). Some of this may be excused on the grounds that differentiation between kind and degree of emotional disorder in this setting can be difficult. GPs often base their management decisions on the strength of the primary presenting symptoms rather than the patients membership of a particular diagnostic group. That this affects choice of treatment was demonstrated by Downing & Rickels (1974) who showed that GPs tended to prescribe, in situations of mixed symptoms, according to the predominance of anxiety or depressive symptoms. 'Mixed' cases in which both symptoms featured equally, tended to come off badly in terms of obtaining appropriate treatment, and this was particularly so when a stressful social origin to the depression could also be identified. Sireling and his colleagues (1985*a*) reported that the more severe and less reactive the depressions were, the more likely it was that the GPs would prescribe antidepressants. The degree of stress did not appear to influence the GPs' decisions to prescribe antidepressants although, interestingly, the presence of sleep disturbance did, which suggests that the antidepressants were being prescribed either for their sedative effects or that complaints of sleep disturbance are an effective alerting signal to the GP of the presence of more serious depression. That GPs are not the only non-psychiatrist clinicians who have difficulty in allocating appropriate treatment to patients with depression is shown by Raft *et al* (1975). Studying hospital physicians, they noted that the presence of hopelessness, loss of interest, or the 'physiological' symptoms of depression tended not to alert the physician that the patient was depressed unless they were also accompanied by visible sadness. The doctors in this study justified their decision to prescribe minor tranquillisers on the basis that the patient appeared 'nervous' or had 'anxiety', a similar finding to that of Clare & Williams (1981) who also found that, where anxiety was judged to be the main complaint by the GP, an anxiolytic was almost invariably prescribed. In the light of studies reporting low rates for antidepressant prescribing in general practice one must acknowledge that GPs are sometimes inhibited by the knowledge that a previous prescription of antidepressants (and referral to a psychiatrist) must be declared on life insurance forms and that patients' premiums are raised as a result.

What about efficacy of antidepressant treatment in general practice? Well, despite that fact that Goldberg & Blackwell (1970) report generally good responses to treatment, trials of antidepressants in primary care are rare and very little is known about the efficacy of standard interventions in standard disorders in that setting. Thompson *et al* (1982) includes a brief review of the few treatment trials there have been in this setting and shows that the majority are flawed for one reason or another. Her own study, however, demonstrated the clear efficacy of tricyclics (amitriptyline) on her general practice depressives. One problem which continues to afflict antidepressant treatment in general practice and probably militates against its wider and more effective use are the patients' low compliance rates. Thompson found that 20% of her patients stopped taking the prescribed antidepressants after only 3 weeks, the main reasons for which seemed to be (1) the presence of unwelcome side-effects, (2) worsening of depressive symptoms, or (3) early recovery. Johnson (1981) found that 60% of his series of treated depressed patients also dropped out after 3 weeks for much the same reasons. Other sources of non-compliance were the GPs failure to warn patients about the delay in therapeutic response, the possibility of side-effects, and the need to continue taking the medication regularly. Patient attitudes also affect compliance: Johnson found that patients who believed that their impressions were responses to identifiable life stresses regarded medication as an unsuitable choice of treatment. Other patients feared becoming dependent on medication, a fear which has only been fuelled by recent media coverage on the benzodiazepines. It is therefore probable that a considerable part of the failure of treatment-efficacy with antidepressants in general practice is due to basic failures of understanding and communication between doctor and patient. This is not to assume that all or even many cases of depression seen in general practice require physical forms of intervention. There are moral objections to patients being prescribed psychotropic medication as an alternative to more appropriate (but also more time-consuming) psychotherapeutic or social measures. Lader (1975) criticises the use of medication in situations of stress-related disorder in that they inhibit the patient's own efforts to organise themselves and meet the stresses. However, this argument cuts both ways. It is just as possible that some depressed patients recover, not because of any direct pharmacological activity of medication, but because the benefits in sleep improvement or lowered anxiety, which such medication indirectly affords, enables them to make better use of their other resources. In such situations low-dose antidepressant or anxiolytic or hypnotic medication may be more 'effective' than is generally believed. Medication aside, many depressed patients who attend their GP receive some form of simple counselling and advice (Shepherd *et al*, 1966). The power and efficacy of such interventions must not be dismissed even though GPs have received no formal training in their use. Formal psychotherapy requiring specialist training is probably prohibitively time-consuming for most GPs even though shortened forms, specifically designed for primary care (such as the '20-minute hour'), have been advocated. Balint's views on the 'massive need for psychotherapy' in this context and the therapeutic usefulness of the doctor–patient relationship are well known. However, these ideas have received criticism from some quarters. Sowerby (1977) argues that much of general practice is concerned with problems for which formal psychotherapy is quite unnecessary and that simple advice and reassurance is probably all that is necessary for such patients. However, this view is in danger of running to the opposite extreme. We seriously doubt whether many primary care patients with depressive disorder will derive much lasting benefit from "simple advice and reassurance" alone. With this in mind it is valuable to note the study into the efficacy of social work intervention in depressed women by Corney (1984). In this controlled and randomised primary care trial Corney was unable to demonstrate any preferential benefit in terms of outcome at 6 months for patients allocated to a social worker. A small group of women with acute chronic depressions and marital difficulties did appear to derive some benefit but the overall effect was disappointing and found to be strongly related to the patients motivation and the amount of purely practical assistance they received. Cognitive therapy, although still in the process of being evaluated as a treatment for depression, may turn out to be a useful tool for GPs especially as the skills required to conduct it are relatively easily acquired. Critics remark that it is still too time-consuming for most GPs. Although Teasdale *et al* (1984) make favourable reports about the efficacy of a combination of cognitive therapy and antidepressants, instead of drugs alone, in the treatment of primary care major depression, the actual amount of therapist attention such patients received was of the order of 15 hours. (In addition, the reported gain over the drugs-only group was lost, with three out of 12 patients suggesting that the benefits from cognitive therapy were mainly short-term.) If GPs lack the time to conduct the essential non-drug therapies for depression then who should conduct them? A number of suggestions have been made, and one enjoying a current vogue is the direct deployment of visiting psychiatrists in primary care. The arguments for and against this are reviewed by Mitchell (1985) although the use of trained psychiatrists (outside of an educative and supervisory role) may not be an entirely efficient use of resources. Other sources of psychiatric care in this setting including community psychiatric nurses, psychologists, psychiatric trainees, and psychiatric social workers, have all been suggested although the arguments relating to the appropriate use of scarce resources remain. It is possible that with the burgeoning of the voluntary organisations geared towards counselling and group therapy, the use of non-NHS counsellors and other psychotherapists, providing a service for which the busy GP does not have sufficient time, may become an increasing feature of general practice in the future. It is important, however, for such organisations to define what it is they are trying to deliver and to whom, and to be prepared to be flexible in their clinical approach and relations with statutory services. For the time being we conclude that considerably more could be achieved within the existing system for the many patients in primary care who are suffering from major depressive disorder and for whom antidepressants would be an appropriate course of management. Such patients have most claim on our concern because their need is greater, their disorders are more severe, and because simple psychosocial manoeuvres will be less effective. The improved deployment of standard courses of antidepressants by GPs would, we believe, go a long way towards relieving the misery of a great many patients in this setting.

Course and outcome of depressive disorder in primary care

Studies of psychiatric disorder in primary care have reported that approximately 50% of those cases identified at a single screening exercise have been ill for at least a year, i.e. 'chronic' (Shepherd *et al*, 1966; Kedward & Cooper, 1969; Wing *et al*, 1978, 1981). The problem facing the interpretation of such claims is the lack of specification of the disorders so included in the analysis. Psychotic disorders, personality disorders, and many phobic disorders are generally chronic, whilst the very much more common forms of affective adjustment disorder or situational disturbance are generally short-lived. Accordingly the proportion of acute to chronic disorders reported in such studies will depend greatly upon the composition of the sample. The choice of sampling frame, too, is important since, as discussed before, it affects the ratio of acute to chronic cases. The bulk of the 80% chronicity identified from Hoeper's sample (Regier *et al* (1985) over the course of 3 months was accounted for by personality, psychotic, and anxiety disorders, not depressive disorder. In their sample of 207 consecutive cases of depressive disorder Johnson & Mellor (1977) obtained a ratio of chronic to acute cases of 2.5 to 1. In terms of course and outcome, non-primary care follow-up studies of depressive illness demonstrate that about 15% of acute episodes go into partial remission or remain chronic (Robins & Guze, 1972; Paykel *et al*, 1974; Weissman & Klerman, 1977). Thus, with time, there will be a 'gathering' effect of older, chronic, patients who, because of their higher consultation frequences, will 'haunt' general practice. One might expect depression outside of specialist settings to run a different course but retrospective studies based on the examination of GP case-records have their weaknesses and cannot be entirely relied on. Watts (1970) reported that 21% of a selected sample of 93 'endogenous depressives' had, over 22 years, become chronic and were resistant to treatment. A further 30% had died although one-third of these had recovered by the time of their death. It must be recalled that all these patients had at one time been in-patients, and many had been ill before antidepressant medication had become available. Dunn & Skuse (1981), reporting on a 10-year case-record follow-up of neurotic patients, found that one in six women and one in 20 men with depressive neurosis had developed truly chronic illnesses, the women being especially at risk from this. Cooper (1972) invited eight GPs to identify patients who, in the course of one month, presented to them with chronic psychiatric illnesses. Of the cases so selected, 42% were diagnosed (by the GPs) as having 'depressive neurosis'. One of the few prospective outcome studies of depression in general practice is that of Johnson & Mellor (1977). Of 119 newly diagnosed patients with depressive disorder, 69% were recovered after 4 months and a further 10% much improved, thereby confirming the report of Goldberg & Blackwell (1970) and others that affective illness in general practice has, on the whole, rather a good prognosis. The group of 88 patients in Johnson & Mellor's study who had already been receiving treatment for depression from their GP at entry, and who tended to have had their depression for longer, had fared less well since 44% of them were still unable to resume their normal lifestyle at 4 months. The authors suggest that a small proportion of new cases of depression in general practice eventually become chronic (as shown by non-primary care studies) and are often quite seriously handicapped as a result. Recognition by, and treatment from, the GP must surely play a part in affecting outcome although it is hard to interpret findings which suggest that they do since both factors may be dependent on other variables which exert their own effects upon outcome. Freeling *et al* (1985) reported that although only a few of the GP-recognised depressives had completed even a minimal course of antidepressants, they had all fared better at three months' follow-up than the unrecognised group. However, the identified depressives differed from the non-identified in having had shorter illnesses at the time of diagnosis so that other factors probably play a part too. Johnstone & Goldberg (1976) overcame this difficulty by randomly allocating patients who were suffering predominantly from affective disorder and who had been 'missed' by their GPs to one of two treatment groups. In one group patients were 'notified' to the GP and in the other group the patients diagnostic status was kept concealed. The 'notified' cases did significantly better in the short term and at 1-year follow-up although the differences became less marked as time went by, suggesting that the main benefits from notification (i.e. GP-recognition and treatment) appeared to be in the short term. The differences in outcome between the groups was less pronounced in those patients with milder disorders presumably due to the effects of spontaneous resolution. Chronicity of depression in primary care may therefore be something to do with non-detection (and therefore non-treatment) of existing cases by GPs but it must be recognised that even under the best conditions a small proportion of new cases will fail to recover and run a chronic course. The reasons for this are unclear but may be due to continuing psychosocial stresses or fewer personal resources in the patients who do. There is evidence to suggest that social factors do play a part in affecting the course and outcome of minor psychiatric illness in primary care. In a prospective study, Mann *et al* (1981) found that 22% of patients pursued a variable intermittent course during the follow-up year, whilst 23% failed to recover at all. Here, the major predictive factor of outcome was the overall severity of disorder at the outset but the presence of social stresses, and the perceived quality of social life (in particular family and marital life) turned out to be further discriminating factors.

As regards the course of depressive illness in primary care, 100% of the women but only one-third of the men in Watts (1970) series of ex in-patients had experienced a further episode of depression which required in-patient treatment suggesting that (as shown Dunn & Skuse 1981) women were especially vulnerable to depression and/or further attacks of the same and less likely to make a full and lasting recovery once identified as depressed. Only 20% of Watts's depressed patients had had a single attack of depression in the whole 22 years. Porter (1970) found that 34% of his 93 patients with 'depressive illness' had a further recurrence within only a year of diagnosis. However, Widmer & Cadoret (1978), examining case-records for 154 patients suffering from depression between 1948 and 1971 (mean follow-up period of 6 years), found that 65% of them had been recorded as having only had a single episode of depression, 26% two episodes, and 9% three or more. The median episode length of these depressions was 4 months and only 13% had suffered episodes lasting longer than 2 years. It is clear from the great variation between these studies that the characteristic course and outcome of primary care depressions is not known, some authors claiming how transient and self-limiting they are whilst others point to their chronicity and resistance to treatment. The severity of disorder, composition of the group followed up, and the length of follow-up are all crucial to the interpretation of such findings. Several new follow-up studies of course and outcome of depression in primary care (including our own) are now underway and will be published in due course.

Conclusion

After Adjustment disorder, Depressive disorder is the commonest formal psychiatric disorder in primary care constituting some 8–10% of consecutive-patient consultations. The findings of recent studies suggest that the traditional notion that general practice depression is a mild, self-limiting—and therefore clinically unimportant—condition, is largely mistaken. The bulk of depressed patients presenting to GPs are young and/or female but related social stresses are ubiquitous and do not appear to distinguish between types or degree of associated depressive response. The problems of 'caseness' and their relation to detection of disorder by the GP are such that, although 90% of persons suffering from depression remain within the primary care sector and never enter psychiatric services, a sizeable proportion of them remain undiagnosed and/or inadequately treated. The prognosis is ultimately a good one for many such patients but this failure of service-provision has important consequences for the patient and his/her family in the meantime. Moreover, this has consequences for the GP in that untreated depressed patients impose an increased burden upon primary care services. The size of this unmet morbidity has important implications for the future development of psychiatric services too. The problems of presentation and 'caseness', syndrome severity and profile, relationship to physical illness, and the efficacy of standard psychiatric interventions in primary-care depression all require further study.

Review Article

The Neuroleptic Malignant Syndrome, So-called

A Survey of the World Literature

A. M. P. KELLAM

Because of its rarity, the neuroleptic malignant syndrome has been studied in a survey of the world literature. Similar conditions which occurred before the advent of neuroleptics have also been included, as they may indicate that the drugs are not totally to blame. It is also apparent that with modern treatments, the condition is not usually lethal. The implications of this for theories of dopaminergic disturbances underlying the mental illnesses involved are considered. An overall picture of the syndrome, its treatment and outcome, is presented from over 200 published references. The spread of recognition of the condition throughout the world and especially across linguistic barriers has been followed.

The neuroleptic malignant syndrome (NMS) is generally agreed to consist of, first, a diffuse rigidity of the muscles often with extrapyramidal signs such as cogwheeling or more rarely with the waxy flexibility of catatonia. Secondly, there is an alteration of consciousness towards either stupor (with negativism) or coma (with confusion). Thirdly, there is a neurovegatitive dysfunction, of which the first and most prominent feature is a sudden pyrexia accompanied by sweating, tachycardia, and sudden falls in blood pressure. Other clinical features are reported (e.g. dyspnoea) but seem to occur more irregularly and, in many cases, may well be secondary. There is often a leucocytosis and the serum creatinine phosphokinase (CPK) is characteristically elevated. I have adopted a pyrexia of more than 37.5°C, and an abnormality of movement, preferably either parkinsonian or catatonic, as the criteria for inclusion as a case of NMS.

The neuroleptic malignant syndrome closely resembles advanced catatonia. Similar syndromes of unexplained fulminating hyperpyrexia, usually described in the setting of catatonia have been regularly described since the beginning of the nineteenth century, especially in the French psychiatric literature as "délire aigué" or "foudroyant, ('acute' or 'fulminating psychosis' are approximate translations) (Fodéré, 1817; Calmeil, 1832). Bell (1849) first described the syndrome in English as "Bell's Mania". Ladame (1919) used these terms to describe essentially similar cases, as did Claude & Cuel (1927). The second of their three cases was described as showing "Hypertonie" (hypertonia), in the setting of a manic episode which ended in a fatal hyperpyrexia. This is the first description of a neuromuscular abnormality in the condition and shows it occurred long before the introduction of neuroleptic drugs. Stauder (1934) described "Tödliche Katatonie" (acute lethal catatonia) as a syndrome marked by hyperpyrexia and catatonia with excitement or stupor and waxy flexibility. The cases usually ended fatally and, as in Claude & Cuel's cases post-mortem changes, if any, were minimal.

The syndrome gained widespread acceptance on the continent, but tended to be denied in the UK. Mayer-Gross *et al* in their influential textbook (2nd ed. 1960) wrote "Sudden death in acute catatonia has drawn the attention of workers hoping to find lesions indicating an underlying metabolic dysfunction. Critical examination of the post-mortem findings in such cases demonstrated as the immediate cause of death a concurrent somatic illness which could not be clinically diagnosed because of the patients' abnormal behaviour." More recently Levinson & Simpson (1986) stated "The cases of extrapyramidal symptoms with fever are too heterogenous to justify the assumption of a unitary and 'malignant' syndrome". They assembled 39 reported cases and after excluding those with medical problems concluded that in only 14 were "no medical causes of fever identified."

Mahendra (1981) even argued that catatonia may always in reality have been an organic psychosis not especially related to schizophrenia, and that this is why catatonia started to disappear in the 1930s well before the advent of neuroleptic drugs. Against this, photographs of catatonic posturing continued to appear in the standard English Textbooks well into the 1950s. There were 17 cases of fairly classical catatonic schizophrenia showing waxy flexibility and partial or complete akinesia and mutism out of 43 patients with stupor in my study between 1967 and 1970 (Kellam, 1970).

More recently, Tolsma (1967) described similar cases as "acute pernicious psychosis" and urged the importance of early diagnosis and treatment with ECT. Gabris & Muller (1983) under the title "La Catatonia dite pernicieuse" (translated as 'The so-called lethal catatonia') examined the records of 1690 patients admitted to the Hôpital de Céry in Lausanne between 1961 and 1981. They identified 270 as having catatonia. Of the 72 patients who had died, 24 were in the catatonic group, and they were especially over-represented in the cases where death had occurred before the age of 50. In one surviving case it appeared that NMS had preceeded the administration of any neuroleptics which here proved beneficial. Mann *et al* (1986), have reported 292 cases of 'lethal catatonia' from the literature since 1960. They conclude that it is a syndrome which may develop in association with both functional and organic illnesses, and that "NMS may be considered a neuroleptic-induced iatrogenic form of lethal catatonia". In all cases hyperpyrexia appears to be the life-threatening problem and usually the ultimate cause of death, unless bronchopneumonia or some other terminal complication supervenes.

It seems probable that a catatonic syndrome has been regularly recorded in schizophrenia since well before the condition was delineated. Certainly, catatonia can occur as a result of numerous other causes, the next most frequent probably being various organic states. The syndrome, however, occurred sufficiently frequently in schizophrenia for it to give its name to a subtype of that diagnostic grouping. In schizophrenic patients at least, this syndrome may rarely take on a fulminating course leading to a potentially fatal hyperpyrexia, which seems clinically indistinguishable from NMS as it is now described, except for the absence of parkinsonian features. The resemblance of these catatonic conditions to NMS is especially striking if the possibility is accepted that the extrapyramidal signs of NMS could be due to the neuroleptic drugs now almost universally involved. This raises the question as to whether catatonia may itself sometimes become a life-threatening condition, and whether in some current cases of apparent NMS, neuroleptics are not pathogenic.

If the syndrome seen in catatonic schizophrenia, other catatonias and the NMS are indeed the same, then it would seem probable that all of them can be produced by a sudden disturbance in the dopaminergic systems of the brain. From this it would follow that alterations in dopaminergic functioning probably occur in this form of schizophrenia, and may well be of quite fundamental importance in its pathogenesis.

In addition to occurring without the involvement of neuroleptics, the NMS can also clearly occur in conditions which are definitely not schizophrenic nor even psychotic, when there is exposure to neuroleptics. Examples of the former group, psychotic but not schizophrenic; are mania, (Goekoop & Carbatt, 1982); hypomania, (Town, 1982); depression (Sumiyoshi *et al*, 1983), two cases; bipolar affective illness (Smith & Carter, 1984); and manic depressive psychosis (Spring & Frankel, 1981; Singh, 1981) three cases. Examples of the latter non-psychotic group: include character disorder, (Bourgeois *et al*, 1971); psychopathy, (Dumont *et al*, 1978); acute grief reaction, (Kaskey & Nasr, 1979); and heroin addiction, (Bleichner *et al*, 1981), all conditions which have never been associated with catatonia. Two cases even occurred in well patients given neuroleptics as pre-operative medication, (Moyes, 1973) and (Konikoff *et al*, 1984).

Some cases not involving neuroleptic drugs occurred in organic states, Huntington's Chorea, (Burke *et al*, 1981); and Parkinson's disease, (Toru *et al*, 1981) and (Fujitake *et al*, 1984), but only when dopamine agonists which were used to treat parkinsonian symptoms were stopped abruptly. In addition Fujitake *et al* (1984) reported eight cases, Toru *et al* (1981) two, and Sechi *et al* (1984) one case of NMS following the abrupt cessation of L-DOPA with, in some cases, the abrupt cessation of amantadine. It has also been recorded as being caused by several other drugs or drug combinations which lower the activity of the dopaminergic receptors. For example Ritchie (1983) reported a case following an overdose of dothiepin and phenelzine; Eiser *et al* (1982) a case involving amitritypline and thioridazine in therapeutic doses; and Burke *et al* (1981) a case involving tetrabenazine (a reserpine-like drug which depletes monoamine stores) and α-methyl-para-tyrosine, again in therapeutic doses. These cases all suggest that sudden alterations in dopaminergic activity can themselves produce NMS.

Judging by the recent increase in articles on NMS in the English language medical literature, there has been a recent upsurge of interest. There was a delay between the first reports in the French language which appeared fairly regularly from 1960 onwards, and those in the English language journals. The first description of NMS as a complication of neuroleptic therapy, was by Delay *et al* (1960) in French. The paper appeared in the proceedings of the Société Médico-Psychologique for December 21, 1959, in a communication on the use of the then new drug haloperidol. It was described as a neurovegetative complication, as opposed to the neurological complications discussed in the next section. The first description in English was by Delay & Deniker (1968) when the term appears as a subheading in a chapter on drug-induced extrapyramidal syndromes in *Handbook of Clinical Neurology*.

In the English language journals the first reference to Delay & Deniker's description of NMS was by Metzler (1973) when he recognised it as a complication of treatment with depot fluphenazine enanthate. Four further papers before 1980 mentioned the term whereas 12 others describing similar cases between 1970 and 1979 made no reference to this work. Since 1980, case descriptions have become far more frequent as has the use of the term "neuroleptic malignant syndrome', probably following the article by Carroff (1980). This delay throws an interesting light on the spread of ideas in a science which aims to be international. Articles have also appeared in the journals of most other European countries with the exception of Scandinavia, and in journals from India, Japan, Australasia, and South Africa, as well as, of course, America.

In the survey by Burke *et al* (1981) 14 cases from the literature were reported plus one of their own. Since then, there has been a large increase in the number reported and I have collected about 300 cases from 164 references and five personal communications. Of these 251 have contained sufficient information to be included in the compilations. These which have had to be excluded because of insufficient information nearly all dated from the nineteenth century and the early years of the twentieth century. The cases quoted here from the French literature are a sample only, because of the difficulty in obtaining French journals in the UK.

Neuroleptic malignant syndrome has a distinct section in an abridged French textbook on psychiatry, (Lemperier & Feline, 1982), but it is not mentioned in any British textbooks including the recently published *Handbook of Psychiatry* (Shepherd *et al*, 1982). It appears in the American *Modern Synopsis of Comprehensive Textbook of Psychiatry IV*, (Kaplan & Sadock, 1985) but is not in the third edition.

Table I shows the number of papers and case descriptions appearing by year, and also the languages in which they were published.

During a 2-year survey of all cases of stupor in central South Wales between 1968 and 1971 (Kellam, 1970), there was one case meeting the criteria of NMS. This level of incidence seems to have continued and that it is certainly not much more than one case per million population every 2 or 3 years. The annual incidence, therefore, should lie between one case per million and one case per five million population. This would give the average psychiatrist about an even chance of seeing a case during his working lifetime.

In their letter to the *New England Journal of Medicine*, Cohen *et al* (1985) suggested that the annual incidence of the syndrome amongst persons being treated with neuroleptics could be as high as 1.4% of treated persons. In the subsequent article Pope *et al* (1986), identified seven definite or probable cases among 1239 patients admitted to their hospital. They estimated that, of these 39% or 483 were exposed to neuroleptics and thus justified their high rate of incidence. Other estimates of the incidence amongst neuroleptic treated cases have been made by Caroff (1980), 0.5% and Shalev & Munitz (1986), 0.4%. The last authors reviewed retrospectively 1250 cases admitted to their ward for neuroleptic treatment since 1972 and found five cases.

There appear to be no definite statistics showing the percentage of the general UK population receiving neuroleptics at any one time, nor for the number of new courses of neuroleptics started each year. Freeman & Alpert (1986) in their survey of the prevalence of schizophrenia in Salford found a prevalence for 1974 of 6.8 cases per 1000 population. This would suggest that between 5 and 10 per 1000 of the population start a course of neuroleptics in any one year and therefore using the work of Cohen *et al* and Pope *et al* that there should be an annual incidence of between 70 and 140 cases of NMS per million. Using the work of Caroff & Shalev, and Munitz it would be between 20 and 50 cases per million. Support for the lower suggested range of incidence comes from surveys such as Sukanova (1985) who among 4000 patients treated with neuroleptics on her service in Czechoslovakia found six cases of the syndrome, over 6 years. This gives an annual incidence of one case per 670 patients treated, or between eight and 15 cases per million population. These are all very different estimates from mine. For this reason there is a need to try and collect prospectively all the cases occurring in a large population.

It has often been said that NMS most commonly affects young men: out of 247 cases collected (with data on sex available), 92 were female. Table II shows the cases divided by sex and into different age-groups. The number of cases in each group is followed by the percentage of the total in brackets. For comparison, the percentage in the same age- and sex-group for the population of Wales is also shown; these are taken from the Registrar General's mid-year estimate for 1985. There does appear to be an over-representation of young men aged between 16 and 44.

TABLE I

A chronological summary of the description of cases of acute lethal or fulminating catatonias and neuroleptic malignant syndromes from 1832

Year	*Author(s)*	*No. of cases*		
1832	Calmeiel, L. F.	Cases in general (French)		
1849	Bell, L. D.	10 cases		
1919	Ladame, Ch.	51 cases (French)		
1927	Claude, H. & Cuel, J.	3 cases (French)		
1934	Stauder, K. H.	3 cases (German)		
1946	Shulak, N. R.	1 case		
1950	Aronson, M. J.	2 cases		
	In English Papers	*Cases*	*In French papers*	*Cases*
1951	1	0		
1952	1	1		
1958	1	1		
1959	2	1	1	2
		(1st description in French as "Syndrome Malin")		
1962			1	4
1965	1	55	1	1
1967	1	5		
1968	Described as "NMS" by Delay & Deniker			
1970			1	0
1971			4	8
1972	3	3	1	1
1973	6	8		
1974	1	4		
1975	2	0		
1976	3	0 (1 case in Italian)	1	1
1977	4	39 (3 cases in Japanese)	4	11
1978	6	3	2	4
1979	4	5 (2 cases in German)		
1980	5	1	1	1
1981	11	11 (1 case in Hebrew)	2	3
1982	12	10 (1 case in Rumanian)	2 +(1 paper in German)	7
1983	35	36 (2 cases in Japanese)	3	3
1984	35	30 (1 case in German)	2 (8 cases in Japanese)	1
1985	19	22 (6 cases in Czech. 2 cases & 2 references in German)		
1986	9	13		

The survival rate has been quoted at about 20% in many articles: Cohen *et al* (1985) quoted a fatality rate of 14.3%. The Committee on Safety of Medicines (CSM) (1986), stated that of 17 cases reported to them, five had been fatal.

In my compilation the reports from the 1960s and earlier showed a 76% mortality, but at this time a fatal outcome was possibly the usual feature leading to the case being recorded. In the cases from the 1970s, the mortality rate had fallen to 22.7% and, for the cases from the 1980s, further to 14.9%. This may reflect the successes of modern treatment methods rather than just less serious cases being recorded in the literature. Table III shows the relationship between the highest pyrexia recorded and a fatal outcome; unfortunately it could be taken to support either view.

It has been suggested that an elevated serum creatinine phosphokinase (CPK) is found in NMS (Metzler, 1973). This is measured in international units: where quoted, the normal range seems rather variable, but usually less than 100 *IU*/litre. In one

TABLE II
Distribution of cases by age and sex

Age	*Under 15*	*16–24*	*25–34*	*35–44*	*45–64*	*Over 65*
Male cases	4(2%)	37(15%)	49(20%)	25(10%)	35(14%)	5(2%)
Welsh population	10.9%	7.4%	6.5%	6.4%	11.1%	6.1%
Female cases	3(1%)	14(6%)	19(7%)	16(6%)	33(13%)	7(3%)
Welsh population	10.3%	7.3%	6.4%	6.4%	11.6%	9.6%

TABLE III
Pyrexia and mortality

Temperature (°C) over	*37.5*	*38*	*39*	*40*	*41*	*42*	*Fever or hyperthermia*
1970s	2	10	11	19(5)	14(7)	3	7(3)
1980s	12	37(3)	32(2)	36(5)	23(6)	9(5)	17(3)

The cases have been tabulated according to the maximum recorded temperature in degrees centigrade, i.e. the 37.5°C column contains all the cases between 37.5 and 37.9°C; the 38°C column all those between 38 and 38.9°C. After the figures for total cases the number of cases with a fatal outcome is shown in brackets.

possibly related condition, malignant hyperpyrexia, there is also a gross elevation of CPK but this is with a considerable proportion of an abnormal isoenzyme. This isoenzyme can be shown to occur both during the illness and at times when the patient is unaffected as well as amongst some of his relatives. It is believed that this indicates a liability to the disease when anaesthetics are administered. In the cases from the 1970s, elevated levels of CPK were recorded in ten cases, seven between 100 and 999 *IU*/litre and three cases between 1000 and 9999 *IU*/litre. For the 1980s, the numbers of cases recorded for the same groups were as follows, 38 between 100 and 999 *IU*/litre, 28 between 1000 and 9999 *IU*/litre and 14 over 10 000 *IU*/litre. In addition there were six cases where the CPK was only described as elevated.

In the cases from the 1970s, cases of organic mental illnesses showed the highest mortality, four out of seven; these cases included those with Parkinson's disease. Cases diagnosed as schizophrenia also had a higher mortality seven out of 43; whereas there was only one fatality among eight cases diagnosed as manic depressive psychoses, and only one out of seven cases diagnosed as non psychotic illnesses (mainly psychopathies and addictions). In the 1980s the mortality rates improved overall: nine of 75 for the schizophrenias and two of 26 for the organic psychoses. The apparent worsening, nine of 33 for the manic depressive psychoses, and four out of 13 for the group of non-psychotic diagnoses, is probably due to the small size of these groups.

Other possibly related conditions include malignant hyperthermia and heat stroke. Malignant hyperthermia (MH) is a genetically transmitted (autosomal dominant) condition. The inherited liability is to an abnormal muscle reaction to anaesthetic agents producing a similar clinical picture to NMS. The abnormal muscle reaction in addition to being shown by an atypical CPK can be demonstrated by subjecting isolated preparations of the patient's muscle to anaesthetics and caffeine *in vitro*. Recently, Caroff *et al* (1983) has shown a similar reaction to fluphenazine in a preparation from a patient who had recovered from NMS; this reaction was quite distinct from those of controls and also MH subjects. Muscle from this patient reacted to halothane but not caffeine, whereas if it had come from an MH patient it would have reacted to both and more strongly. This work was felt to suggest that there might be a closer relationship between these two conditions than had previously been the view, and of course suggests that the mechanism might not be entirely central. Dantrolene is the treatment of choice for MH but is not always effective in NMS. When dantrolene was only partially effective in NMS it reduced the rigidity and with it the fever which may be produced at the level of the muscles, but not always the confusion, stupor, tremor, or the psychotic symptoms, which are probably more central in origin. In heat stroke and anticholinergic poisoning, the skin is hot and dry and rigidity and tremor, absent which should make differentiation possible. These clinical features are summarised in Table IV.

TABLE IV

Clinical features of catatonia, malignant hyperpyrexia, and neuroleptic malignant syndrome

	Confusion	*Akinesia mutism*	*Rigidity*	*Tremor*	*Pyrexia*	*Neuroleptics involved*
Catatonia	Common	Mandatory	Usual	Possible	Absent	Possible (except in acute lethal)
NMS	Usual	Usual	Essential	Usual	Essential	Mandatory
Malignant hyperpyrexia	—	—	Usual	Usual	Essential	Absent

In the 1970s, depot neuroleptics were involved in 21 cases, with eight fatalities, and oral neuroleptics in 45, with seven fatalities. In the 1980s, the corresponding figures for depot neuroleptics were 28 cases, with eight fatalities, and for the oral drugs 109, with 17 fatalities. During this period there were 21 cases not associated with neuroleptic drugs three of which ended fatally. Nearly all of these cases appeared to be caused by the sudden cessation of dopamine agonists.

Among the injected neuroleptics, there were 16 cases attributed, at least in part, to fluphenazine enanthate with six fatalities; 20 to fluphenazine decanoate, with three fatalities; two to injected haloperidol, five to injected thioxanthines with two fatalities and five to pipothiazine palmitate.

Among the oral drugs, phenothiazines were recorded in 74 cases, with ten fatalities, butyrophenones in 89 cases, with ten fatalities, a thioxanthine in 14 cases, with one fatality, pimozide in three cases and substituted benzamides in seven cases, with four fatalities. Cases produced by non-neuroleptic drugs have only been recorded since 1980. They include reactions apparently to tetrabenazine (one case who survived); monoamine oxidase inhibitors (again one case who survived and one who died); trycyclic antidepressants (three cases - one died); and cessation of dopamine agonists (14 cases - again one died). In many of these, more than one drug may have been involved in a single reaction, and this will have been recorded against each of them.

Finally, the cases have been analysed for the treatment used and their success or failure as recorded in the case records. Between 1970 and 1979, 69 cases were treated by supportive measures, with sometimes the addition of benzodiazepines in three cases, ECT in two cases, and antiparkinsonian drugs in seven cases. Of these, 17 died. One case was noted as treated successfully with anticholinergic drugs.

In the 1980s, in the group receiving supportive treatment only fatalities occurred in 19 of 69 cases, in the benzodiazepine-treated group three cases of 14 died, and in the dantrolene-treated group two cases out of 33 died. Sometimes, an active treatment was not successful and an alternative had to be used. Sometimes treatments such as dantrolene cured the rigidity and hyperpyrexia, but left psychotic symptoms needing further treatment such as ECT, and this, as well as the patient's death, is described as failure of treatment in some cases.

Dantrolene was used in 34 cases and failed in five; bromocriptine was used in 13 cases and failed in one; anticholinergic drugs were used in ten cases and failed in two; amantadine was used in ten cases and failed in one; L-DOPA was used in nine cases and failed in three. Finally ECT was used in eight cases. In a series of eight cases from Japan, (Fujitake *et al*, 1984), antiparkinsonian medication was stopped, producing the syndrome; which was then successfully treated by restarting it. They have not been included in the above figures.

In two cases dantrolene was noted to cure the hyperpyrexia but not the rigidity or the mental disturbance. Intravenous administration of lorazepam has also been shown to be of value in treating catatonic symptoms, and of the four cases reported by Frichione *et al* in 1983, two were apparently suffering from NMS.

From the point of view of treatment, most patients will already have been prescribed neuroleptics, and it would seem essential to stop them immediately and at least for the duration of the pyrexial phase, as there is no way of knowing that they are not doing harm. I have adopted the French practice, whenever I use large doses of neuroleptics or fear the onset of the condition, of maintaining a 4-h temperature chart and making any unexplained rise above 37°C an absolute indication to withhold the drug until the case can be investigated further.

These results show that active treatment is associated with a much lower mortality than supportive treatment alone or combined with benzodiazepines or anticholinergics. The conclusion of the CSM (1986) that "Apart from withdrawal of the drug, treatment is essentially supportive," is also refuted. Probably the best treatment at present would be to combine dantrolene with either amantadine or bromocriptine, or both. If these failed, intravenous lorazepam would be worth a trial, especially if catatonic symptoms were prominent. If dopamine agonists have cured the rigidity and hyperpyrexia but psychotic symptoms persist, then ECT may well be the treatment of choice. ECT may well only have been dangerous when before the advent of effective symptomatic treatments with dantrolene and dopamine agonists, it had to be used on hypertonic, hyperpyrexial patients. Recent experience using it later has apparently been more successful (Greenberg & Gujavarty, 1985). In any event, a patient developing NMS should be moved immediately into medical intensive care and supportive measures should also be used.

In the pre-neuroleptic era, three of 12 cases were recorded as in stupor, and seven as confused; three showed catatonia, two parkinsonism, and two rigidity. Between 1959 and 1968, two out of ten cases were recorded as confused and four as in stupor; three were noted to be catatonic and two parkinsonian, with one recorded as rigid with no indication as to which type. In the cases from the 1970s, 18 out of 66 cases were recorded as confused, and 26 as in stupor; nine were noted as being catatonic, and 29 as parkinsonian with 18 only recorded as rigid and two as flaccid. In the 1980s, 68 out of 161 cases were confused, and 47 stuporose; 79 were parkinsonian, 18 catatonic, 49 rigid, and three recorded as flaccid.

Acknowledgements

I am grateful to Messrs Lundbeck, who searched their records and could find no recorded cases of NMS in Scandinavia; Messrs Jannsen for considerable help in providing references, and to my secretary Mrs J. Clarke. I should be grateful if any member of the College coming across a case of NMS (a fever over 37.5°C accompanied by motor disturbances) would notify me. I will request either a loan of the case notes or the completion of a very short form.

Communicating with Cancer Patients

S. GAUTAM and M. NIJHAWAN

In a prospective study, 100 cancer patients and their relatives were separately interviewed using a structured interview to examine whether the diagnosis of cancer should be communicated to patients and relatives; the reasons for doing so or not, the emotional reactions of patients and families; any change in the attitude of relatives; behaviour of patients and patient's expectation, on diagnosis, of the course of their illness. The majority of patients, who knew their diagnosis (71%), wanted to be told the truth. The majority of relatives wanted to know the truth themselves (81%) without the patients being told (77%). Patients did show immediate emotional reactions like anxiety and dejection, however they appeared to accept the diagnosis. Findings suggest that in an Indian setting the attitude of family members is more positive. The role played by sociocultural factors in the acceptance of the truth is discussed.

The word 'cancer' connotes an incurable disease followed by a distressing and inevitable death which is an ultimate challenge to the knowledge and skills of physicians, and a disturbing reminder of their limitations. Some doctors experience their failure to save the patient as a personal defeat and humiliation. They may respond with feelings of guilt, shame and resentment. To cope with his own emotions, the doctor may simply avoid the patient or become awkward or detached when they meet. The doctor's withdrawal tends to increase the patient's sense of helplessness and loneliness. Often the patient, his family and the doctor, attempt to maintain the denial of impending dissolution and an awkward game of mutual deception and avoidance of facing the facts takes the place of open communication.

The issue to be faced and settled by all concerned is that of communication of the diagnosis and its consequences. The perennially controversial question is whether or not to tell the truth. It is remarkable that extensive studies conducted among physicians and layman, respectively, reveal almost diametrically opposing views on this issue: 80–90% of healthy subjects questioned as well as cancer patients, responded that they wished to be told that they had cancer or another fatal illness (Cappon, 1962; Kelly & Friesen, 1950). However, 40% of dying patients who were asked if they wanted to be told when they would die, responded that they did not (Cappon, 1962).

Of 219 physicians questioned by Oken (1961), 90% said that they did not disclose diagnosis of cancer as a usual policy. In a general poll of 5000 American doctors, 22% said that they never told patients that they had cancer. Yet doctors usually affirm that they would personally want to be told if they were critically ill (Oken, 1961).

Whether or not the patient is told that he has cancer, he sooner or later guesses the truth from non-verbal clues. How this problem should be handled is a difficult issue often confronted by psychiatrists. The question is not only whether to tell, but who should do it, how, when and what should be told. Practical difficulties such as these, led to the present investigation.

Aims of the study

A prospective study was carried out at SMS Hospital Jaipur (India) to find out:

(a) whether diagnosis of cancer should be communicated to patients and relatives
(b) why the diagnosis of cancer should be revealed or not to patients and relatives
(c) the emotional reaction of patients and their relatives when patients know that they are suffering from cancer
(d) if patients perceive a change in their own behaviour after they know the diagnosis
(e) whether there is any change in the attitude of relatives towards the cancer patients on knowledge of diagnosis and if so, what is the change
(f) whether knowledge of having cancer is related to the patient's expectation of the course of the illness.

Method

In a prospective study, 100 consecutive patients, with an established diagnosis of cancer, attending the radiotherapy out-patient department of SMS Hospital, Jaipur, were included. The assessment of patients was done any time within 2 to 4 weeks of establishment of the diagnosis. The patients and their relatives were interviewed separately. Out of 100 patients included in the study, 33 had cancer of the head and neck organs, 32 had involvement of the genitourinary system, and 35 had cancer of sites other than those mentioned above.

All the available 77 relatives were interviewed, using a semi-structured interview schedule. This was designed to elicit the responses of relatives on disclosure of diagnosis both to them and the patients and their emotional reactions towards patients on knowledge of diagnosis (Appendix 1). All 100 patients were interviewed using another interview schedule. This was designed to elicit from patients a) what they thought they were suffering from; b) how they knew about it; c) their emotional reactions to their diagnosis; d) any change in their behaviour (as perceived by themselves) after the onset of illness; e) any change in the behaviour of others towards them; and f) their own expectation of outcome to treatment (Appendix 2). Special care was taken to see that at no time during the interview with the patients, were the words 'cancer', or, 'malignancy' used – or any indirect clue given to indicate their diagnosis. However, 48 patients already knew that they were suffering from cancer – either from the treating physician – or from the case files where diagnosis of malignancy/cancer was written – or they guessed from the fact that they were being treated at the cancer out-patient department – or they guessed it from behaviour towards them. These 48 patients were asked whether they thought their diagnosis should be revealed to them or not – and the reasons for their answers.

We designed the semi-structured interview schedules used for this study in a pilot study for interview of patients and relatives separately. Both of us were well versed with the technique of administering the interview schedule. Rates of literacy were judged according to the educational status of the informant; a person who had no schooling and did not know how to read and write was rated as 'illiterate', while those who had primary education were rated as 'low literate'. A rating of 'moderately literate' was given to those who had finished their school education (12th standard); and those with degree qualifications etc. were rated as 'highly literate'.

The responses were recorded and the results analysed.

Results

Of 100 cancer patients, 51% were ignorant about their illness and only 48% knew about their diagnosis and its outcome, while one patient could not be interviewed since he had a secondary metastasis in the brain (Table I). Of the 48 patients who knew their diagnosis, 23 clearly accepted the fact, while 25 were reluctant and used denial as a defence. It was observed that the majority of the illiterate patients (63%) did not possess the relevant knowledge, most of the low literate (42%) tended to use denial more frequently, while moderately and highly literate patients expressed their knowledge, and denial was infrequently used.

An enquiry into the immediate emotional reactions of patients on knowledge of their diagnosis, revealed that anxiety was the predominant immediate emotional reaction (77%), followed by feelings of dejection (42%); 8% did not initially accept the diagnosis, 4% felt that their anxiety was relieved and 6% reported no specific change. These emotional reactions were not found to be related to the site of cancer, while they appeared to have some relationship with age. The higher the age-group, the greater percentage of patients reported anxiety – while feelings of dejection were found to be maximum in the age-group 30–50 years, and comparatively less common in patients under 30 and over 50 years of age.

When patients were asked whether they perceived any change in their own behaviour after the onset of illness,

TABLE I
Interviews with cancer patients

Patients' knowledge about the illness (distribution according to literacy status)

Responses	*Illiterate* *n*=57	*Low literacy* *n*=12	*Moderately literate* *n*=19	*Highly literate* *n*=2	*Total* *n*=100
No knowledge	42(63%)	3(25%)	6(32%)	—	51
Knowledge	10(15%)	4(33%)	8(42%)	1(50%)	23
Denial of illness	14(21%)	5(42%)	5(26%)	1(50%)	25
Information not available	1	—	—	—	1
Whether truth should be told	*n*=24	*n*=9	*n*=43	*n*=2	*n*=48
Yes	17(71%)	6(67%)	10(77%)	1(50%)	34(71%)
No	2(8%)	1(11%)	2(15%)	—	5(10%)
Undetermined	5(21%)	2(22%)	1(8%)	1(50%)	9(19%)

57% gave an affirmative answer. Changes included preoccupation with illness (77%), loss of interest in daily routine (51%), irritability (40%), increased/reduced intensity of involvement in family affairs (23%). More than one type of change was reported by many patients.

Patients were also asked how they perceived the attitude of relatives towards them. It was found that 46% of the patients felt no change, while 52% felt it; 48 out of 52 patients (92%) reported that relatives were paying more attention to them.

The subsequent emotional state of patients and their perceptions of the course and outcome of their illness was examined. A comparison of responses in those who knew and those who did not know about their diagnosis showed that the majority (53%) of those who did not know or denied it, were hopeful about the outcome while only 29% of those who know, were hopeful about the outcome; 19% withheld expression of their emotional reaction, 17% expressed helplessness, 12% showed features of depression and 41% were not sure of the course and outcome.

When patients were asked if the truth should be told to them, out of 48 respondents who knew of their illness 71% were of the opinion that they should be told, 10% said the truth should not be told, while 19% were indecisive on this issue. The literacy level of the patients, unlike their knowledge of the disease, did not affect their opinion on this issue.

Of those who wanted the diagnosis revealed to them, 68% were of the opinion that it would increase their sincerity, and co-operation with treatment, 29% said that it would help them accept reality, 6% said that they would be in a position to plan for their dependents, while 3% said they could fulfil their last wishes. (More than one answer was given by some respondents.)

Of the five patients who said that the truth should not be told, 60% felt that the revelation would make them feel depressed and 40% anxious. Two of the respondents could not attribute any specific reasons for what they believed. (Two patients gave more than one response.)

We also explored the relationship between the presence of psychiatric morbidity and duration of illness, and found that higher psychiatric morbidity was found among patients with 1–3 years duration.

Interview with relatives

The majority of relatives of cancer patients were of the opinion that the disease and its outcome should be revealed to the relatives (81%) but should not be revealed to the patient (77%) (Table II). A small percentage (3%) of those who thought that the relatives should be informed, expressed the view that distant relatives should not be informed as this would lead to distancing the patient. Only 12% of the relatives were of the opinion that they should not be told while only 10% were of the opinion that the patient should not be told. A small percentage (10–13%) of relatives were indecisive on this issue. The literacy status of respondents was not found to have any bearing on this question.

Of those 62 relatives who said that the truth should be told to them, 73% felt that it would lead to better patient care in terms of medical facilities, early initiation of treatment and sympathetic attitudes from others, while 18% thought that the truth should be told so that the patient could be separated from others; 13% felt that it would assure the relatives about the progress of disease and 8% thought it would help relatives make financial and social arrangements (if need be) for the patient. One thought that it was his duty to know the truth, while another gave no specific reason for knowing.

The nine relatives who felt that the diagnosis should not be revealed to them, thought that knowing the diagnosis and its outcome would lead to a feeling of helplessness, sadness and thus a lowering of their morale.

The majority of relatives (87%) thought that the diagnosis and its outcome should not be told to the patient because it would make him more worried and restless (71%), apprehensive and fearful (49%) and would lead to an early deterioration of patient's general condition (15%). (Some respondents gave more than one response.)

The small percentage of relatives (13%) who wanted the patient to be informed about his disease and its outcome felt that this should be done to remove the patient's fears,

TABLE II
Interviews with relatives of cancer patients

Whether truth should be told
(responses according to literacy status of respondents)

Response	*Illiterate* *n* = 22	*Low literacy* *n* = 17	*Moderately literate* *n* = 30	*Highly literate* *n* = 8	*Total* *n* = 77
To the relatives?					
Yes	13(59%)	14(82%)	28(93%)	7(88%)	62(81%)
No	5(23%)	1(6%)	2(7%)	1(22%)	9(12%)
Undetermined	4(18%)	2(12%)	—	—	6(7%)
To the patient?					
Yes	3(14%)	—	4(13%)	1(13%)	8(10%)
No	14(64%)	14(82%)	24(80%)	7(87%)	59(77%)
Undetermined	5(22%)	3(18%)	2(7%)	—	10(13%)

apprehensions and curiosity (50%) while 25% felt that he should be told so that he himself could take steps to prevent the spread of disease to other family members. Another 25% felt that sooner or later the patient would find out about his disease so one should not hide the facts from him.

An assessment of relatives' emotional reactions towards cancer patients revealed that 86% felt that they should be affectionate and give emotional support to the patient, 10% expressed their helplessness while 9% were indifferent and were just performing their duties towards the patient to meet his daily physical needs.

Discussion

It is evident from the above findings that only 48% of the patient population knew about their illness, which is quite different from those of Albeit (1959) and Peck (1972) who reported that about 80% of their subjects knew their diagnosis. A possible reason could be that these studies were conducted in western countries where the literacy rate of the general population is higher.

When diagnosis is revealed, individuals exhibit different immediate emotional reactions, of which anxiety is predominant. These findings are quite similar to those reported by Bhatt (1963), Bronner-Huszar (1971), Peck (1972), Krant (1972), Hintan (1966), and Patel *et al* (1980). In this study, although a clear depressive reaction was not seen, a feeling of dejection and helplessness was reported by 42.5% of patients. Bhatt (1963) reported such feelings in 15.4% of her patients. It is also interesting to note that other immediate reactions like guilt feelings reported by western authors (Abrams, 1951; Harley *et al*, 1951; Abrams & Finesinger, 1953; Peck, 1972) were not seen so commonly in this sample.

Bhatt (1963) reported that knowledge of illness leads to two different kinds of emotional reactions – immediate as well as delayed, and found that depression and insecurity were the most common (53%) delayed reaction in her sample. Similar results have also been found in the present sample. Possible reasons for similarities in these findings are that patients in both studies came from similar cultural backgrounds and that acceptance of disease is known to be affected by the cultural setting and prevailing attitudes towards the illness.

The attitude of relatives towards patients when they know the diagnosis was found to be most sympathetic and they paid more attention to the patients. No discrepancy was found between patient's perception and relative's expression. These findings were similar in many respects to those reported by Bhatt (1963) where 42% of patients were reportedly treated with deep sympathy by their families and friends. A feeling of being neglected was reported by only two patients in the present study. Although the knowledge of diagnosis made relatives experience anxiety and panic they reported that this did not affect their attitudes towards patients.

Most of the patients (71%) in this series who knew of their diagnosis were of the opinion that truth should be told to them. These findings support the observations of Kelly & Friesen (1950); Aitken Swan & Easson (1959); Albeit (1959); Bo *et al* (1960); Gilbertson & Wangenstten (1962); Hintan (1966); and Peck (1972).

It has also been observed that the maximum number of psychiatric symptoms can be identified in those patients who have suffered from cancer for 1–3 years (94%) or at least for more than 6 months. The frequency of psychiatric symptoms becomes less after 3 years. Probably as the time passes the patient tries to accept his life as such, and makes realistic adjustments to his illness, with altered goals in life.

The above findings indicate that Indian patients tend to accept the diagnosis of cancer rather easily. The authors feel that the concept of death prevalent in Indian culture based on the philosophy of 'Geeta' where the soul is accepted as immortal and it is believed to transfer through death from one to another human/species (Bhagwat Geeta translated by Swami Adidevanand, 1973) plays a significant role in the easy acceptance of the diagnosis and planning of the rest of life. It is probably the cultural background, close emotional family ties and the tendency in the Indian population to come together at times of crisis which cause these responses about why the truth should be told.

Concerning the questions who should reveal the diagnosis, and how and when, we subscribe to the view of Krant (1972) that communication should be the responsibility of someone close to the patient and his family. Time must be allowed for the facts to be absorbed and questions to be raised. The patient should not be told that there is nothing more than can be done for him. The way the news is broken should depend upon patient's personality, intelligence, religion and the indirect clues he provides about how he is likely to deal with the disclosure. Some patients should not be told until a strong relationship with a member of the therapeutic team has developed. Clearly a general rule of thumb has no place here.

Appendix 1
Questionnaire for the relatives of cancer patients

Question 1 What do you know about cancer?

2 Suppose one person in the family has cancer and another person has some other physical illness, will the attitude of the family members be the same towards both? *Yes/No*

3 In your opinion what is society's attitude towards a cancer patient?
  - a) That he has got an illness which is incurable.
  - b) That he needs other people's sympathy
  - c) That he has some communicable disease and he should be isolated.
  - d) Any other.

4 If someone known to you has cancer what do you think the relatives should be told about it and i seriousness? *Why*

5 In your opinion should the patient himself be tol about the disease and its seriousness? *Yes/N* *Why*

6 If someone in your family has cancer what would b your reaction towards him/her?
  - a) Show your helplessness
  - b) Become indifferent
  - c) Just perform duties towards the patient to me his physical needs.
  - d) Give him emotional support/and affection
  - e) Any other.

Appendix 2
Questionnaire for patient

Question 1 What do you think you are suffering from?

2
(A) How did you come to know about it?
(B) What was your reaction when you came to kno about the diagnosis?
  - a) Did you become very serious?
  - b) Did you become very anxious?
  - c) Was your anxiety relieved?
  - d) Did you feel dejected?
  - e) Did you accept it?
  - f) Was there any other reaction?

3 Did you find any change in your behaviour after th onset of illness? *Yes/N*
If *Yes* –
  - a) Do you feel more involved in family affairs?
  - b) Do you feel uninvolved in family affairs?
  - c) Have you become irritable?
  - d) Have you lost interest in daily routine?
  - e) Are you mostly preoccupied with your illness?
  - f) Is there any other change?

4 Do you find any change in your family member' attitude towards you after the illness? *Yes/N*
If *Yes* –
  - a) Do they pay more attention to you?
  - b) Do they pay less attention than you expect?
  - c) Are they rejecting?
  - d) Are they indifferent?
  - e) Are they hostile?
  - f) Is there any other change?

5 Do you feel yourself socially cut off after the onse of illness? *Yes/N*

6 Do you find yourself physically weak after the onse of illness? *Yes/N*

7 How long do you think it should take you to get well'

8 (In case the patient knows the nature of his illness? Do you think it should be revealed to the patients tha they are suffering from cancer?

*Shiv Gautam, MD (Psych), DPM, MNAMS, *Reader in Psychiatry*; Madhu Nijhawan, MD (Psych), *Lecturer i Psychiatry, SMS Medical College, Jaipur 302004, India*

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

ifferential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female atients will usually present with symptoms of both. The potential risks of an inappropriate choice of reatment for these patients can often be a cause for concern.

rothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this oncern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left ntreated.

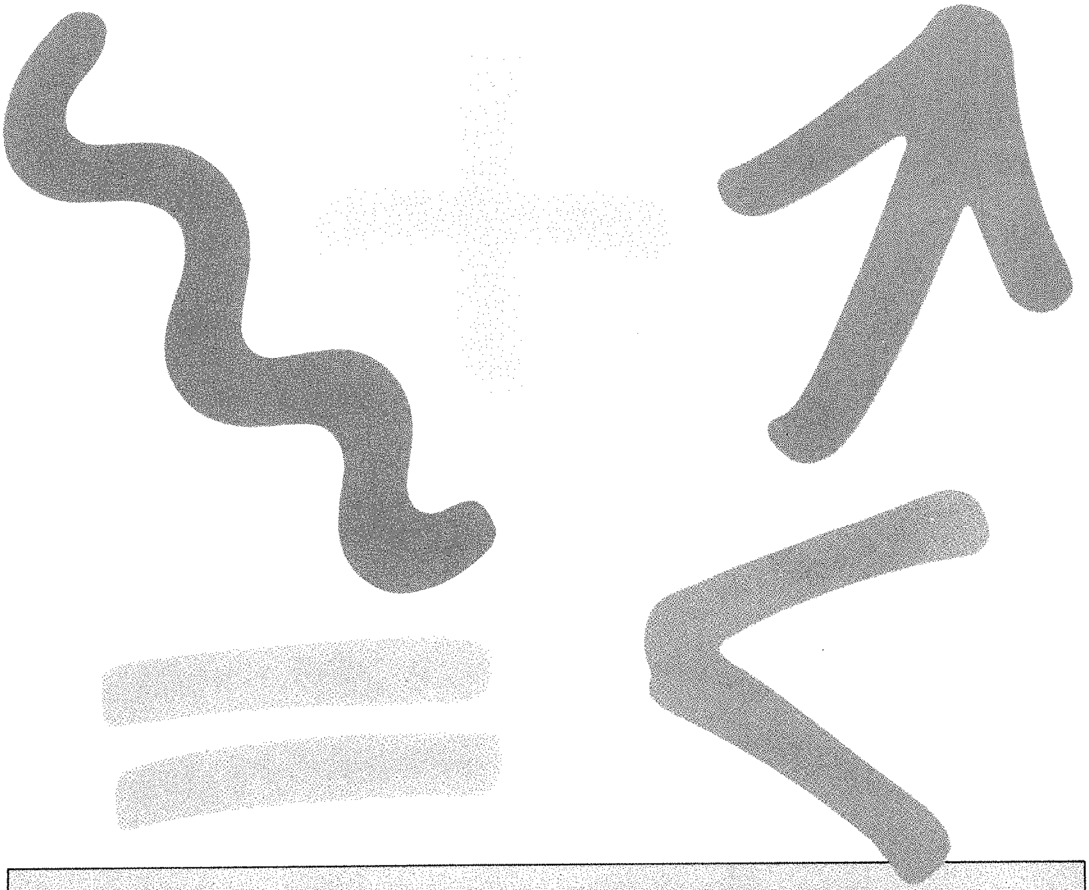
o, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well s that of your patients.

RESCRIBING INFORMATION

resentation: Prothiaden is Dothiepin Hydrochloride B.P. an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is dicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may e taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal dose may be fficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use hould be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating ileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the ction of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following ave been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 5mg £4.00 as at 1st Nov. 1986. **Product Licence Numbers:** PL0014/5941, PL0014/0209. The Boots Company PLC, Nottingham, England. Further information available request.

THE DEPIXOL

cis(Z)-flupenthixol decanoate



DIFFERENCE

= Proven antipsychotic effect (1-7)

↑ Restores mood (1-3) **∿ Dosage flexibility** **< Cost-effective therapy (8)**

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.

Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.

Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children. Not recommended for children.

Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.

Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.

Further Information Overdosage should be treated; (a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

Ethnic Differences in Self-poisoning

A Comparison of West Indian and White Groups

J. MERRILL and J. OWENS

The characteristics of West Indian patients admitted to a Birmingham hospital following deliberate self-poisoning were compared with those of White self-poisoners. West Indian patients were more likely to be young, female and single. They were less likely to have previously self-poisoned, have received previous psychiatric treatment, or be suffering from a personality disorder or alcoholism, but were more often followed-up by a social worker. Rates of self-poisoning for those aged under 25 were similar but for those aged over 25 were lower for West Indians than Whites.

Despite an abundance of American papers comparing Black and White suicide attempts (e.g. Pederson *et al*, 1973; Tardiff *et al*, 1981; Baker, 1984), few British studies have addressed themselves to this subject.

Bagley & Greer (1972) compared suicidal behaviour in 25 Blacks with controls. They found that Blacks were younger and more likely to suffer from acute situational stress. They were less likely to be sociopathic, addicted to drugs or alcohol, suffer from serious psychiatric illnesses or receive social or psychiatric support. The 'Black' group was heterogenous, comprising West Indians, Asians, Africans and Cypriots.

Burke (1976*b*) studied case notes of West Indians admitted to Birmingham hospitals after attempting suicide between 1969 and 1972. He found that West Indians were under-represented and that they were young, rarely abused drugs or alcohol and rarely repeated the attempt. He drew attention to an association between recent pregnancy and attempted suicide in West Indian females.

A pilot study from this centre (Wright *et al*, 1981) found that West Indian self-poisoners were more likely to be young, single and female than Whites. The mean annual rate of increase in self-poisoning between 1975 and 1979 was higher for West Indians than for Whites.

In the present study a comparison is made of demographic, social and psychiatric characteristics of West Indian and White self-poisoning. From such data the rate of self-poisoning is calculated for each group.

Method

The study was carried out at Dudley Road Hospital, Birmingham. The hospital serves a catchment area of 194 720, 22.3% having birthplaces outside the UK, 5.6% being born in the West Indies. Patients attending the casualty department after deliberately taking more than the prescribed dose of a medical substance, or after taking substances not intended for human consumption, were routinely admitted to the West Midlands Poisons Unit pending psychiatric assessment and completion of a comprehensive coding sheet. Between January 1 1979 and December 31 1981, 130 West Indians and 975 Whites were admitted to the Poisons Unit following deliberate self-poisoning. The West Indian (Afro-Caribbean) group consisted of 55 West Indian-born patients (42.3%) and 75 patients of West Indian parentage who were born in the UK (57.7%). The White group consisted of all whites born in England, Scotland and Wales. When patients were admitted on more than one occasion during the 3 years of the study, details of their first admission only were included. Patients of mixed ethnic origin were excluded as were patients borns in Northern and Southern Ireland, the latter because of Burke's finding that Irish-born attempted suicides in Birmingham were over-represented (Burke, 1976*a*).

Coding sheet data on the two ethnic groups were compared by means of the χ^2 test using Yates' correction for all items except the age distribution for which the Mann-Whitney *U* test was used. The two groups were well matched for social class, 87.8% of the Whites and 89.2% of the West Indians being in Social classes IV and V according to the Registrar General's classification (OPCS, 1970). Characteristics found to be age-dependent (previous psychiatric treatment, psychiatric diagnosis, psychiatric follow-up and pregnancy) were compared for those aged under 35 years only. Comparison of those aged over 35 years was precluded due to the small number of older West Indians. 'Marital problems' were recorded if, on interview, the patient indicated that difficulties in their marriage were at least part of the reason for self-poisoning. Note was made of the presence or absence of a general factor of cultural or racial conflict which here is called 'culture conflict'. This was identified only when patients volunteered information on conflict.

Overall rates were calculated for patients born in England, Scotland and Wales (UK-born) and the West Indies (West Indian-born) using the Small Area Statistics for the hospital catchment area (OPCS, 1981*b*). Age-specific rates were calculated by extrapolating from the age group/country of birth analysis for the West Midlands Metropolitan County (OPCS, 1981*a*).

Further details of patients, assessment and comparisons have been previously described (Merrill & Owens, 1986).

Results

Sex, age and civil status

See Table I. Compared with the White group (383 males and 592 females, ratio 1:1.5), the West Indian group (35 males and 95 females, ratio 1:2.7) had a significant excess of females ($P < 0.01$). The mean age of both male and female West Indians was much younger than that of the White group. This was due to an excess of older White patients and the modal age group for West Indian males being younger than for White males. Both male and female West Indians were significantly more likely to be single. When compared with White patients West Indian females were significantly less often 'divorced and separated' or widowed but the same was not true when comparing West Indian and White males.

Marital problems and culture conflict

Marital problems among those married were reported by a similar proportion of West Indians (males 66.7%, females 52.9%) and Whites (males 48.3%, females 49.1%). Culture conflict was apparent only in single females (1.4% of West Indians and 1.8% of Whites). All of these were due to parental disapproval of relationships with boys of a different colour.

Previous self-poisoning and psychiatric treatment

A previous self-poisoning was significantly more common in White patients (males 33.2%, females 34.0%) than West Indian patients (males 14.3%, $P < 0.05$, females 15.8% $P < 0.001$). West Indian females aged under 35 years were significantly less likely than Whites to have received previous psychiatric treatment (West Indians 10.2%, Whites 20.1%, $P < 0.05$). The difference for males however was not significant (West Indians 21.4%, Whites 30.5%).

Psychiatric diagnosis

Significantly fewer West Indian females aged under 35 years were diagnosed as suffering from a psychiatric illness (West Indians 17.4%, Whites 29.3%, $P < 0.05$). Among males there was no significant difference (West Indians 42.9%, Whites 23.3%). The actual diagnoses made were similar for each group, depression being the most common. Personality disorder was diagnosed in significantly fewer West Indian than White females (West Indians 6.3%, Whites 22.1%, $P < 0.005$) but not males (West Indians 14.3%, Whites 25.7%, NS). Although there was no significant difference in the incidence of alcoholism between ethnic groups when male and females were compared separately, when added together alcoholism was found to be significantly more common in White patients (West Indians 1.5%, Whites 6.6%, $P < 0.05$).

Follow-up

The type of psychiatric follow-up offered to the groups was similar. In-patient treatment was given to 5.6% of White males, 4.4% of White females, 7.1% of West Indian males and 4.5% of West Indian females. Out-patient treatment was given to 31.1% of White males, 26.2% of White females, 32.1% of West Indian males and 30.7% of West Indian females. Significantly more West Indians of both sexes were followed up by the psychiatric social worker

TABLE I

Age and civil status of self-poisoning patients compared by ethnic group

Widowed: %	3.3	8.0	0.0	0.0	NS	$P < 0.01$

attached to the unit (West Indian males 14.3%, White males 3.7%, $P<0.025$; West Indian females 28.4%, White females 12.4%, $P<0.0005$).

Others

Other items included the incidence of self-poisoning and suicide in relatives and friends of the patient, the accumulation of debts, a history of violence by and against the patient in the previous year, and living in overcrowded conditions. None of these revealed significant differences between groups. Significantly more West Indian females had been separated from their parents before the age of 10 years. Separation from the father occurred in 23.2% of West Indians and 12.0% of Whites ($P<0.01$) and separation from the mother in 16.8% of West Indians and 9.1% of Whites ($P<0.005$). Teenage pregnancies were significantly more common in West Indians (9.1%) than Whites (1.8%, $P<0.05$) but overall pregnancy in under 35-year-old females was not significantly greater among West Indians (6.8%) than Whites (3.3%). Only three of the 13 pregnant Whites and one of the six pregnant West Indians were married; all four had marital problems.

Rate of self-poisoning

The annual rates of self-poisoning for males and females are shown in Table II. Overall rates were significantly lower for West Indian males than for White males and West Indian males aged between 25 and 34 were significantly under-represented. The annual rate of self-poisoning for females over 45 years was significantly lower for West Indians. Rates for patients aged over 25 years were significantly lower for both West Indian males ($P<0.001$) and females ($P<0.005$).

Discussion

This study provides reliable data on the prevalence of self-poisoning among West Indian-born and UK-born residents at one of Birmingham's general hospitals. Self-poisoning among males was almost twice as prevalent for UK-born as compared to West Indian-born and this finding was significant. Among females the West Indian-born prevalence was less than that for UK-born but the difference was not significant. The study compares social and demographic factors among these populations and gives data on psychiatric diagnosis and follow-up.

While much of the data used in this study is highly reliable (e.g. sex, age, marital status and follow-up) some items (e.g. cultural and marital problems, previous self-poisoning and previous psychiatric treatment) were dependent on the information supplied by the patient and others (e.g. alcoholism, psychiatric illness and personality disorder) both on the information supplied and the assessor's interpretation of it. One author (J.O.) assessed the majority of patients and supervised the assessment of the remainder.

The calculated rate of self-poisoning is subject to inaccuracies. An unknown number of patients came from outside the hospital's catchment area and some cases of self-poisoning from within the catchment area will have attended other hospitals. Census data contains information on the country of birth but not on ethnic group, the number of persons born in the UK to West Indian parents is not known. Furthermore, the UK-born group in the present study includes non-white patients of West Indian and Asian parents. It is possible that a number of West Indians were wrongly classified by place of birth but every effort was made to reduce this likelihood. It is of interest to note that among the 130 West Indian patients in the present study the male/female ratio of those born in the West Indies (17:38) is not significantly different from that of patients born to West Indian parents but of British birth (18:57). Finally, there is a small number of self-posioining patients (which in our view is less than 5% of the total) who refused hospital admission. Once again the ethnic distribution of such cases is not known.

The under-representation of West Indian males and older West Indian females, the predominance of unmarried and the decreased frequency of

TABLE II

Significance (West Indian compared against White rates) *$P<0.05$, **$P<0.025$

alcoholism, personality disorder and previous self-poisoning support the findings of previous research (Bagley & Greer, 1972; Burke, 1976*b*; Wright *et al*, 1981).

Although pregnancy in those aged under 20 years old was significantly more common among West Indian than White patients, pregnancy rates for young West Indians in the general population are higher than for whites (Joint Working Party on Pregnant Schoolgirl Mothers, 1979). Similarly the increased occurrence of early parental separation found in West Indian patients seems likely to be a reflection of the common practice of grandparents raising children in the West Indian community and of children migrating after their parents have settled in the UK.

The increased likelihood of West Indians being followed up by the social worker is not easily explained. The social problems that West Indians had were similar to those of Whites and were commonly due to financial difficulties, poor housing and family disputes. It was felt that rather than these problems being more common in West Indians than Whites, the West Indians were perceived as being less likely to have the social support networks of friends, relatives and parents to help them cope.

Self-poisoning rates for West Indian-born and UK-born under the age of 25 were similar. However, rates for West Indian-born males and females aged over 25 years were significantly lower than for UK-born. No recent rates of self-poisoning in the West Indies are known but from Burke's finding of an overall female attempted suicide rate of 16 per 100 000 per year in Trinidad and Tobago (Burke, 1974) it seems likely that West Indians in Britain are much more likely to attempt suicide than native West Indians. The annual rates of attempted suicide among West Indians aged 16–64 years in Birmingham between 1969 and 1972 were 56 per 100 000 for males and 180 per 100 000 for females (Burke, 1976*b*). Although the rates found in the present study are higher, a reversal of the 31.5% mean annual increase in West Indian self-poisoning found by Wright *et al* (1981) has occurred. Over the three years of the present study a mean annual decrease in West Indian rates of 1.8% was similar to that of 1.2% for Whites.

Many of the characteristics of West Indian self-poisoners resemble those of Asian self-poisoners who have been compared previously with the same group of White patients in a previous paper (Merrill & Owens, 1986). Compared to Whites both West Indian and Asian groups had a preponderance of young females, lack of past psychiatric treatment and more often received social work follow-up. Further, Asian and West Indian females were both less likely to be diagnosed as psychiatrically ill or having a personality disorder. Interestingly however, culture conflict was common among Asians but not West Indians.

The findings of this research support the conclusions of the study by Pederson *et al* (1973) on White and Non-White suicide attempters in the United States that "in future research on suicide attempts, it would seem imperative to consider race as a separate factor".

Acknowledgements

We would like to thank Dr N. Wright, Dr J. A. Vale, Sister J. Whalley, Mrs R. Ahmed and all those whose work in the West Midlands Poisons Unit made this study possible. Thanks also to Dr R. Littlewood for his helpful comments on the manuscript.

From Clinic to Community

CLOPIXOL®

zuclopenthixol dihydrochloride/decanoate

TABLETS • INJECTION • CONC INJECTION

PRESCRIBING INFORMATION

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses. Not recommended for children.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerence to other neuroleptics. Pregnancy (relative). Use with caution in patients with Parkinsonism, severe arteriosclerosis, senile confusional states; serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.

Package Quantities and NHS Price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00.
PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia.
Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Not recommended for children.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked.
Package Quantities & NHS Price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23.

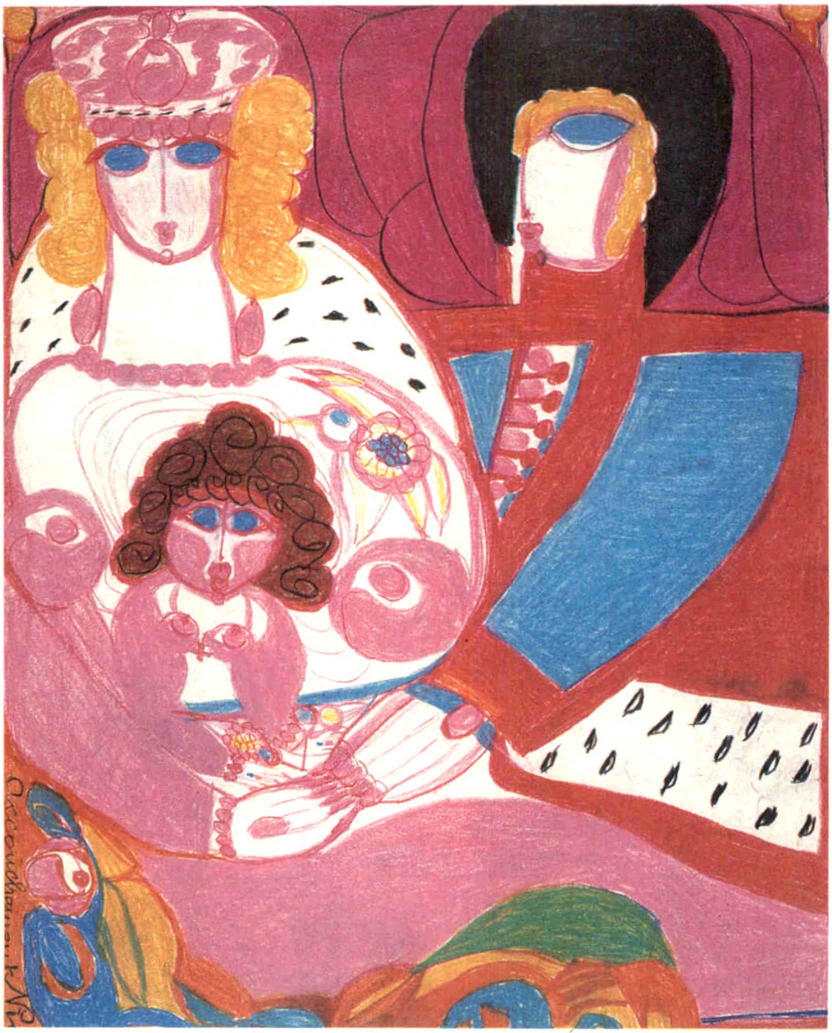
AN EXPRESSION OF SCHIZOPHRENIA.

Aloise was diagnosed as schizophrenic at the Cery Asylum, Lausanne. She was later transferred to the Asylum de la Rosiere where she remained for over 40 years until her death in 1964.

During the last 20 years of her life she worked steadily at her drawings.

The illustration below is produced with kind permission of the Musee Cantonal Beaux-Arts, Lausanne.



A TREATMENT.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone halopheridol, it has become widely established throughout the world as an effective anti-psychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration of action following a single deep intramuscular injection.

In mild symptomatology the dosage for Haldol* Decanoate is from 50-100mg given 4-weekly, whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation[1] and a reduced requirement for antiparkinsonian medication[2] leaving him/her better able to participate in other forms of therapy.

DECANOATE

Meeting the needs of the schizophrenic.

Presentation: Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses**: As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side effects, precautions, contra-indications**: Haloperidol is not recommended during lactation. Use in Pregnancy: The safety of haloperidol in human pregnancy has not been established. Precautions: Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side effects: In common with all neuroleptics, the following side effects may be observed, sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Occasional local reactions such as erythema, swelling or tender lumps have been reported. In common with other anti psychotics, haloperidol has been associated with rare cases of neuroleptic malignant syndrome. **Dosage**: Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. An initial dose of 50mg every 4 weeks is recommended increasing if necessary after 2 weeks by 50mg increments to 300mg every 4 weeks. The dosage should be tailored to suit the individual patient and to reflect previous oral dosage. In adults 100mg Haldol* Decanoate is approximately equal to 500mg chlorpromazine (or equivalent) per day. Caution is required with the elderly, starting doses of 12.5mg to 50mg monthly should be tried first. **Product Licence Numbers**: 0242/0095, 0242/0094 **Basic NHS Cost**: 1ml x 100mg/ml x 5 £24.00 1ml x 50mg/ml x 5 £15.60. (Correct at time of printing). Further information is available on request from: **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

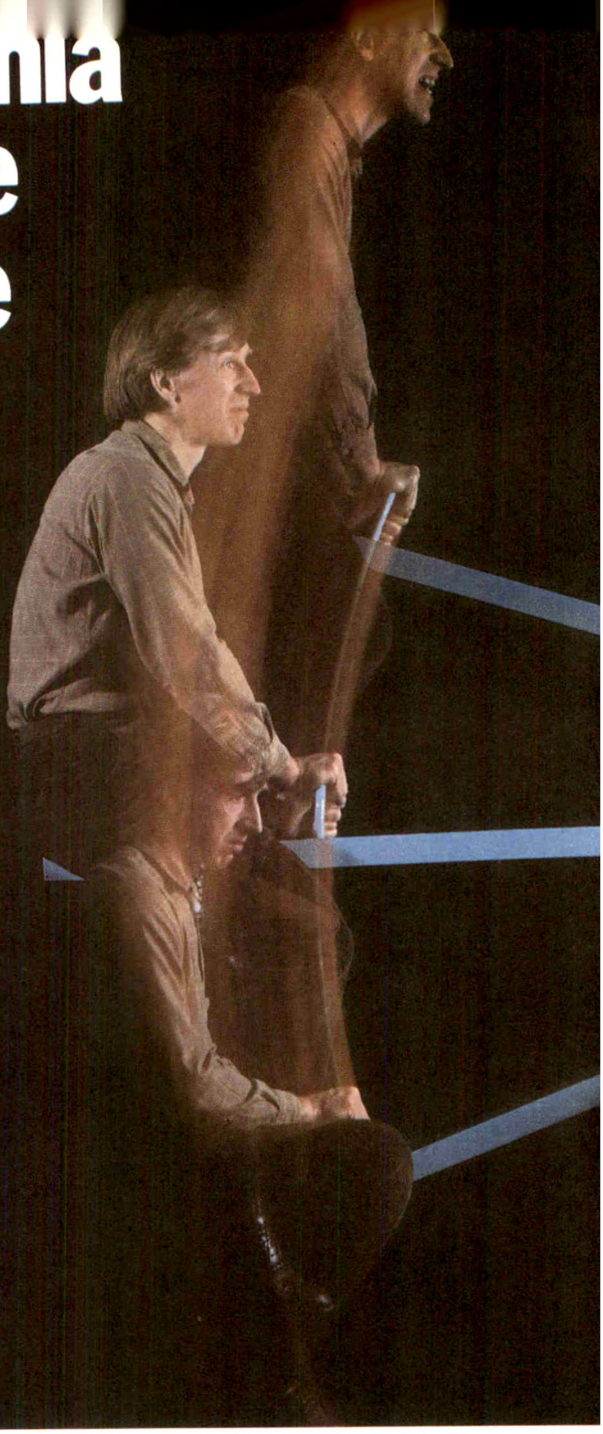
Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.[1]

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,[2-5] and because injections need only be given every four weeks, patients hardly know they are being treated.



Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information
Dosage: *(Adults)* Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg 1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral therosclerosis, phaeochromocytoma, renal or liver failure, evere cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, epression, blurred vision, asthenia, impotence, dry mouth, ausea, amenorrhoea, galactorrhoea, hypotension, hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. Phenomenology of Intoxication with Toluene-based Adhesives and Butane Gas

A. C. EVANS and D. RAISTRICK

The phenomenology of solvent inhalation was investigated comparing a group of young people who misused toluene ($n=31$) with a group misusing butane ($n=12$). Marked changes of mental state were invariable. Most users reported elevation of mood and hallucinations but a rich variety of phenomena was elicited. Nearly one-quarter of subjects had the potentially dangerous delusion of believing they were able to fly or swim. In the toluene group thoughts were more likely to be slowed, time appeared to pass more quickly and tactile hallucinations were more commonly reported than in the butane group. Withdrawal phenomena and tolerance were also looked at.

Epidemiological research has shown that 3–5% of 15-year-olds in the UK have misused volatile substances at some time (National Opinion Poll, 1982; Plant *et al*, 1984). Impressions suggest that the numbers are rising and that this figure is a gross underestimate of the number currently misusing. It has been said that dependence and tolerance may develop (Press & Done, 1967; Watson, 1982) but withdrawal states are reported to be rare (Barker & Adams, 1963; Press & Done 1967) although several papers have defined a withdrawal syndrome (Lindstrom, 1960; Merry & Zaccariadis, 1962; Nylander, 1962; Ackerley & Gibson, 1964; Watson, 1979). Deaths from misuse of volatile substances in the UK have been surveyed (Anderson *et al*, 1985). A common cause of death is accident or trauma while intoxicated, but all volatile substances can cause fatality probably by direct cardiotoxicity.

There has been very little research into the phenomenology of volatile substance misuse. Press & Done (1967) wrote that the effects of solvent sniffing are greater than those of alcohol ingestion and are closer to those seen with LSD. Tolan & Lingl (1964) found that the effects of gasoline sniffing compared closely with the psychotic syndromes produced by mescaline, LSD, and psilocybin. Lawton and Malmquist (1961) reported hallucinations in gasoline sniffers as did Ackerley & Gibson (1964) in lighter fuel sniffers.

More recently, the various clinical features of solvent intoxication have been described as being similar to those of alcohol intoxication with initial stimulation followed by depression. Other symptoms are said to include euphoria, blurring of vision, tinnitus, slurring of speech, ataxia, feelings of omnipotence, headache, abdominal pain, anorexia, nausea, vomiting, jaundice, chest pain, bronchospasm, impaired judgement, irritability and excitement, and it is said that less often, a delirious state is seen with clouding of consciousness, illusions, and hallucinations (Francis *et al*, 1982; Watson, 1982; Sourindhrin & Baird, 1984). It has been reported that chronic users describe transient symptoms of toxic psychosis which often have an affective component (Skuse & Burrel, 1982). The primary reason for the present study was to produce a systematic account of the phenomenology of volatile substance misuse.

Method

The sample consists of 43 subjects, of whom 18 were the total referrals for volatile substance misuse to the Leeds Addiction Unit between January and August 1985. The remainder were drawn from the three CHE establishments (Community Homes with Education on the premises) administered by the DHSS in Leeds, for young offenders. These 25 were young people identified by the staff of the CHEs as having particular problems with volatile substance misuse.

All subjects had a 40–60 minute interview with one researcher (A.E.). Subjects were asked to recall recent episodes of intoxication and a detailed phenomenological analysis was made. This part of the interview was open-ended and as far as possible descriptions were recorded verbatim for phenomenological allocation later. Data on withdrawal symptoms and tolerance were also collected.

Results

Thirty-one subjects used toluene-based adhesives as their preferred substance and 12 used butane gas. The mean age of the toluene group was 16 years, while the mean age of the butane group was 15 years.

The majority of both the toluene (74%) and butane (67%) groups had been misusing for more than a year, putting them into the chronic class of volatile substance abuser. Nearly 50% of both groups had misused on a daily basis. All subjects had experimented with several solvents before deciding on the preferred one.

Phenomenology

The results are summarised in Table I.

Reports on general behaviour and talk are based on observations of others as well as on subjective experiences. Most users said that they could make phenomena occur if they thought about them, but that experiences were also spontaneous.

General behaviour

Behaviour was reported to have been disturbed in the majority of cases and most said that they behaved as though they were drunk. Those who said they were in control of themselves were usually the more experienced users.

Talk

In general, talk was either slow and slurred or faster than normal, the latter being commonest with the toluene group. A word frequently used by them to describe their speech was "blurred". Other descriptions used were "missing letters out", "talking in unknown language", "baby talk", "voice sounds like someone else".

TABLE I

Summary of phenomena experienced during intoxication with toluene and butane

	Toluene (*n=31*) %	*Butane* (*n=12*) %

Thought

Thoughts were most commonly slow and difficult in the toluene group or fast and easy in the butane group. Phrases used to describe the fast form of thought were "think a lot better", "just so much easier", "as if you're really brainy", "thoughts feel free".

Words used to describe slowness and difficulty in thinking were "wasn't able to think", "thoughts blocked by something", "mind went blank", and "thoughts slipping away – like a vapour going through my brain". One patient said "I say it in my mind and like an amplifier in my mind it echoes for about ten minutes".

Mood

Mood was nearly always altered and often differently in the same session. Most users experienced getting high which they described as "feeling good", "no worries", "feel brilliant". Many users experienced unpleasant mood states, especially fear. The fluctuations in mood were invariably a response to the content of other abnormal experiences.

Illusionary misinterpretations

There was often no clear distinction between illusionary and hallucinatory phenomena. Readily available objects were commonly the catalysts for an illusionary creation, which could develop to an hallucination. Thus one youngster said that trees "become scarey, the branches go all curvey and seem like they're grabbing out to get you. They look like they're alive and their notches look like eyes and mouths". A girl said that when she looked in the fire she saw hands and animals and faces coming out of the flames. Another description was "the gravestones changed into orange aliens with big, round heads, pointed ears and one eye in the centre. They came towards me. I shot them with a long white gun with two buttons on the side. The trees changed into spaceships, long silver things, with three legs and a door". A boy described wall paper patterns moving around like footballers knocking balls to each other. His friend saw it first, then told him about it and then he could see it. Another said "I take my toy soldiers, that's the best thing. I put them on the floor and they grow and talk to me, or they stay small and walk about on my hand. I had a toy ambulance and it grew to its proper size and two plastic men grew and became proper men and put me in the back to take me away because I was glue sniffing".

Glue bags were frequently reported to change shape – "my bag changed into a hat – I put it on my head and had glue all over me." "I was sitting in front of a wall. A big shiny egg appeared in the glue bag; it was talking. A hole came in the wall and I pushed the egg through. My teacher walked in – she looked like a rabbit; she asked 'Have you got the Queen's birthday present?' She sent me home for glue sniffing. I was Alice in Wonderland." Other objects often altered similarly. "My bed changed into a dog, and barked." "I saw the TV moving towards me - it tried to eat me." "I look on a blank wall and draw on it and it comes alive. A house I drew came alive and came out and got big. I went in to the house and had fun. There were lots of toys inside and I played."

Hallucinatory experiences

Tactile hallucinations were much commoner in the glue group. A girl said "something came into my throat - a long, greasy, slimy worm trying to climb out". A boy described sitting on a sofa, "I could feel knives sticking in my legs and my back".

Auditory and visual hallucinations were experienced by nearly all youngsters in both groups. A buzz was heard by most of them when they first began sniffing, but this commonly wore off after the first few weeks and is not included as an auditory hallucination. Several people reported that trees started talking to them. A girl heard voices talking about what she was doing and telling her to do things. "You are sitting on the bed, you are standing up, get up, pack your bags". Another girl heard a voice in a graveyard telling her to cut her wrists; she did so.

The visual hallucinations described were florid and colourful. A boy saw a little cat putting its head through the fence. "I looked over the fence and saw loads of witches with black hats and cloaks in a garden running around. They were having a fancy dress party. I asked where the cat was and they said I was it. I looked down and I had a tail and was black. I was a cat. I started screaming and ran and jumped over the fence".

One glue user saw how the Universe was formed. "It was like a little ball dropped out of someone's pocket and there was something like an electric light bulb which gave day and night." Another always saw a white box in front of his face telling him what he was going to dream about. "It is about 2 × 3 inches and has words printed on it like 'you are going to dream about spaceships.'" A boy thought he was walking through a Chinese market and down a Chinese street. He saw Bruce Lee and fought with him. A girl thought she was in a garden sunbathing. "The trees came to life and came over to me. The grass wrapped itself around me." Stories of graves in cemeteries opening up and things coming out were frequent. Several saw demons and werewolves appearing out of the graves. Tales of spaceships and little green men were also heard often.

A glue user thought he was in Paris at the Eiffel Tower. "I climbed up and fell off. There was a fellow with an umbrella to catch me. The umbrella opened or closed depending on whether or not I opened or closed the glue bag." Once his bedroom was on a turntable. "It went round slowly, and went into another time when there was slavery. There were Roman men in leather armour trying to make us slaves. We escaped by climbing through the ceiling and through the drawers and back into the bedroom". He also said "Ernie told us he had just been to China. We all tried to go but couldn't. Then four of us got to China at the same time. Then six of us got to China at the same time. Our spirits came out of our bodies and we watched our bodies being chased, by Samurai warriers." Several children reported seeing space invaders. A boy said "I used to fire at them with lasers coming out of my eyes. They would then disappear". Others had lasers coming from their heads or bullets coming out of their minds.

Time perceptions

Slowing of time was commoner in the butane group but time passed more quickly in the toluene group. A boy using glue felt that he could control time as on a video machine by saying "Stop, forward, rewind, and fast forward". Another boy said that time went so slowly during 15 minutes sniffing that when he stopped he thought it was the next day.

Colour perception

Colour perception was distorted in over a third of the two groups and often a darkening of colours was described. "An orange colour became light brown", "brown wood went black". It was more often in the toluene group that everything became lighter and brighter. Individuals reported that "silver paint went nearly white", "grey graves went orange," "trees went silvery". "Everything's brighter and lighter - fresh like first thing on a morning when you have been for a run."

Perception of body form

There were many reports of the body feeling lighter. "I feel half my size, as though I'm floating". Less common were reports of "feel heavier". Other more complicated experiences were "I go big and small in time with the glue bag. Once I dropped my glue bag in thorns and I couldn't get it out when I was big, but I could when I was small".

Perception of size

Approximately a quarter of the subjects said that things around them became larger and rather fewer said that things became smaller. Descriptions included, "everything seems bigger - on top of flats looks a long drop down", or "people get bigger, about twice the size of me", or "my mates get smaller; I am always having to look down at them".

Delusions

Delusional ideas were experienced most commonly among the toluene users. Two were convinced they were dead during sessions. A boy thought he had changed into his best friend. Another boy thought that the devil was operating everything from an underground city where UFOs were buried. One boy was convinced that he had the power to change the weather around. A girl thought that her boyfriend had been killed by her best friend and she tried to strangle her best friend. Another believed that her grandfather had died, another that she could walk through things and a boy said he could get rid of people by "glazing" them, that is he looked through them and they disappeared.

Delusions of control were experienced with glue but not with gas. One boy felt there was a force making him do the things he did when intoxicated, and another felt that he was being controlled by the devil and by God. "I knew that if I didn't jump over cracks in the pavement I would go to hell. I wanted to go to heaven – there were points for the devil and points for God. Sometimes I looked into the mirror and was trying to change into the devil. I knew that if I couldn't do it, the devil got points and I went to him."

Eight children had had the delusion of being able to fly and one girl had thought she was a fish and could swim, (she couldn't). "Once in a cemetery I knew I was Batman. I had to jump out of a tree. I was laughing on the ground". Another boy jumped out of a first floor window and fell on a mattress; he had thought his friend was flying and fell when he tried to join him. Others said "I thought I was superman and I tried to fly out of a tree but my friend stopped me", and "I thought I could fly so I jumped off the top floor of a three storey block of flats; I broke my ankle".

None of the youngsters who thought they could fly suffered any serious injury though all had minor injuries and indeed potentially fatal outcomes. Similarly, the girl who thought she could swim came close to death. "I thought I was a fish and could swim very well. I jumped in the lake and nearly drowned". The subjects had a total of eight friends who had also thought they could fly and one friend who had thought he could walk on water.

Withdrawal phenomena and tolerance

There was clear evidence that tolerance had developed in 71% of the toluene cases and 100% of the butane cases. A history of withdrawal syndrome similar to that of central nervous system depressants was elicited, in 62% of the toluene cases and 50% of butane gases. The prominent features were sleep disturbance, irritability, shakiness, sweating, fleeting illusions and nausea. Stomach cramps, lower chest pain and facial tics were also consistently reported. There was a correlation between frequency of symptoms reported and frequency of solvent use (toluene $r=0.58$, $P<0.05$, butane $r=0.57$, $P<0.001$).

Withdrawal symptoms usually took 24–48 h to emerge after solvent use had been discontinued, and they lasted for between 2 and 5 days.

Discussion

Intoxication with toluene-based glue or butane gas presents with a clinical picture of a toxic confusional state. There is general depression of the central nervous system, disorientation and perceptual changes from which secondary mood states and delusional systems may arise. Florid symptoms subside within minutes for butane and half an hour for toluene. The characteristic odour of solvents, circumstances of use and subsequent course will rarely leave doubt about the diagnosis. The picture may be complicated by concurrent drug use or other psychiatric disorder; these problems were not encountered in this study. In the acute phase when elevation of mood and overactivity are prominent features, intoxication may be mistaken for manic-depressive disorder and when auditory hallucinations and paranoid ideas dominate, the mental state may be misdiagnosed as indicating schizophrenia.

Both solvents studied here are highly plastic substances and it was apparent that users are able to create illusions and hallucinations almost at will. 'Sniffing' was associated with very positive expectancies by users and initial elation of mood and pleasant perceptual change was almost invariable. The continued use of a solvent was often associated with a release of internal conflicts and, in particular, unresolved feelings about death about their parents. Compared to intoxication with cannabis and LSD, persecutory thoughts were uncommon though one young girl did try to strangle a friend. Fearful mood was most usually a response to frightening hallucinations. The content of abnormal experiences was strongly influenced by the dominant TV programmes and films to which the young people were exposed.

There were interesting differences between reported effects of toluene and butane though these will need confirming using matched comparison groups. In this study the toluene group most often reported thoughts being slowed but time passing quickly while the opposite was the case for the butane group. The toluene group were more likely to experience paranoid ideas that were not directly related to perceptual change but nonetheless emerged from the intoxicated state. Taken in overview the toluene group experienced more phenomena than the butane group, but then they experienced longer periods of intoxication.

The forensic investigation of death in young people does not include routine testing for the presence of solvents and the authors believe that there may be many more solvent related fatalities than officially recorded. This raises the argument of counselling towards safe use of solvents in young people who are judged to be unwilling to stop their habit.

In this study neuroadaptive change, notably withdrawal symptomatology, was only assessed retrospectively and indeed it would be difficult to do otherwise given the nature of solvent use. The symptoms were essentially similar to withdrawal from central nervous system depressant drugs with the notable addition of stomach and chest pains, and facial tics. The implication is that admission to hospital for detoxification may be indicated more frequently than previously thought.

In conclusion this study has highlighted several aspects of solvent misuse which have not previously been considered in depth and which we believe have important implications for management of these cases.

Patterns of Use and Related Harm with Toluene-based Adhesives and Butane Gas

A. C. EVANS and D. RAISTRICK

The patterns of use and related harm of solvent inhalation were investigated in a group of young people who misused toluene ($n = 31$) and a group misusing butane ($n = 12$). The two groups were similar in terms of patterns of use and solvent related harm. The toluene users were more likely to sniff only in a group setting, probably because of the long duration of intoxication. The toluene group were more approving in their attitudes towards taking other drugs.

In the UK, 3–5% of 15-year-olds are said to have misused volatile substances at some time (National Opinion Poll, 1982; Plant *et al*, 1984). It has been reported that the activity predominates in boys in the 13–15 age-group and that it is usually a group activity (Masterton & Sclare, 1978; Watson, 1982; Sourindhrin & Baird, 1984). Some studies show a high incidence in children from single-parent families with paternal unemployment (Masterton & Sclare, 1978; Sourindhrin & Baird, 1984); others refute this (Press & Done, 1967; Kaufman, 1973).

A number of papers have studied the adverse physical consequences of volatile substances misuse. Antisocial and self-destructive acts occur (Press & Done, 1967; Skuse & Burrel, 1982), and there is often associated misuse of alcohol and multiple illicit drugs (Skuse & Burrel, 1982). The progression of addiction careers in young adult solvent misusers has been commented upon and research is under way to identify the characteristics of the minority who go on from volatile substances to the misuse of alcohol and illicit drugs (Davies *et al*, 1985). Deaths from misuse of volatile substances in the UK have been surveyed (Anderson *et al*, 1985). A common cause of death is accident or trauma while intoxicated, but all volatile substances can cause fatality – probably by direct cardiotoxicity. The aim of this study was to investigate patterns of use. We also assessed related harm. Information was gathered during a study on the phenomenology of solvent abuse. The paper is not intended as a comprehensive study of patterns of use and related harm.

Method

The sample consists of 43 subjects, of whom 18 were the total referrals for volatile substance misuse to the Leeds Addiction Unit between January and August 1985. The remainder were drawn from the three CHE establishments (Community Homes with Education on the premises) administered by the DHSS in Leeds. These 25 were young people identified by the staff of the CHEs as having particular problems with volatile substance misuse.

All subjects were interviewed by one researcher (A.E.). Semi-structured sheets were used to collect data about home circumstances, background and pattern of substances misuse. Subjects also completed an attitude questionnaire. The attitudes to various drugs were assessed using a 10 cm line method to tap the constructs 'safe - dangerous' and 'enjoyable not enjoyable'.

Results

Social characteristics

Thirty-one subjects used toluene-based adhesives as their preferred substance and 12 used butane gas. The mean age of the toluene group was 16 (range 13–19) and male:female sex ratio was 4:1, while the mean age of the butane group was 15 (range 10–19) and sex ratio was 1:1.

The social characteristics of the cohort are undoubtedly distorted by the sampling method, and in particular both groups lived mainly in institutions or hostels (toluene 77%, butane 67%). There is a high incidence of family trauma, with separation of true parents, single parent families and periods of care from an early age. This was more marked for toluene users than the butane users. It is noteworthy that a number of children, particularly in the glue group, had found the transition from middle school to high school at 12–13 years a difficult one, often on account of the fact that they found themselves separated from friends they had made at middle school.

Pattern of misuse

The majority of both the toluene (74%) and butane (67%) groups had been misusing for more than a year, putting them into the chronic class of volatile substance abuser. Nearly 50% of both groups had misused on a daily basis. All subjects had experimented with several solvents before deciding on the preferred one. Thus, aerosol sprays, petrol, nail polish, nail polish remover, paint thinner, correcting fluid, and boot polish had been tried and rejected.

As the survey progressed it became clear that the toluene-using cohort represented a hard core of users. Many of the users knew each other before being institutionalised. They often lived in quite separate parts of the city but would meet

TABLE I
Patterns and consequences of solvent use

	Toluene *n=31*	*Butane* *n=12*

LSD	15	62	10	20
Heroin	4	39	0	20
Solvents	8	92	20	50

in a group to take solvents. Details of the pattern of use are presented in Table I.

A criminal record, usually of theft to support the habit, was almost universal among the misusers. The number having accidents was the same in both groups, despite the very different times taken for the effects of the substances to wear off. Intoxication with toluene takes at least 30 mins for the effects to subside, in contrast to only a few minutes with butane. It is noteworthy that 74% of the glue sniffers only indulged in a group setting. Many said that they were afraid of the consequences if they did it alone. On the other hand, 83% of gas sniffers sniffed alone at least some of the time, again indicating the essentially different natures of the practices.

More people in the toluene group than the butane group had experimented with other groups of drugs. These were most likely to be cannabis, amphetamines and magic mushrooms. None could afford heroin. Smoking was almost universal among the group. Drinking regularly was more common among the toluene group than the gas group, as was regularly taking time off school or work in order to misuse their substance.

Attitudes

The results of attitudes to other drugs are presented in Table II. It is interesting that the toluene group in particular regard their habit as unsafe (92%) but enjoyable (92%) and that this group favours alcohol as being safe (54%) and enjoyable (89%). This finding supports the view that most 'glue sniffers' will mature out of the habit and move on to drinking alcohol. Both groups had powerfully negative views about heroin and, to a lesser extent, other 'hard drugs'. All subjects were also asked to complete a section on their attitudes to work. Every individual in the survey thought that work was a good thing and 77% of the toluene and 90% of the butane group thought work would be enjoyable. A majority of both groups thought that their lives would be shortened on account of their solvent abuse and that their happiness in the future would be diminished because of it.

Discussion

The characteristics of the cohort studied are unlikely to be those of solvent misusers generally. Selecting young people referred to the Addiction Unit or resident in Local Authority institutions might be expected to bias the sample in favour of the most problematic users and this impression of a 'hard core' of users was supported by the fact that many of the young people, particularly in the toluene group, knew each other and had become acquainted only through their connection with solvent misuse gangs in Leeds. It was not surprising to find chaotic family backgrounds and social deprivation although this was less marked in the butane group. The most striking demographic difference between the two groups is the male:female ratio which was 4:1 for toluene and 1:1 for butane. It may be that the mess and persistent smell of toluene adhesives is unattractive to females compared to the quick, clean and short-lived odour of butane gas.

After some experimentation all users settled for a preferred solvent, but contrary to perceived patterns of use elsewhere in the country, none used aerosols as first choice and less than one-fifth had ever tried them. The cost and dangers of aerosols were given as reasons.

There was a significant difference in group – only use for toluene users and this seemed related to the prolonged period of intoxication associated with these solvents and the recognition by the users of the dangers of accidents or untoward behaviour while intoxicated. In spite of the different elimination rates, the number of users involved in solvent-related accidents was the same for both groups, namely one-third; accidents were both the result of behaviour while intoxicated and acting on delusional beliefs. The frequency and potential seriousness of solvent-related accidents has not generally been properly recognised. These results suggest that much more strenuous efforts should be made to prevent solvent inhalation rather than accepting, as most workers do now, that the youngsters will grow out of the habit unharmed.

There has been speculation that use of solvents might lead to use of hard drugs and in order to contribute evidence to this debate some measures of attitudes of this 'hard core' group were taken. The views of youth workers and involved professionals are that solvent misuse is something that the great majority of young people mature out of. Almost all subjects believed heroin to be dangerous and it was the drug fewest (toluene 39%, butane 20%) thought would be enjoyable. The drugs thought to be safest and most enjoyable by both groups were alcohol and nicotine, though two-thirds of the toluene group also expected enjoyable effects from illicit drugs other than heroin. The results suggest that these young people will turn to alcohol and cigarettes as their recreational drugs when they can afford them but both groups are, nevertheless, clearly vulnerable to an increase in availability of illicit substances, particularly if alcohol and cigarettes are found wanting in terms of psychoactive properties. Predicting the future behaviour of these young people was not the purpose of this paper. However, the fact that all of the toluene group and 83% of the butane group reported that they were already regular cigarette smokers and a quarter of both groups reported regular drinking is a matter for concern. This, taken with the very high rates of offending, some use of illicit drugs and time missed from school, should alert professionals to a group of socially and possibly physically damaged young people whose difficulties will not be resolved simply as a result of maturing out of solvent misuse. This applies particularly to toluene misuse. In our view, chronic toluene misuse requires careful investigation and follow-through by health and social workers.

Bulimia Nervosa

The Impact of Pregnancy on Mother and Baby

J. HUBERT LACEY and G. SMITH

This study examines the impact of pregnancy on the reported eating behaviour of 20 untreated normal body weight bulimia nervosa women; it also reports foetal and obstetric abnormalities and indicates the initial eating habits of the infants. The prevalence of binge-eating and self-induced vomiting reduced sequentially during each trimester of pregnancy. By the third trimester 15 women (75%) had stopped all bulimic behaviour and in the remainder the disturbed eating was less severe. Symptoms tended to return in the puerperium and in nearly half the sample abnormal eating was more disturbed after delivery than before conception. However, the improvement associated with the pregnancy described by seven patients was maintained and for five it appears to have been curative. The common fear among pregnant bulimics that their abnormal eating behaviour may damage their unborn child cannot be dispelled by this study; the incidence of foetal abnormality (including cleft palate and cleft lip), multiple pregnancies and obstetric complications (including breech presentation and surgical intervention) was high. The nutrition and development of the infants was good although three mothers (15%) reported slimming their babies down within the first year.

Early morning sickness, nausea and faddism are often reported concomitants of pregnancy. However, the incidence of these behaviours in pregnant women with bulimia is unknown. Certain aspects of bulimia, particularly the self-induced vomiting (Russell, 1979), the major fluctuations of calorific intake (Lacey & Gibson, 1985), the concern about shape and weight (Birtchnell *et al*, 1985) and the often associated fluctuating dysphoria, lead to the premise that the normal body weight bulimic could be liable to major difficulties during pregnancy and lactation. Further, because of the high co-prevalence of eating disorders in the families of bulimics (Hudson *et al*, 1983) the impact of the patient's eating disorder on her child's initial feeding warrants examination.

The aim of this study is to examine the impact of pregnancy on the dietary difficulties of the normal body weight bulimic woman and to report the eating habits of her child during the first year of life. The relevance of such a study is heightened by two further points. First, the finding of the first author (Lacey *et al*, 1986*a*) that 9% of the patients presented at his clinic do so, inter alia, because they desire to have a child but believe that binge-eating, if left untreated, could damage the unborn infant. Second, and perhaps consequentially, there appears to be a tendency for such women to become pregnant at the end of treatment (Lacey, 1983; Lacey & Gibson, 1985).

Method

All patients were attending the first author's Eating Disorders Clinic. The sample consisted of 20 consecutive bulimic women, of normal body weight, who reported having given birth within 2 years of the initial assessment but prior to receiving any treatment. All patients fulfilled the criteria for bulimia as laid down by the St George's Clinic (Lacey *et al*, 1986*a*, 1986*b*) and DSM-III (American Psychiatric Association, 1980).

A full psychiatric, obstetric and gynaecological history was taken. The patient then completed a questionnaire and any uncertainties were checked on face-to-face interviews. The questionnaire consisted of five sections, each of which in sequential order, dealt with a stage of pregnancy or the puerperium. The first stage – which we called 'pre-conception' – referred to the 3 months prior to known conception; the second, third and fourth sections dealt with the three trimesters of pregnancy, and the fifth section dealt with lactation, weaning and the infant's subsequent eating habits. As far as possible questions were asked such that the replies were either numerical or 'yes/no'. Space was provided after each question for the patient to amplify her answer. If the patient had had more than one child, she was asked to base her answers on her last pregnancy.

Results

Age of delivery ranged from 23–34 years, with an average of 28 years. Sixteen patients were primagravida; of the remainder, only one had more than one previous child. Seventeen patients were married, one was separated (her husband being the father of the child) and two were unmarried. Including the separated woman, three were living apart from the father of their child. The median social class was Social Class III.

Clinical state

All patients described current episodes of distressful binge-eating (mean = 2.5/day s.d. = 1.1). All had a well-established binge-eating pattern (duration from 3–22 years).

The patients reported the following behaviours currently associated with their binge-eating. All 20 engaged in self-induced vomiting and four also abused laxatives. All were attempting to lose small amounts of weight, on average, desired weight being half a stone (3.2 kg) less than presenting weight. Eleven patients had experienced fluctuations in body weight which distressed them. No patient felt an irrational fear (phobia) of normal body weight; their mean body weight was 106% of their matched population mean weight (MPMW), the range being 94–115% MPMW. All realised that their eating pattern was out of control and 16 had at some point felt a lack of control which had extended beyond food abuse into other areas of their life, such as interpersonal relationships. All felt self-depreciatory thoughts and 17 had felt depression in association with eating binges.

Fourteen patients had Type I bulimia (Lacey, 1984*a*) i.e. they did not describe a history of previous anorexia nervosa, weight phobia or massive weight loss. Five patients described Type II bulimia, i.e. they had a previous history of anorexia nervosa but had 'recovered' to normal body weight and no longer had a weight problem. One patient had Type III bulimia, i.e. she gave a history of massive obesity being some 50% above MPMW. Her weight had been within a normal range prior to conception and during the 18 months since delivery. The number of Type II bulimics in the sample (25%) was somewhat less than the number (34%) who regularly present at our clinic.

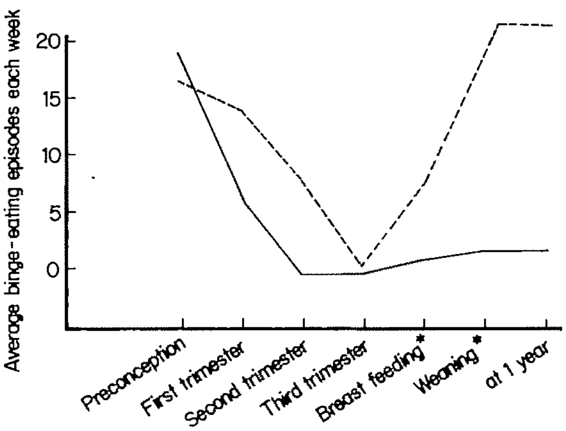
The eating disorder and pregnancy

The number of women who were binge-eating and vomiting reduced sequentially during each trimester of pregnancy but increased again in the puerperium (Table I). It can be seen that only five patients were binge-eating during the final trimester and in four of these the frequency of bingeing was less than in the first 3 months of pregnancy. In fact, 19 of the 20 subjects reduced the frequency of binge-eating over the course of their pregnancy, the exception increased the frequency of her binge-eating, but decreased the frequency of self-induced vomiting and stopped abusing laxatives.

TABLE I
Number of patients binge-eating in each 3-month period

Before conception	20
First trimester	16
Second trimester	14
Third trimester	5
Puerperium	12

All 20 patients reported that they were determined to improve their eating during pregnancy. Three patterns of response were found. Nine patients showed a reduction in the frequency of binge-eating during pregnancy with an increase afterwards to a level in excess of that occurring in the pre-conception period (Fig. 1). Four more patients showed a similar pattern but the frequency during lactation and weaning was not in excess of the frequency before conception. Most interestingly, however, seven of the patients who had stopped binge-eating during pregnancy maintained this improvement not only during lactation but also during weaning, and, in the case of five of them, this improvement had continued for over a year after confinement. These five patients were either pregnant when first assessed or became pregnant shortly afterwards: none have needed formal treatment.



*Sample size = 19 patients (one baby died)

FIG. 1 The changing pattern of binge-eating in seven women (-) who maintained their improvement and 13 who returned to bulimia (—).

The pattern and frequency of self-induced vomiting is similar to the binge-eating data above with the exception of the one patient already described. Four patients abused laxatives. All stopped using them as soon as they discovered they were pregnant but all had returned to laxative abuse either during weaning or bottle feeding. In two cases the amount of laxative abuse was higher during the puerperium than prior to conception. Alcohol abuse was described by three patients. Only one continued to drink during the first trimester of pregnancy and she returned to alcohol abuse after delivery.

Prior to conception the four most preferred binge foods were in order: starchy foods, sugars, 'junk' food and cheese. Little change occurred during pregnancy apart from cheese being more abused among those women who bottle-fed.

Other findings

Prior to conception nine of the patients described an irregular menstrual cycle, although none were amenorrhoeic.

Five described difficulties in conceiving. Fifteen patients had planned their pregnancies.

During the pregnancy all patients reported being 'worried' about what they were eating, ten because they thought their binge-eating might affect their baby and six because of weight gain. Seven patients reported being 'faddy'. Thirteen patients became constipated and all of these took fruit, bran or other fibre rather than proprietary laxatives. All patients took iron or vitamin supplements and one patient took an unprescribed dietary supplement (Complan). Seventeen patients (85%) reported 'morning sickness' but all were able to distinguish it from self-induced vomiting.

Five patients (25%) found the change in body shape disturbing ("I felt my shape would be permanently changed"; "I felt ugly and huge"; "I felt sexually unattractive"), while six patients (30%) liked the change ("I felt proud and pleased").

After having their baby, 17 patients (85%) felt that having a child had altered the need to have a binge. However, only six of these felt that the pregnancy had been a positive help ("My need to be a good mother helped me to stop it"; "I have a horror of my baby witnessing my bingeing"). Eleven believed that the stresses of pregnancy and looking after a child had caused a deterioration ("It is more of a problem now because I cannot throw away the baby's food"; "It has created more problems in our marriage"; "I binge at night when I am feeding the baby"; "I feel so tired and I eat when I cry"). Eleven (55%) of the patients believed that the presence of their babies inhibited the binge-eating, either because they felt that the child was noticing or they were frightened that the child would copy them, or simply that looking after a baby left insufficient time to binge-eat. Six patients reported having their children in the same room as themselves when binge-eating and seven (35%) reported ignoring their child because they were pre-occupied with vomiting. Only six had felt that they had regained their figure after the delivery, but half the sample had felt they had lost the extra weight gained, six by pathological means.

The eating habits of the child

All babies were breast-fed either wholly or in combination with bottle-feeding. All the patients felt that the damage to the figure caused by breastfeeding was more than compensated for by "giving him the best", "not having to concern myself about sterilisation or food preparation" and "in any case I enjoyed it!" However, the majority (70%) of the women had problems with breastfeeding and reported sore nipples, not enough milk, engorgement, inverted nipples, or slow feeding. This resulted in 13 patients using partial bottle feeding – although all regretted the necessity. Weaning took place between 3 and 6 months and the first solid food given to the child showed, in our view, excellent judgement. All the women had informed themselves about childhood nutrition either from their Health Visitor or, more usually, from a popular but responsible women's magazine. All the children – save one (see later) – have grown satisfactorily.

Seven mothers reported concern that their children might be overweight. Three (15%) had slimmed their babies down. Their GPs clinical records showed the babies to have been plump, but well within a normal range of weight. Discussion with the GPs concluded that the mother's behaviour was not justified and in our judgement was related to their psychopathology. In fact, 12 patients reported being concerned that their children would become overweight "like me". Seven babies had had a period of vomiting but in only one case was this behaviourally induced "It happens when I play too much with him". Sixteen children had periods of constipation but none were given laxatives. No mother gave an emetic. Half the babies had periods of diarrhoea due to infection. Four mothers reported trying to avoid giving their children carbohydrate foods and five had prevented him/her having sweets. Three mothers thought their babies were 'faddy' eaters and seven reported uncooperative behaviour at mealtimes. Half the sample had given their children vitamin drops and two mothers had established their babies on a vegetarian diet.

Five mothers (25%) had used food to punish their children, usually by the withdrawal of sweets, and nine had reported giving food for comfort: "it cheers him up". Ten mothers believe that they had used food as a means of expressing the love they felt for their babies.

Abnormalities in pregnancy and delivery

Of 22 babies born, 13 were girls and nine boys. One was born prematurely and died shortly after birth at 29 weeks. The child weighed 950 g and was normal; his mother had a long history of alcohol and soft drug abuse and fulfilled our criteria for multi-impulsive bulimia (Lacey *et al*, 1986*a*). All other children were born at full term and weighed between 2500 and 3700 g (mean = 3200 g). There were two sets of twins. One baby had a cleft palate and one a cleft lip; neither mother was taking benzodiazepines. A number of women reported abnormalities in their pregnancy or in delivery. Nine reported hypertension, including two with pre-exclampsia. Eight deliveries were breech. Four were delivered by forceps and three by Caesarian section. These findings were confirmed by the patient's GP or Obstetrician.

Discussion

The chaotic eating pattern of the bulimic is not made worse by pregnancy. In fact, the reverse is true: pregnancy is associated with an improvement in the condition. Of the 20 patients in our study, 19 reduced the frequency of their binge-eating and all of them reduced the frequency of self-induced vomiting. Further, the rate of binge-eating fell with each trimester as did alcohol abuse in those patients who reported it. Although in most cases, symptoms returned after delivery, (and in some the symptoms were worse than prior to conception), in a quarter of the sample pregnancy appears to have been curative.

It is not possible on the basis of this study alone to determine the reasons for this pattern of response. However, the clinical evidence is strongly suggestive that there was a positive and strong attempt on the part of these mothers to control their eating disorder because they feared harming their babies. Normal body weight bulimics report a sense of being out of control which we believe to be essential for diagnosis (Lacey *et al*, 1986*a*). These findings suggest that this feeling can be overcome by the motivated patient and that pregnancy provides such motivation. Interestingly, it has been noted (Gayford, 1984) that pregnant alcoholic women similarly control their abuse – and probably for the same reason.

Certain other factors – physical, metabolic, perceptual and psychological – also appear to be involved. Physical restraint certainly operates in some patients. As the fundus of the enlarging uterus pushes out of the pelvis, the stomach is restricted and the volume of food it could contain thereby limited. The vast food intake reported by some of our patients (detailed calorific intakes are published in Lacey & Gibson, 1985) would not be possible. Thus the classical cycle of bulimia – binge-eating, vomiting and then bingeing again – is broken and the patient has the opportunity to re-learn a normal eating pattern. Although pregnancy is a time of increased and increasing energy demand this cannot explain our findings. If this were the case the effect would persist during lactation: a time when calorific requirements are higher still. Certainly, some patients maintain their improvement during breast feeding, but the majority show a deterioration.

A change in weight and shape is a normal part of pregnancy, and sensitivity about both are prevalent in bulimia. It is thus noteworthy that not only did the patients in our sample accept that body shape must change, doing nothing to minimise the effects of the pregnancy, but 75% did not even find the change disturbing. Bulimia is associated with a disturbance of body perception. This over-perception becomes significantly less following short-term behavioural and psychodynamic treatment (Birtchnell *et al*, 1985). It could be that pregnancy provides, at least for some bulimics, a similar forum for change. It is an acceptable, if not venerated 'largeness' which provides a break from the pressure of conforming to a cultural ideal of thinness.

It is not possible in any academic sense to differentiate those patients who return to binge-eating after pregnancy from those who maintain their improvement. It is noteworthy that the latter stopped their binge-eating completely when they discovered they were pregnant and that they tended to have stable and meaningful relationships. On the other hand, those who returned to bulimia tended to be women with inter-personal problems and a sense of failure as women – and they used pregnancy as an attempt to combat this, by achieving in an obvious feminine role – that of procreation. We would not be so crass as to suggest that pregnancy is an answer to bulimia. It does, however, provide a period of dietary stability, similar to that attempted in certain treatment programmes (Garner & Garfinkel, 1984). Both pregnancy and treatment reduce the drive to 'diet', both provide external restraint to prevent gross binge-eating, both encourage the acceptance of body shape and weight, both provide motivation to change and both are time-limited and provide an opportunity for self-reflection (Lacey, 1983).

Our findings have implications for treatment: counselling should be given on first interview particularly as a large number of the women (9%) intend shortly to have a child and a number become pregnant before formal treatment can begin. Our own treatment programme (Lacey, 1983, 1984*b*) is composed of short-term weekly sessions of focused behavioural and brief psychodynamic therapy, followed by 3-monthly appointments which continue the counselling and insight-directed therapy and which form an integral part of the treatment (Lacey *et al*, 1986*a*). We believe that treatment for the pregnant woman should be concentrated during the weeks of the third trimester when the eating behaviour is quiescent and deeper issues not thereby obscured. The 3-monthly follow-up sessions take place during the puerperium fitting well with the schedule of the busy young mother.

We do not wish to imply that binge-eating in the first trimester is implicated in foetal abnormality. The sample is too small and other factors – heredity, drugs and alcohol – cannot be discounted. However, the common fear among these patients that their abnormal eating behaviour could damage their unborn child cannot be dispelled by this study. The incidence of foetal abnormality, multiple pregnancies and obstetric complications was high. National figures (OPCS Monitor, 1983) sampled the same year as this project and in a similarly aged maternal population suggests a prevalence for multiple births of 0.82% of pregnancies. The prevalencies of cleft lip and cleft palate were respectively 9.9 and 4.3 per 10 000 total births. In a further case a patient gave birth to a boy with pyloric stenosis, which we have reported elsewhere (Lacey, 1983). This patient was outside this study because she became pregnant *after* treatment. Although the frequency of binge-eating was reduced, it nonetheless continued throughout the first trimester. These findings, even if considered within the context of all pregnant women seen in our clinic, are disturbing and warrant further investigation probably in collaboration with other research centres.

Detection of Postnatal Depression

Development of the 10-item Edinburgh Postnatal Depression Scale

J. L. COX, J. M. HOLDEN and R. SAGOVSKY

The development of a 10-item self-report scale (EPDS) to screen for Postnatal Depression in the community is described. After extensive pilot interviews a validation study was carried out on 84 mothers using the Research Diagnostic Criteria for depressive illness obtained from Goldberg's Standardised Psychiatric Interview. The EPDS was found to have satisfactory sensitivity and specficity, and was also sensitive to change in the severity of depression over time. The scale can be completed in about 5 minutes and has a simple method of scoring. The use of the EPDS in the secondary prevention of Postnatal Depression is discussed.

In the last decade several studies (Paykel *et al*, 1980; Cox *et al*, 1982; Kumar & Robson, 1984; O'Hara *et al*, 1984; Watson *et al*, 1984) have provided substantial confirmation for the earlier finding of Pitt (1968) that the months following childbirth are frequently characterised by psychiatric disorder, and that at least 10–15% of mothers experience a marked depressive illness at this time.

Furthermore, the results of a follow-up study showed that postnatal depression was usually accurately recalled by the mothers 3 years later; and that at least half of the depressed mothers had not recovered by the end of the first postpartum year (Cox *et al*, 1984). The finding that the children of such depressed mothers may show behaviour disturbance at 3 years (Wrate *et al*, 1985) or cognitive defects at 4 years (Cogill *et al*, 1986) suggests that postnatal depression may have a long-term negative impact on the family.

In our earlier study (Cox *et al*, 1982), we found that 13 of the 101 women interviewed had a marked post-natal depressive illness and yet the majority of these depressed mothers had not received any sustained treatment from their primary care workers nor had they been referred to a psychiatrist; the three women who had been referred were not those who were depressed. This failure to identify depression in the puerperium, especially when such mothers were usually known to their GP, Community Midwife or Health Visitor, was obviously a cause for much clinical concern.

A further difficulty in identifying depressed mothers is that screening scales for depression appear to have a number of limitations when used on childbearing women. In our earlier study from Edinburgh, for example, the Anxiety and Depression Scale (SAD) of Bedford & Foulds (1978) was found to have uncertain validity; of the 13 pregnant women who scored 6+ (Foulds' threshold for personal illness) only three had any form of psychiatric disorder, while four had minor symptoms only and six had no psychiatric illness whatsoever (Cox *et al*, 1983). The 30-item General Health Questionnaire of Goldberg *et al* (1970) has been assessed by Nott & Cutts (1982) for possible use in the puerperium and was also found to require some slight modifications. These authors reported that 89 (45%) of 200 puerperal women scored highly on the 30-item GHQ, but only 37 (18%) were found to be psychiatric cases. Similar difficulties with the Beck Depression Inventory (Beck *et al*, 1961) for use in identifying depression in the puerperium were reported by O'Hara *et al* (1983). In this study only 11 of the 19 women who scored above the cut-off score fulfilled Research Diagnostic Criteria (RDC) for Depression, and of the 23 who scored below the cut off there were four false negatives. Furthermore, the finding that measures of self control predicted postnatal depression as measured by the Beck Scale were not confirmed when a clinical syndrome diagnosis of depression was made using Research Diagnostic Criteria suggests that studies using this scale as the only measure of depression following childbirth may give misleading results (O'Hara *et al*, 1984).

The possible explanation for these apparent limitations of well established scales when used on childbearing women include their emphasis on the somatic symptoms of psychiatric disorder which may be caused by normal physiological changes associated with childbearing, as well as the reluctance of community workers to use questionnaires which may be regarded as time-consuming or which appear to lack face validity. These limitations may also be relevant to a consideration of the Zung Depression Scale (Zung, 1965) for use in the puerperium.

To be useful as a screening test for depression following childbirth, therefore, a self-report scale must be fully acceptable to women who may not regard themselves as unwell, or as in need of medical help. The scale needs also to be simple to complete, and not require the health worker to have any specialist knowledge of psychiatry. It must have satisfactory reliability and validity.

Furthermore, Williams *et al* (1980) have appropriately emphasised that rating scales which had been validated on hospital samples must be revalidated if they are used in community populations where the differences between psychiatric illness and normality is often less distinct. The earlier work of Snaith (1981, 1983) in this regard was also important, as he clearly recognised the need to modify existing scales of depression for use in new specific clinical situations and in particular was aware of the need to develop a screening questionnaire to detect postnatal depression. Others, such as Kumar (1982) and Cox *et al* (1983), had also emphasised that this task was an important current research priority.

Spurred on by these observations of our colleagues as well as by the pressing need for primary care workers to have practical help in identifying postnatal depression, we therefore decided to develop a self-report scale to detect mothers who were depressed following childbirth.

Method

A detailed analysis of the suitability of the Irritability, Depression and Anxiety Scale (IDA) (Snaith *et al*, 1978), the Hospital Anxiety and Depression Scale (HAD) (Zigmond & Snaith, 1983), and the Anxiety and Depression Scale of Bedford & Foulds (1978) was carried out and we eventually selected 21 items, including several of our own construction, which we thought to be appropriate for the detection of postnatal depression. These items were then tested during extensive pilot interviews with mothers of young babies. The detailed wording of items, their acceptability to mothers and health workers, as well as their likelihood of detecting postnatal depression was then carefully evaluated. Thirteen items were eventually selected as being those most likely to detect postnatal depression; seven of these were items constructed by ourselves and the other six were adapted from the IDA and the HAD.

The validity of this 13-item scale was then established on a sample of 63 purperal women who attended a health centre in Livingston (see Cox, 1986 for details). This study showed that these 13 items distinguished clearly between depressed and non-depressed women, although a rotated factor analysis revealed that the two items from the irritability subscale of the IDA, together with an item concerning the enjoyment of motherhood, formed a separate 'non-depression' factor; this latter finding providing confirmation of Snaith's earlier observation that irritability was often identified as a separate mood from depression and anxiety. As this analysis of our data had suggested that the specificity of the scale might be increased by omitting these three items, we decided to carry out a further validation study using only the 10 items which were more clearly related to depression. This 10-item scale would also have the advantage of taking less time to complete.

The validation study of the 10-item EPDS to be reported in this paper was carried out on 84 mothers living in Edinburgh or at Livingston new town. Most of the mothers, who were taking part in a study to determine the effectiveness of counselling by health visitors in the treatment of postnatal depression, had been identified by their health visitors at about 6 weeks following delivery as being potentially depressed. The health visitors had been asked to indicate whether, in their opinion, these mothers were 'normal', 'depressed', or were considered as having 'problems'. As we envisaged that a useful function of the scale would be to confirm the diagnosis of depression in women already suspected by their primary care worker as being possibly depressed, this sample was particularly appropriate. We also considered it important to determine whether the scale would satisfactorily identify postnatal depression when it was administered in a domestic environment. The mother's home was, therefore, an optimum setting in which to validate the 10-item scale; home visits by health visitors being regarded as an important link between the assessment of puerperal mothers and other members of the primary care team. Mothers in our sample were interviewed by R.S. using Goldberg's Standardised Psychiatric Interview (SPI) (Goldberg *et al*, 1970) and the majority of such interviews took place in the mothers own home (SPI-1). At this home visit the EPDS was first completed by the mother and was then placed in a sealed envelope so that the interviewer remained blind to the score while subsequently administering the SPI. To prevent any possible bias effect caused by the interviewer knowing that the subject may have been regarded by the health visitor as being 'depressed' or as having problems, 12 normal women were also included in the sample. The criteria used for the diagnosis of a depressive illness were the Research Diagnostic Criteria of Spitzer *et al* (1975). Mothers who were observed to have a depressed mood but who did not meet full RDC criteria for depression were, however, also separately identified. As recruitment of subjects into the study was slower than expected, a further 12 women were interviewed by J.C. at a local health clinic. Both interviewers had been trained in the use of the SPI and difficult ratings were jointly discussed. The validation of the 10-item EPDS was determined for the total sample by comparing the EPDS scores with the RDC clinical diagnosis of depression.

Results

Validation sample

The mean age of women was 26 years, and that of their babies was 3 months. Seventy-five percent had had normal deliveries, 15% Caesarian sections and a further 10% had forceps delivery. The majority (81%) were married, whilst 13% had a permanent partner. Only 6% were single parents. Social class distribution (according to husband's, or partner's occupation where one was present, or according to the mother's previous occupation in the case of single parents) was as follows: Social Class II:7%, III:35%, IV:31%, V:27%.

Validation of the 10-item EPDS

The results of the validation of the 10-item EPDS are shown in Fig. 1.

A threshold score of 12/13 was found to identify all of the 21 women with an RDC diagnosis of Definite Major Depressive Illness and two of the three women with Probable Major Depressive Illness. Four of the 11 women with Definite Minor Depression were false negatives, i.e. they scored 12 or below, and there were 11 'false positives', although six of these 11 women had depressive symptoms but did not meet full Research Diagnostic Criteria for depression. The subject with the highest false positive score (21) had a marked personality disorder; while the three women with a psychiatric diagnoses other than depression all scored below the cut-off.

The sensitivity of the EPDS, the proportion of RDC depressed women ($n = 35$) who were true positives ($n = 30$), was 86%; the specificity, proportion of non-depressed women ($n = 49$) who were true negatives ($n = 38$), was 78%. The positive predictive value, the proportion of women above threshold on the EPDS ($n = 41$) who met RDC criteria for depression ($n = 30$), was 73%. As it is important in some clinical or research settings for actual cases of depression not be missed, our data suggest that the failed detection of cases can be reduced to under 10% with a cut-off score of 9/10.

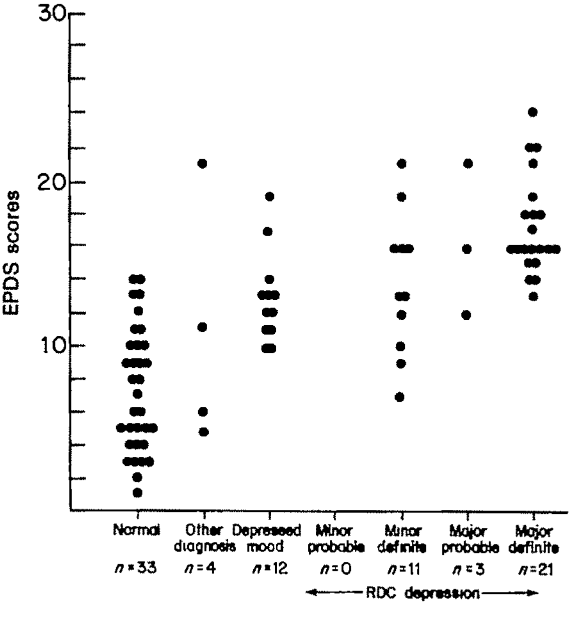

FIG. 1 Validation of Edinburgh Postnatal Depression Scale.

When analysis of our data was carried out on only those women ($n = 60$) interviewed by R.S. (excluding the 12 women with no previously identified problems, as well as the 12 subjects interviewed by J.C. at the Health Centre) the optimum threshold score was almost the same as in the larger sample, sensitivity 85%, specificity 77%, the positive predictive value having increased to 83%. The split-half reliability of the scale was found to be 0.88, and the standardised α-coefficient 0.87.

Sensitivity to change in the severity of depression over time was also established on a subsample by comparing the EPDS score at the first interview (EPDS-1), when mothers were taken into the counselling intervention study, with that obtained at the 11-week follow-up interview. At this second home interview the EPDS was completed for a second time (EPDS-2), and a repeat SPI (SPI-2) was carried out, the interviewer again remaining blind to both the EPDS-1 and the EPDS-2 scores.

Analysis of this data showed that those mothers who were depressed according to RDC criteria at both interviews ($n = 15$), showed no significant difference between their EPDS-1 (16.5) and EPDS-2 (15.38) mean scores on these two occasions, whereas mothers who were depressed at Interview 1 but not at Interview 2 ($n = 16$) had a reduction of score between EPDS-1 and EPDS-2 which was highly significant. (EPDS-1 mean score = 15.8, EPDS-2 mean score = 9.8, $t = 3.72$, $P = 0.002$). The EPDS-2 score in all but one subject fell to below the threshold of 12/13; the mother whose EPDS-2 score increased, but who was not depressed, had a probable cancer of the cervix and was diagnosed as having an anxiety neurosis.

Analysis of the possible influence on the EPDS score of another family member being present when the scale was completed suggested that under these circumstances women tended either to exaggerate, or to minimise, their psychiatric problems. Thus three subjects who had the highest 'false positive' score, and three of the four 'false negatives', had not been alone when they were interviewed.

Discussion

Our study has shown that the 10-item Postnatal Depression Scale, which was derived from the earlier work of Snaith, had satisfactory validity, split-half reliability and was also sensitive to changes in the severity of depression over time. Furthermore, we found that the scale was fully acceptable to the child-bearing women and was usually completed within 5 minutes. The simple method of scoring was an advantage and the health visitors recognised that the scale would greatly assist them in the detection of mothers who were depressed postpartum.

We believe it to be a substantial advantage that this validation study of the 10-item scale was carried out in a community setting and on women who were as close as possible to mothers regarded by their primary care workers as having problems. Our data nevertheless suggested that sensitivity and specificity of the scale may be increased if it is completed when other family members are not present.

It seems likely that the scale will be useful in the routine work of community health workers (e.g. health visitors, community psychiatric nurses and General Practitioners) and assist to identify postnatal depression in mothers thought by their health worker to be at risk. It may also be of use in treatment studies of postnatal depression when carried out on mothers living in the community.

Our data suggested that women who scored above a threshold of 12/13 were most likely to be suffering from a depressive illness of varying severity, and should therefore be further assessed by the primary care worker to confirm whether or not clinical depression is present. The EPDS is not a substitute for this clinical assessment, and a score just below the cut-off should not be taken to indicate the absence of depression, especially if the health professional has other reasons to consider this diagnosis. Our data also suggest that a threshold of 9/10 might be appropriate if the scale was considered for routine use by primary care workers.

We now plan to validate the scale for possible use during pregnancy and also to determine its usefulness in other populations. The scale could, for example, be administered by a computer at a mother's visit to an antenatal or postnatal clinic, and it may be useful as a more general screening scale for depressive illness. The revalidation of the scale for use in these other clinical settings must be carried out, however, before this wider use is recommended.

Acknowledgements

We are indebted to the many GPs and Health Visitors at Livingstone and Edinburgh who collaborated with us. We thank Mr R. J. McGuire for his statistical advice and for encouragement at various stages of the study. The research was generously supported by a grant from the Scottish Home and Health Department.

Appendix
Edinburgh Postnatal Depression Scale (EPDS)

The Edinburgh Postnatal Depression Scale (EPDS) has been developed to assist primary care health professionals to detect mothers suffering from postnatal depression; a distressing disorder more prolonged than the 'blues' (which occur in the first week after delivery) but less severe than puerperal psychosis.

Previous studies have shown that postnatal depression affects at least 10% of women and that many depressed mothers remain untreated. These mothers may cope with their baby and with household tasks, but their enjoyment of life is seriously affected and it is possible that there are long-term effects on the family.

The EPDS was developed at health centres in Livingston and Edinburgh. It consists of ten short statements. The mother underlines which of the four possible responses is closest to how she has been feeling during the past week. Most mothers complete the scale without difficulty in less than 5 minutes.

The validation study showed that mothers who scored above a threshold 12/13 were likely to be suffering from a depressive illness of varying severity. Nevertheless the EPDS score should *not* override clinical judgement. A careful clinical assessment should be carried out to confirm the diagnosis. The scale indicates how the mother has felt *during the previous week*, and in doubtful cases it may be usefully repeated after 2 weeks. The scale will not detect mothers with anxiety neuroses, phobias or personality disorders.

Instructions for users

1. The mother is asked to underline the response which comes closest to how she has been feeling in the previous 7 days.
2. All ten items must be completed.
3. Care should be taken to avoid the possibility of the mother discussing her answers with others.
4. The mother should complete the scale herself, unless she has limited English or has difficulty with reading.
5. The EPDS may be used at 6–8 weeks to screen postnatal women. The child health clinic, postnatal check-up or a home visit may provide suitable opportunities for its completion.

EDINBURGH POSTNATAL DEPRESSION SCALE (EPDS)

J. L. Cox, J. M. Holden, R. Sagovsky

Department of Psychiatry, University of Edinburgh

Name:
Address:
Baby's age:

As you have recently had a baby, we would like to know how you are feeling. Please UNDERLINE the answer which comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.

Here is an example, already completed.
I have felt happy:
Yes, all the time
Yes, most of the time
No, not very often
No, not at all

This would mean: "I have felt happy most of the time" during the past week. Please complete the other questions in the same way.

In the past 7 days:

1. I have been able to laugh and see the funny side of things
   As much as I always could
   Not quite so much now
   Definitely not so much now
   Not at all
2. I have looked forward with enjoyment to things
   As much as I ever did
   Rather less than I used to
   Definitely less than I used to
   Hardly at all

* 3. I have blamed myself unnecessarily when things went wrong
   Yes, most of the time
   Yes, some of the time
   Not very often
   No, never

4. I have been anxious or worried for no good reason
   No, not at all
   Hardly ever
   Yes, sometimes
   Yes, very often

* 5. I have felt scared or panicky for no very good reason
   Yes, quite a lot
   Yes, sometimes
   No, not much
   No, not at all

* 6. Things have been getting on top of me
   Yes, most of the time I haven't been able to cope at all
   Yes, sometimes I haven't been coping as well as usual
   No, most of the time I have coped quite well
   No, I have been coping as well as ever

* 7. I have been so unhappy that I have had difficulty sleeping
   Yes, most of the time
   Yes, sometimes
   Not very often
   No, not at all

* 8. I have felt sad or miserable
   Yes, most of the time
   Yes, quite often
   Not very often
   No, not at all

* 9. I have been so unhappy that I have been crying
   Yes, most of the time
   Yes, quite often
   Only occasionally
   No, never

*10. The thought of harming myself has occurred to me
   Yes, quite often
   Sometimes
   Hardly ever
   Never

Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptom.
Items marked with an asterisk are reverse scored (i.e. 3, 2, 1 and 0). The total score is calculated by adding together the scores for each of the ten items.
Users may reproduce the scale without further permission providing they respect copyright (which remains with the *British Journal of Psychiatry*) by quoting the names of the authors, the title and the source of the paper in all reproduced copies.

The Prognosis of Primary Depressive Illness

Its Relationship to the Dexamethasone Suppression Test

P. C. W. BOWIE, A. Y. BEAINI and L. J. BOWIE

We followed up 30 recovered depressives for an average of 2 years. At 18 months, despite prophylactic medication, 30% had relapsed. Persistent DST suppression during the index illness was found to be a predictor of good prognosis.

In an earlier study (Bowie & Beaini, 1985) three categories of dexamethasone suppression test (DST) response were defined on the basis of serial DST results. These three categories – normalising non-suppressors, fluctuating non-suppressors, and persistent suppressors – did not appear to differ demographically, nor in their response to biological treatments. However, it was postulated that the fluctuating non-suppressor category remained at risk of relapse despite symptomatic improvement, i.e. an underlying disease process remained unresolved. This postulate was supported by evidence from studies employing a repeat DST just prior to discharge from hospital (Greden *et al*, 1980; Goldberg, 1980*a*,*b*) which have shown that patients with abnormal (non-suppressed) DST response at that time were at significally higher risk of relapse. As persistent DST non-suppression is a rare finding and perhaps an indicator of poor treatment response (Albala *et al*, 1981), then it seemed likely that these 'at risk' patients were fluctuating non-suppressors.

Further supportive evidence was produced when patients with recurrent affective disorder taking lithium prophylaxis were re-tested (Coppen *et al*, 1983) and DST fluctuation was noted.

The present report is a follow-up of patients approximately 2 years after they were studied and categorised on the basis of serial DST response. The aim was to investigate the longer-term prognostic implications of the three serial DST categories.

Method

An attempt was made to trace and contact all 36 patients who had completed the previous research protocol.

Those patients who were traced and still lived locally were contacted by letter and asked if they would agree to a short semi-structured interview, and a DST.

At interview the following points were covered:

(a) length of time that antidepressant medication had been continued after the index illness
(b) evidence of any relapse
(c) the current medication, if any, that was being taken
(d) current depressive symptomatology was assessed using the Montgomery and Asberg Depression rating scale (Montgomery & Asberg, 1979).

A DST was arranged for patients in the week following the interview. This consisted of 1 mg of oral dexamethasone being taken at 21:30–22:00 and a plasma sample being collected at 16:00 the following day.

Plasma samples were stored at $-20°C$ until required for the estimation of cortisol concentration using the Amerlex direct radioimmunoassay method.

As in the previous study, a plasma cortisol level of above 140 mmol/litre was taken as the criterion for 'non-suppression'.

In addition the hospital/out-patient notes and GP records of all the patients were examined and the following points noted:

(a) length of time that antidepressant medication had been continued after the index illness
(b) evidence of any relapse
(c) the current medication, if any, that was being taken.

For the purposes of the study, relapsed was defined as 'any depressive episode requiring a change of treatment'.

Data was not normally distributed and was therefore analysed using non-parametric statistics (Mann-Whitney *U* test, χ^2 test with Yates' correction, and the Fisher exact probability test, and Kendall's rank correlation coefficient). Relapse/survival rates were extended beyond 18 months using the method of Kaplan & Meier (1958).

Results

Little or no information was available on six patients, but they did not differ from the remainder on the original variables (e.g. categorisation). Twenty-four patients were interviewed, rated for depressive symptoms and had a DST. Five patients were unavailable for interview and one had committed suicide; these patients have been included in the final analysis because sufficient information was available from hospital notes, GP records and the coroner's report on the suicide case.

Two of these patients were originally categorised as persistent suppressors and the remaining four as fluctuating non-suppressors, otherwise they did not differ on the original variables.

TABLE I

Characteristics of patients with non-suppressor DST response at follow-up

Patient	*Serial DST category*	*Follow-up MADSR score*	*No. of relapses*
K.L.	NN	31	2
D.M.	NN	0	0
D.C.	NN	21	1
S.K.	NN	14	2
R.S.	FN	14	3

NN: Normalising Non-Suppressor
FN: Fluctuating Non-Suppressor

Of the 24 patients interviewed six had an MADRS score greater than 10 (range 14–31), and five had non-suppressor DST response; their characteristics are shown in Table I.

As shown in Fig. 1, all three groups were followed up for a similar period and received antidepressant continuation therapy for a similar period.

While there was no significant difference in relapse between the normalising and fluctuating non-suppressors, the persistent suppressors had a trend towards a better prognosis (Fig. 2), which was significant at 27 months (Fisher exact probability, 1-tailed test, $P=0.045$).

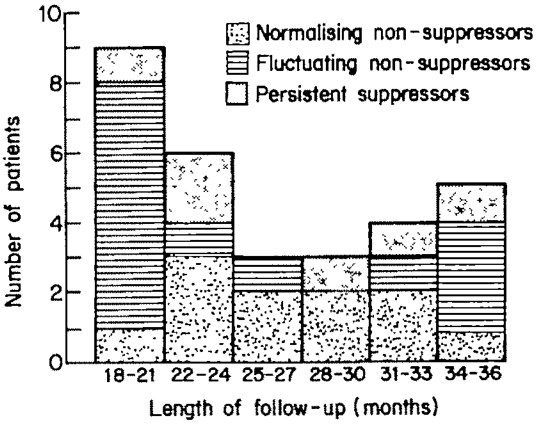

FIG. 1 Distribution of follow-up length.

Other factors which might have predicted long-term outcome were also examined. These findings are shown in Table II. These factors did not prove to be significant prognostic indicators.

However, when the proportion of abnormal DSTs (during the index episode) was examined, a significant correlation was found with the rate of relapse ($r=0.81$, $P<0.05$).

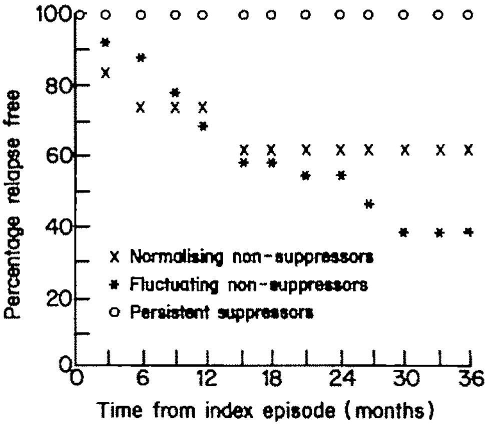

FIG. 2 Relapse rates for the three categories

Discussion

The results do not support the postulate that fluctuating non-suppressors are more likely to relapse than normalising non-suppressors. There are several possible explanations for this finding.

Firstly, the results do suggest a trend supporting the postulate. The non-significance of this trend may be due to the prolonged use of continuation medication in the patients studied. Prophylaxis was continued for an average of 21 months, the three categories receiving prophylaxis for similar periods. The original postulate implied a need for continuation medication for the fluctuating non-suppressors, but not for the normalising non-suppressors. This retrospective study has not adequately tested the postulate.

Alternatively the category of fluctuating non-suppressors may be spurious, and may not reflect an underlying suppressed disease process, but may have been generated by intra-patient changes in dexamethasone pharmacokinetics in the original study. Carroll *et al* (1980) suggested that DST non-

TABLE II

Factors examined for prognostic significance

	Sex		*Family history*		*Previous episode(s)*		*Pre-treatment DST*	
	M	*F*	*Yes*	*No*	*Yes*	*No*	*Non-suppressor*	*Suppressor*
No. of patients relapsing: *n*	3(8)	8(22)	1(8)	10(22)	6(12)	5(18)	9(19)	2(11)

suppression in depressives was not due to increased dexamethasone metabolism, but a more recent report from Berger *et al* (1984) found that a substantial proportion of tested patients fail to absorb dexamethasone adequately enough to produce serum levels that would suppress the hypothalamic-pituitary-adrenal axis.

While we can see no reason why dexamethasone pharmacokinetics should change from one week to the next, the test/re-test pharmacokinetics of dexamethasone have yet to be studied in this population, and therefore changes in dexamethasone pharmacokinetics may be an explanation.

Thirdly, perhaps the original method of categorisation has masked the results. The normalising non-suppressors were categorised on the basis of seven consecutive DST results. At one extreme there could have been one non-suppressor response followed by six suppressor responses or at the other extreme six non-suppressor responses followed by one suppressor response.

Certainly patients with serial DST profiles approaching the latter extreme could have been miscategorised fluctuating non-suppressors since fluctuating non-suppressors would automatically change categories to normalising non-suppressors at their first fluctuation.

The DST profiles of the four normalising non-suppressors who relapsed are shown in Table III. Patients 1 and 3 could certainly have been miscategorised, and this would explain their non-suppressor DST response at follow-up. Patient 2 is unlikely to have been miscategorised, and therefore implies that normalising non-suppressors do relapse, patient 4 not only implies this, but also shows DST fluctuation at follow-up which suggests that distinguishing between normalising and fluctuating non-suppressors is not valid.

TABLE III

DST profiles of the four relapsing normalising non-suppressors

	DST Profile non-suppressor: suppressor	*Follow-up post-dexamethasone cortisol (mmol/litre)*
Patient 1	6:1	244
Patient 2	1:6	97
Patient 3	4:3	304
Patient 4	1:6	391

However, distinguishing between non-suppressors and persistent suppressors does seem worthwhile as the results do show that persistent suppressors have a significant trend towards a better long-term prognosis when compared with all of the non-suppressors. This result suggests that this serial DST category is a more useful predictive tool than the category of DST suppression on the basis of a single test. It is also possible that persistent DST suppression is a more valid category when reflecting normal hypothalamic-pituitary-adrenal activity.

Two questions remain unanswered about this category. Firstly, does persistent DST suppression indicate a good long-term prognosis for primary depression, or does persistent DST suppression reflect a distinct entity within the broad heterogeneous concept of depressive illness?

Secondly, is the prognosis of persistent DST suppression dependant on medication or not?

Another prognostic indicator appears to be the proportion of abnormal DSTs during the index illness, the higher the proportion of abnormal DSTs indicating a worse prognosis. However, this finding has undoubtedly been influenced by the persistent suppressors, and when this influence is removed there is not a significant correlation ($r=0.73$, $P>0.05$). Nevertheless the correlation is high and probably warrants further investigation in a larger scale study.

Finally, we would like to comment on the prognosis of primary depressive illness, comparing our findings with other follow-up studies.

There is little doubt about the efficacy of prophylactic medication for depressive illness (Mindham *et al*, 1973; Glen *et al*, 1984) and the prognosis of our depressives has therefore been modified from its natural course by the use of such prophylaxis.

However, while prophylaxis may postpone relapse it certainly does not abolish it altogether – Mindham *et al* (1973) found that 22% of those on active medication relapsed within 6 months, Glen *et al* (1984) in a 3 year follow-up study found that 66% of those on active medication had relapsed.

Our results are somewhat similar – after 18 months (the shortest follow-up period) nine (30%) of our depressives had relapsed, only one of these not having continued with prophylaxis. Using the method of Kaplan & Meier (1958) the estimated relapse rate at 3 years is 40%.

The question of when is the risk of relapse highest is also worth considering. Our findings are similar to those of Glen *et al* (1984) with half of the relapses occurring after only 6 months (relapse rates of 20% and 33% respectively). Therefore both studies suggest that the risk of relapse is highest in the first 6 months after the index episode. This may be as a result of the re-appearance of symptoms associated with the index illness in some patients. Such as explanation has been discussed by Fleiss *et al* (1978). The difference in actual relapse rates probably reflects the difference in original patient selection.

The index episode was the first illness for the majority of our depressives, but Glen *et al* studied depressives with at least one episode prior to the index episode. Other follow-up studies beyond 6 months (Prien *et al*, 1984) have also involved depressives with episodes prior to the index episode. However, our relapse rate at 6 months compares well with the 22% relapse rate found by Mindham *et al* (1973) studying a demographically similar population.

A Combined Study of Cortisol, ACTH and Dexamethasone Concentrations in Major Depression

Multiple Time-Point Sampling

B. G. CHARLTON, A. LEAKE, C. WRIGHT, H. W. GRIFFITHS and I. N. FERRIER

The pathophysiology of hypercortisolaemia in major depression was examined. ACTH was measured using a novel immunoradiometric assay of high specificity and sensitivity. Twenty-eight patients with major depression and 18 control subjects were studied. Blood samples for basal hormone concentration were taken at 09:00, 16:00 and 23:00 on day 1, followed by administration of 1 mg dexamethasone at 23:00. Further samples were taken at 09:00 and 16:00 on day 2. Dexamethasone concentration was measured in day 2 samples and no significant difference was found between the depressed group and control subjects. In the depressed group cortisol concentration was elevated at 23:00 on day 1, and ACTH concentrations were elevated in post-dexamethasone samples. ACTH and cortisol concentrations were not directly correlated in individual patients. The elevated plasma cortisol associated with major depression is not solely mediated by changes in ACTH.

Elevated secretion of corticosteroids is probably the best-validated biochemical abnormality in depression (Arana *et al*, 1985; Rubin, 1985) and is characterised by reduced diurnal rhythmicity and resistance to the suppressive effects of dexamethasone: DST non-suppression (Carroll *et al*, 1981). DST non-suppression has been related to endogenous type depression (Holden, 1983), increased severity of depression (Klein *et al*, 1984) and enhanced treatment responses to antidepressants (Nelson *et al*, 1982) and ECT (Coryell, 1982). The abnormality is usually reported to normalise upon clinical recovery (Bowie & Beaini, 1985); if the DST does not normalise there is an increased risk of relapse (Targum, 1984). DST non-suppression is not specific to major depression (Berger *et al*, 1984), but occurs in other conditions such as mania (Christie *et al*, 1986) and dementia (McKeith, 1984) and in normal subjects (Hallstrom *et al*, 1983). Some previous studies are unreliable as normal control groups were not used and the studies have indiscriminately applied the cut-off value for elevated cortisol suggested by Carroll (1982). In spite of this research, little is known of the pathophysiology underlying hypercortisolaemia in depression.

Cortisol is generally considered to be under stimulatory control by ACTH. Studies of plasma ACTH concentrations in depression have yielded contradictory results, some showing normal concentrations (Fang *et al*, 1981; Yerevanian & Woolf, 1983; Linkowski *et al*, 1985) and others showing elevated concentrations (Kalin *et al*, 1982; Demisch *et al*, 1983; Reus *et al*, 1983). These contradictory results may reflect the lack of suitable control groups (i.e. those studies which compare DST suppressors and non-suppressors), infrequent blood sampling, or failure to measure ACTH both before and after dexamethasone administration. Furthermore, serious problems arise when measuring ACTH using radio-immunoassay (RIA) systems. Most RIA methods for ACTH tend to be non-specific (Schoneshofer *et al*, 1981); insensitive, requiring large volumes of plasma (Rees *et al*, 1971); or prone to plasma interference, requiring prior extraction (Krieger, 1979). In this study we have overcome these difficulties by using a recently developed two-site recognition immuno-radiometric assay (IRMA) for the measurement of ACTH (Hodgkinson *et al*, 1984). This uses antibodies directed at both terminals of the ACTH molecule, so cross-reactivity with other species is minimal. Furthermore, the assay is very sensitive and uses only small volumes of unextracted plasma.

Dexamethasone causes suppression of ACTH and cortisol secretion. Variability in the absorption and metabolism of orally administered dexamethasone may be expected to alter the plasma concentration, and therefore its effectiveness at causing suppression. Recent studies have demonstrated lower plasma dexamethasone concentrations in depressed DST non-suppressors when compared with DST suppressors

(Berger *et al*, 1984; Johnson *et al*, 1984; Morris *et al*, 1986). This suggests that altered disposition of dexamethasone may help to explain abnormal DST results. In contrast, Carroll *et al* (1980) showed no significant differences in dexamethasone concentrations in a similar study. These contradictory findings seem to require further clarification, and accordingly plasma dexamethasone concentrations were measured on the day following oral administration.

This study is the first to measure cortisol, ACTH and dexamethasone plasma concentrations in a single group of patients and control subjects.

Patients and methods

Ethical permission for the study was obtained from the Newcastle NHS ethical committee. Patients were drawn from the psychiatric wards of two general hospitals. The criteria for DSM-III Major Depressive episode were employed (American Psychiatric Association, 1980), and patients were further subclassified according to presence or absence of melancholia. Severity of depression was measured using the 17-item Hamilton Rating Scale (HRS) (Hamilton, 1960) and 'endogenicity' was measured using the Newcastle Endogenous Depression Diagnostic Inventory (NEDDI) (Carney *et al*, 1965). Eight patients were drug-free and the remainder were taking a variety of medications, principally low dose benzodiazepines ($n=15$), tricyclic antidepressants ($n=5$) and lithium carbonate ($n=4$). We were careful to exclude any subjects taking drugs known to influence the DST (Carroll, 1982). Control subjects were healthy volunteers.

The study involved 28 depressed patients (9 male, 19 female, age range 36–63) and 18 control subjects (8 male, 10 female, age range 19–57). Among the depressed patients, 59% were classified as having major depression with melancholia; and 61% scored $\geqslant 6$ on the NEDDI ('endogenous' depression). The mean HRS score was 25, (s.d. = 5).

Venous samples were collected in lithium heparin coated tubes at 09:00, 16:00 and 23:00 on day 1, after which 1 mg of dexamethasone was administered orally, and further samples were collected at 09:00 and 16:00 on day 2. Blood was maintained at 4°C during collection and centrifugation, and enzyme inhibitors (Aprotinin 200 KIU per ml blood and phenylmethanesulphonyl fluoride, *p*-hydroxymercuribenzoate, *N*-ethylmaleimide and EDTA to a final concentration of 1 mmol/litre were added to prevent degradation of peptides (Hodgkinson *et al*, 1984), before storage at −30°C.

Cortisol was measured using a modification of the competitive protein binding (CPB) assay (Murphy, 1967). Cortisol is the most abundant of the glucocorticoids present in plasma. We will use 'cortisol' to refer to the whole range of corticosteroids which are measured by the assay system (Meltzer & Fang, 1983). This convention, although not explicitly stated, is used in most previous research and we have adopted it to avoid confusion. Cross-reactivities are as follows: cortisone 17.5; corticosterone 124.5; 11-deoxycorticosterone 83.4; 11-deoxy-, 17-hydroxycorticosterone 87.5; 17-hydroxy progesterone 89.3%. Dexamethasone has negligible cross-reactivity at 0.001%. Mean intra-assay variation was 8% and inter-assay variation was 6%. The minimum detectable concentration was typically 55 nmol/litre. ACTH was measured using an IRMA. Mean intra-assay variation was 6% and inter-assay variation was 17%. The minimum detectable concentration was 10 pg/ml. Dexamethasone concentration was measured in the samples collected on day 2 using an RIA (Kream *et al*, 1983). Cross-reactivity with endogenous corticosteroids was negligible. Mean intra-assay variation was 8% and inter-assay variation was 14%. The minimum detectable concentration was 2 nmol/litre.

Statistics involved comparisons of depressed patients with normal subjects at each time-point. Student's unpaired *t* test was employed, and differences were considered significant for values of $P<0.05$.

Results

Cortisol

Cortisol results are shown in Table I and Fig. 1. The only time-point at which there was a significant difference between patients and control subjects was at 23:00 on day 1, when cortisol was elevated in major depression. Cortisol values in post-dexamethasone samples were not significantly different in the two groups. Cortisol concentration was not significantly correlated with HRS scores or different between those patients with and without melancholia or 'endogenicity'.

TABLE I
Cortisol concentrations at different time-points

	Cortisol (nmol/litre); mean ± s.d.				
	Day 1			*Day 2*	
	09:00	*16:00*	*23:00*	*09:00*	*16:00*
Control subjects	480 ± 169	285 ± 114	145 ± 57	91 ± 57	93 ± 29
Major depression	499 ± 168	354 ± 120	264 ± 188*	120 ± 69	146 ± 124

*Significantly greater than control subjects, $P<0.05$.

TABLE II
ACTH concentrations at different time-points

	ACTH (pg/ml); mean ± s.d.				
	Day 1			*Day 2*	
	09:00	*16:00*	*23:00*	*09:00*	*16:00*
Control subjects	43 ± 13	35 ± 10	29 ± 9	25 ± 8	24 ± 6
Major depression	47 ± 24	41 ± 19	36 ± 13	34 ± 12*	34 ± 10**

*Significantly greater than control subjects, $P < 0.05$.
**Significantly greater than control subjects, $P < 0.01$.

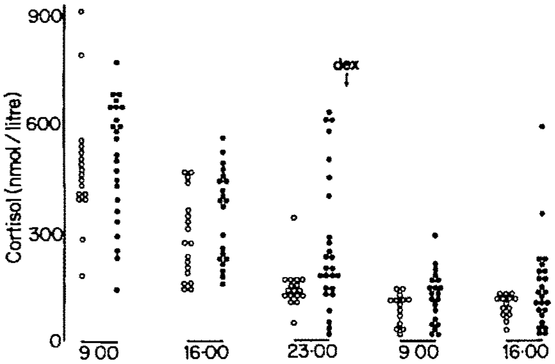

FIG. 1 Plasma cortisol concentration at different time-points; 1 mg dexamethasone (dex) administered orally following 23:00 sample; open circles = control subjects; closed circles = depressed patients.

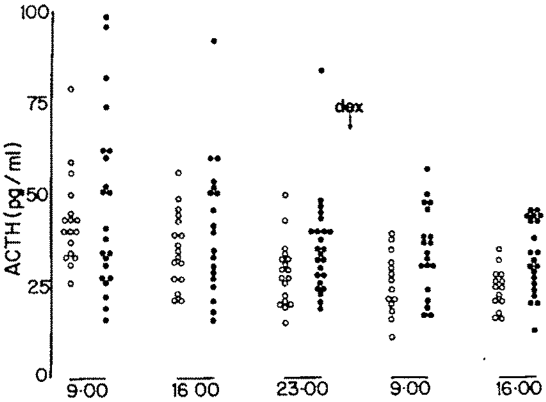

FIG. 2 Plasma ACTH concentrations at different time-points: 1 mg dexamethasone (dex) administered orally following 23:00 sample; open circles = control subjects; closed circles = depressed patients.

ACTH

ACTH results are shown in Table II and Fig. 2. Plasma ACTH concentration was elevated in the depressed group in samples taken on day 2 (i.e. following dexamethasone administration). Day 1 samples showed no significant differences. ACTH concentrations were not significantly correlated with cortisol at any time-point and were not related to HRS score or the presence of melancholia and/or 'endogenicity'.

Dexamethasone

Dexamethasone results are shown in Table III. All subjects had detectable dexamethasone concentrations at 09:00, showing that they had complied with medication. There was no significant difference between control subjects and depressed patients at either time-point, and no significant correlation between dexamethasone concentration and either cortisol or ACTH concentration.

Analysis using 'cut-off' values

The DST cut-off value of 138 nmol/litre (5 μg/dl) of cortisol in the post-dexamethasone samples was employed (Carroll, 1982): 58% of depressed patients and 7% of control subjects were defined as DST non-suppressors.

Hypersecretion was defined as a concentration of hormone greater than one standard deviation above the control subjects' mean. Thirteen depressed patients (46%) showed hypersecretion of cortisol at 23:00, and 13 depressed patients (46%) showed ACTH hypersecretion following dexamethasone. However, only seven patients (25%) exhibited both abnormalities. This group was not distinguishable from the other patients on the basis of HRS score, 'endogenicity' or melancholia, nor on dexamethasone concentration.

TABLE III
Dexamethasone concentrations on day 2

	Dexamethasone (nmol/litre); mean ± s.d.	
	09:00	*16:00*
Control subjects	7.9 ± 3.4	5.1 ± 3.0
Major depression	8.2 ± 3.7	6.0 ± 3.3

Discussion

The group of depressed patients contained 58% DST non-suppressors using the cut-off value of 138 nmol/litre. This figure is broadly comparable with previous studies on similar groups of patients. However, we did not show elevation in post-dexamethasone cortisol concentrations, and the cortisol data did not fall into a bimodal distribution. Many groups have employed the 138 nmol/litre cut-off value determined by Carroll (1982), despite the recommendation by Carroll's group (Ritchie *et al*, 1985) and others (Meltzer & Fang, 1983) that each laboratory should define its own values using normal subjects. We contend that the use of cut-off values is often misleading and suggest that data is more informative if presented in full, with comparisons between depressed and normal groups being performed before the use of cut-off values. In contrast to the DST data, a significant elevation in the cortisol concentration at 23:00 was noted in depressed patients, which reflects a blunting of diurnal rhythmicity.

The ACTH results in this study are more extensive than in most previous studies, demonstrating both diurnal rhythm and the effect of dexamethasone. The highly specific and sensitive assay was able to detect ACTH even after dexamethasone administration. Basal concentrations of ACTH were not altered in depression, but ACTH was resistant to dexamethasone suppression in this group. ACTH concentrations did not correlate closely with cortisol and there was only a partial overlap between the group with elevated cortisol and the group with elevated ACTH. Dissociation between ACTH and cortisol has been noted in several previous studies; for example, following haemorrhage in dogs (Gann, 1979), following pain in cats (Bereiter *et al*, 1982), with increased intracranial pressure in humans (Feibel *et al*, 1983), and in depression (Fang *et al*, 1981; Kalin *et al*, 1982; Reus *et al*, 1983; Yerevanian & Woolf, 1983). It is probable that factors additional to ACTH are responsible for modulating cortisol secretion (Lowry, 1984; Fehm *et al*, 1984). Depressed patients have been found to secrete more cortisol in response to synthetic ACTH 1–24 than control subjects (Amsterdam *et al*, 1983). It would therefore seem that some other factor is potentiating the effect of ACTH on the adrenal. A possible candidate is *N*-terminal pro-opiocortin (*N*-POC) which is secreted from the same precursor as ACTH (Lowry, 1984) and has been shown to potentiate the action of ACTH on cortisol secretion *in vitro* (Pederson *et al*, 1980) and in animal studies (Al Dujaili *et al*, 1981). *N*-POC has been measured in elevated concentrations following cardiac arrest, when cortisol was elevated but ACTH remained at normal concentrations (Wortsman *et al*, 1985). Taken together, the above observations suggest that increased *N*-POC concentration could contribute to the hypercortisolaemia seen in depression.

Plasma dexamethasone concentrations were similar in depressed patients and normal subjects, implying that the end result of dexamethasone absorption and metabolism is not altered in depression, and therefore the reduced suppressive effect of dexamethasone on cortisol secretion may be mediated at the receptor level. To avoid these uncertainties, the 23:00 basal cortisol concentration seems to be a better index of hypercortisolaemia in depression.

This study showed no variation in cortisol or ACTH concentrations which were related to melancholia, 'endogenicity' or to HRS score. Disagreement in the literature could be due to differences in populations studied (for example, this population consists predominantly of patients with 'endogenous' depression of moderate severity) and to differences between hormone assay systems.

It has been suggested by Gold (1985) that CRF hyperactivity underlies the hypercortisolaemia associated with depression. Gold proposes a model of sequential changes in the hypothalamo–pituitary–adrenal axis whereby tonically elevated CRF causes initial ACTH hypersecretion, resulting in adrenal hypertrophy. Following this, cortisol feedback causes normalisation of ACTH secretion, which then produces elevated cortisol from enlarged adrenals. No time-scale is suggested for these changes but it may be anticipated that patients with a short history of depression would have higher ACTH concentrations than those with a long history. We tested this hypothesis using a retrospective analysis of casenotes to determine the duration of depressive illness at the time of endocrine testing. There were 18 sets of casenotes suitable for this analysis. Length of illness varied from 3 weeks to 10 years. We analysed the data to determine whether length of illness was correlated with ACTH at any time-point, and we found no such relationship. Therefore this finding does not provide support for the hypothesis of Gold (1985).

This study defines a group of depressed patients with reduced diurnal rhythmicity of cortisol and another, overlapping, group with ACTH resistance to dexamethasone suppression. The hypercortisolaemia associated with depression is not mediated by ACTH alone, and the nature of its pathophysiology remains to be elucidated.

Depression Assessment in Brazil
The First Application of the Montgomery-Åsberg Depression Rating Scale

L. DRATCU, L. da COSTA RIBEIRO and H. M. CALIL

Cross-cultural investigation in psychiatry is revealing the need for standardised instruments in diagnosing and assessing depression. Recently, a new instrument was developed to evaluate depressed patients, namely the Montgomery-Åsberg Depression Rating Scale (MADRS). The present study introduced the MADRS in Brazil, comparing it to the Hamilton Depression Rating Scale, the Visual Analogue Mood Scale (a self-rating scale), and with the global clinical assessment of independent Brazilian psychiatrists. The results show correlation between MADRS and the three other assessments, indicating that it is a useful and operational instrument to evaluate depressed patients. They also support the application of the MADRS in cross-cultural studies of depression in Brazil and other countries. These results are critically discussed.

Adequate epidemiologic data are necessary for planning mental health care programs (Sartorius, 1976). Thus, standardised diagnostic criteria and rating scales seem to be operational instruments, as they allow a common language between researchers and practitioners, as well as comparative studies of mental diseases in different cultural settings (Jablensky *et al*, 1981; Sartorius *et al*, 1983).

Cross-cultural studies have revealed that depressive disorders constitute a public health problem in most societies. However, there is still little coordination among the various institutions and workers in this field (Sartorius, 1974; Jablensky *et al*, 1981). Thus, the introduction of cross-culturally applicable methods, such as depression rating scales (Hamilton, 1960, 1967; Beck *et al*, 1961; Zung, 1965; Carney & Sheffield, 1972; Folstein & Luria, 1973) would allow the conjugation of efforts in several countries. Since its introduction, the Hamilton Depression Rating Scale (HDRS) has had a widespread use and has been considered a standard instrument to assess depressive symptoms, and even to compare with other rating scales (Carroll *et al*, 1973). A few cross-cultural studies have analysed rating scales performance in different societies (Zung, 1969; Åsberg *et al*, 1973).

The Comprehensive Psychopathological Rating Scale (CPRS) is a rating scale, recently elaborated, to be sensitive to changes in symptoms induced by several psychiatric treatments (Åsberg *et al*, 1978). It was applied to English and Swedish patients (Montgomery *et al*, 1978), the most frequent symptoms of primary depressive disorders were identified, and finally rearranged as the Montgomery-Åsberg Depression Rating Scale (MADRS) (Montgomery & Åsberg, 1979). Therefore, the MADRS cross-cultural English and Swedish roots suggest its adequacy for studies on depression in different societies. Thus, it was applied to a Brazilian depressed population, and its performance compared with those of the HDRS, the Visual Analogue Mood Scale (VAMS), and the global clinical assessment (Dratcu *et al*, 1985).

The present paper reports on further data from the first application of the MADRS in Brazilian depressed patients, comparing its performance with those from the HDRS and VAMS. Furthermore, the rating scales evaluation will be compared with the independent clinical assessment of depression prevalent in a group of Brazilian psychiatrists.

Method

The study was carried out at the Department of Psychiatry and Medical Psychology, Hospital do Servidor Público Estadual "Francisco Morato de Oliveira", São Paulo, where there are three care modalities: in-patient, day-hospital and out-patient facilities.

Subjects were patients consecutively admitted by the staff-psychiatrists to the three care facilities, during a 6-month period, and diagnosed as depressed according to several clinical criteria. Their treatment and prescription were the staff-psychiatrists' responsibility. Those who, after being informed, consented to participate in the study were re-evaluated, within 1 week of admission, by two trained and independent psychiatrists. A total of 40 patients (60–70% of the interviewed depressed patients) met the criteria for Major Depressive Disorder (MDD) of the Research Diagnostic Criteria (RDC; Spitzer *et al*, 1980).

The re-evaluation interview, lasting an average of 75 min, included the application of three depression rating scales

Table I

Mean scores ± s.d. and variation range (in parens) of MADRS, HDRS, and VAMS of depressed patients

	MADRS	*HDRS*	*VAMS*
Evaluation			
First	38.5 ± 8.1	31.2 ± 6.1	20.7 ± 22.6
($n = 40$)	(23–55)	(12–41)	(88–0)
Second	12.9 ± 16.1*	12.0 ± 12.9*	61.5 ± 31.4**
($n = 10$)	(02–51)	(03–43)	(91–00)
Possible variation	0–60	0–52	100–0

The first evaluation was carried out within 1 week from beginning of treatment ($n = 40$), whereas the second ($n = 10$) occurred after week 4 of antidepressant therapy or at the end of an ECT series. Paired t-test, one-tailed of first and second evaluations: (*$P \leqslant 0.001$; **$P = 0.005$).

Table II

MADRS, HDRS and VAMS mean scores ± s.d. of depressed patients (n = 40) admitted, according to clinical assessment, to the hospital, day-hospital or out-patient clinic

	Hospital *(n = 18)*	*Day-hospital* *(n = 5)*	*Out-patient clinic* *(n = 17)*
MADRS	45.2 ± 5.6	36.0 ± 4.9*	32.2 ± 4.3*
HDRS	36.2 ± 3.3	27.4 ± 3.4*	27.1 ± 5.0*
VAMS	13.9 ± 19.1	17.8 ± 21.3	28.6 ± 23.8

Duncan's multiple range test showed difference between day-hospital and out-patient clinic groups compared with the hospital group (*$P < 0.01$)

to the patients who met the RDC criteria for depression: Montgomery-Åsberg Depression Rating Scale (MADRS), Hamilton Depression Rating Scale (HDRS) and a self-rating scale, the Visual Analogue Mood Scale (VAMS). A second re-evaluation (clinical global assessment and the three rating scales application), of ten of the 40 patients, was carried out 4 weeks from the beginning of antidepressant treatment or at the end of an electroconvulsive therapy (ECT) series.

The scores of the three rating scales were analysed taking the group mean and the standard-deviation. Correlation between the scales scores was obtained with the Pearson's correlation coefficient. MADRS, HDRS and VAMS mean scores from in-patient, day-hospital and out-patient groups were compared with the Duncan's Multiple Range Test (Steel & Torrie, 1960).

Results

Of the total 40 patients with the RDC diagnosis of Major Depressive Disorder (MDD), 30 were women and 10 were men. Their mean age was 53 ± 12.9 years (± standard deviation, s.d.), and ranged from 23 to 77 years. The subtypes of MDD were: primary ($n = 37$), secondary ($n = 3$), recurrent ($n = 17$), psychotic ($n = 8$), incapacitating ($n = 29$), endogenous ($n = 39$), agitated ($n = 11$), retarded ($n = 23$), situational ($n = 10$) and simple ($n = 37$). Eighteen were in-patients, five were being treated at the day-hospital facility, and seventeen were attending the out-patient clinic.

The mean scores of the rating scales at the first re-evaluation ($n = 40$) as well as the possible variation range, are shown in Table I. The highest MADRS and HDRS scores point towards a more severe depressive symptomatology, whereas the VAMS scores go the opposite way: lowest scores rate indicates worst mood. The MADRS mean score was 38.5 ± 8.1 (s.d.), with a variation from a minimal score of 23 to a maximal score of 55. The HDRS mean score was

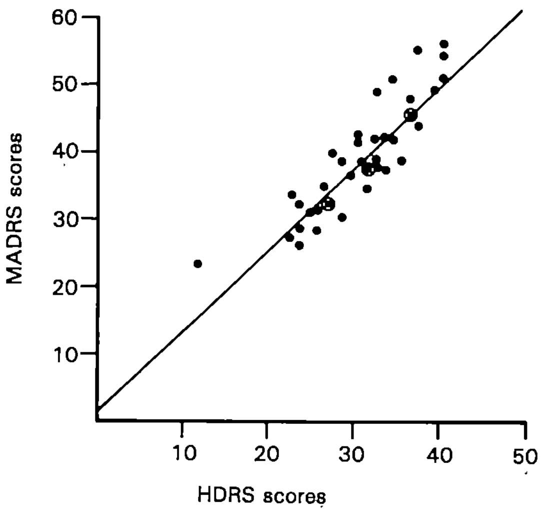

Fig. 1 Correlation ($r = 0.89$, $P < 0.01$) between the total scores of 40 patients assessed with the Hamilton Depression Rating Scale (HDRS), and the Montgomery-Åsberg Depression Rating Scale (MADRS).

31.1 ± 6.1 (s.d.); the lowest score was 12, and the highest 41. The VAMS mean score was 20.7 ± 22.6 (s.d.), with scores ranging from 88 through 0 mm. The correlation between MADRS and HDRS scores was positive and significant ($r = 0.89$, $P < 0.01$) and is shown in Fig. 1. The correlations between MADRS and VAMS, and HDRS and VAMS were, as expected, negative and significant ($r = -0.41$, $P < 0.02$; $r = -0.50$, $P < 0.01$, respectively).

The MADRS, HDRS and VAMS mean scores from the second re-evaluation ($n = 10$) are also shown in Table I. The scores obtained with the three scales were different from those of the first re-evaluation (paired t-test, one-tailed, MADRS: $t = 5.13$, HDRS: $t = 5.00$; VAMS: $t = 3.20$; $P \leq 0.005$) although the highest scores of the variation range remained almost the same. There was a significant and high correlation between the three scales scores: MADRS × HDRS ($r = 0.996$, $P < 0.01$) MADRS × VAMS ($r = 0.919$, $P < 0.01$) and HDRS × VAMS ($r = -0.925$, $P < 0.01$).

The MADRS and HDRS mean scores of the in-patient group were significantly higher than those obtained from the day-hospital and out-patient groups (Duncan's Multiple Range Test, $P < 0.01$) (Table II). There were no significant differences between MADRS and HDRS mean scores of day-hospital and out-patient groups, although the day-hospital group mean scores were higher than those of the out-patient group. The VAMS mean score of the in-patient group was lower than those of the day-hospital and out-patient groups, but these differences also did not reach statistical significance.

Discussion

The sex and age characteristics of the depressed patient sample studied correspond to those reported in the classical psychiatric literature.

All the patients, except one, met the RDC criteria for the endogenous subtype of Major Depressive Disorder. In fact, a careful analysis and the practical application of these diagnostic criteria led to the observation of an overlap of them for the diagnosis of Major Depressive Disorder and its endogenous subtype. Both the RDC and the Diagnostic and Statistical Manual of Mental Disorders, (3rd edition) (DSM-III, American Psychiatric Association, 1980) still constitute matter of discussion and controversy, and should not be used as a 'gold standard' for diagnosis (Klerman *et al*, 1984). It is feasible that the staff-psychiatrists have emphasised the features of endogenicity in diagnosing depression, as they are closer to the classical description of melancholia. Thus, non-endogenous depressed patients might have been previously excluded from this study. In addition, almost half of these patients had been admitted to the hospital, probably because they were considered by the staff-psychiatrists as severely depressed. Therefore, this study have included patients with more severe depression, perhaps due to the endogenous features of their depressive disorders. Anyway, the experimental design (double diagnostic selection), and the results found (sex and age distribution, predominance of endogenous depression, and high HDRS mean score) point towards the reliability of the diagnosis of depression.

The high correlation between MADRS and HDRS scores indicates that both scales are equally consistent instruments to evaluate the intensity of depressive symptoms. However, some differences between them seem important. The HDRS has 17 items while the MADRS only has 10, and is apparently simpler. Every MADRS item rates on a 6-point scale, and there are intermediate points between them. Thus, the rater has more flexibility to assess and decide on the rating of those symptoms which do not correspond exactly to those described. Furthermore, the MADRS discriminates between observed and reported symptoms avoiding doubts which could mislead the evaluation. In addition, the MADRS does not emphasise somatic symptoms as much as the HDRS does, therefore minimising the interference of organic disfunctions or treatment side-effects. Finally, the MADRS does not present contradictory items, such as those found in the HDRS (e.g. inhibition and agitation), which make virtually impossible the maximal score (52 points). The HDRS highest score in this study was 41 (79% of the maximal possible score), whereas the MADRS highest score was 55 (92% of the maximal possible). Some of these HDRS limitations have been already observed, discussed, and modifications made to improve it (Bech *et al*, 1981; Miller *et al*, 1985). Thus, the MADRS would be more sensitive to subtle and earlier changes in symptoms. In fact, it might contribute to its capacity to evaluate treatment responses, specially of severely depressed patients, with a higher precision and precedence. It confirms its sensitivity to treatment-induced changes in symptoms, the main purpose of the scale developers (Montgomery & Åsberg, 1979).

The negative correlation between the VAMS and the Montgomery-Åsberg and Hamilton Scales, applied by the raters, indicates that both follow the patients self-rating. However, the high self-rating standard deviation value reveals the individual variability, as the way of filling in the VAMS differs from one patient to the other.

There was a decrease in intensity of symptoms, as might have been expected, in the mean scores of the three scales applied to ten of the 40 patients during the post-treatment re-evaluation. Eight patients improved with tricyclic antidepressants or electroconvulsive therapy, whereas the remaining two (one received an antipsychotic, and the other nomifensine) did not. Consequently, their MADRS and HDRS scores have not changed. It explains the practically unchanged high value of the variation range as well as the high standard deviation.

The higher correlation between the scales found at the re-evaluation was obviously due to the decrease of number and intensity of the remaining symptoms. Therefore, the three scales were sensitive enough to evaluate treatment-induced changes. Nevertheless, the MADRS and the HDRS seem to offer advantages, as they allow to a better quantification of these changes.

The global clinical assessment of depression is reflected on the staff-psychiatrists' choice of the treatment care program. The patients considered as severely depressed were admitted to the hospital, those with a moderate depression were admitted to the day-hospital, and those with a mild depression were followed at the out-patient clinic. The MADRS, HDRS and VAMS scores accompanied the staff-psychiatrists clinical assessment, as the rated symptoms intensity was indeed in the same order of patients grouping. The mean scores differences did not reach statistical significance for all the groups probably because of the limited sample size. Thus, if the sample size were increased, the found correlation between the global clinical assessment and the three rating scales scores would become more evident.

Finally, the Montgomery-Åsberg Depression Rating Scale, as adequate as the Hamilton Depression Rating Scale, was a useful instrument to assess depression in a Brazilian depressed population sample, in spite of having been developed in an European context. Furthermore, it has some practical advantages, such as higher simplicity, specificity and sensibility than the HDRS. Therefore, it might be considered a valid instrument for research information exchange, as well as for cross-cultural studies on depression in Brazil and other countries.

Mental Health and Psychological Well-being Among the Old and the Very Old Living at Home

K. MORGAN, H. M. DALLOSSO, T. ARIE, E. J. BYRNE, R. JONES and J. WAITE

Using four brief assessment scales, profiles of mental health and psychological well-being were obtained from 507 old (aged 65-74 years) and 535 very old (aged 75+) individuals randomly sampled from the community. Assessments of dementia and depression were subsequently validated against diagnostic ratings made by experienced psychogeriatricians. Levels of agreement between psychometric and clinical ratings of dementia ($\kappa=0.83$) and depression ($\kappa=0.66$) were satisfactory. The old and very old groups reported similar levels of anxiety and personal disturbance, and showed a similar prevalence of depression. However, those aged 75+ showed higher levels of dementia and significantly lower levels of social involvement and morale.

Epidemiological studies of mental disorders among the elderly are becoming increasingly important in guiding policy making and service provision (Kay & Bergmann, 1980; Arie & Jolley, 1982; Henderson & Macfadyen, 1985). Instruments for assessing mental health in the aged vary greatly in content, detail, and administration time, but it is generally agreed that brief screening tests are clinically useful in case identification and in monitoring change over time in known cases (Hinton & Withers, 1971; Gurland, 1980; Blessed, 1985). In the present study extensive use has been made of brief rating scales to assess cognitive and affective status and social functioning in a large representative sample of elderly individuals living in the community.

While there is broad agreement concerning the value of screening for mental disorders among the elderly, there appears to be less agreement concerning the appropriate age structure of target populations for such assessments. It is widely acknowledged that the group traditionally defined as elderly (i.e. that section of the community at or above statutory retirement age) is neither clinically nor socially homogeneous. When such a group is further divided into older and younger subgroups, dementing illness (e.g. Kay & Bergmann, 1980), social deprivation (e.g. Abrams, 1978) and dependency (e.g. Hunt, 1978) are more common among the 'older' elderly. Nevertheless, in only a small minority of epidemiological studies in geriatric psychiatry are the old, and the very old considered separately (see Kay & Bergmann, 1980; Henderson, 1986). Rather, descriptive statistics are frequently reported only for a single group comprising all those above a criterion age, usually 60, 65 or 70 years. In Britain, data from the 1981 census show 4.93 million individuals aged 65-74 years compared with 3.05 million aged 75 years and over - an old to very old ratio of 1.62:1 (OPCS, 1983). Simple random selection of those over the age of 65 years ensures that the oldest and most dependent individuals are numerically under-represented. Selection of the present sample, therefore, was such as to allow those aged 65-74 years, and those aged 75 years and over to be equally represented.

In addition to the assessment of mental health the present survey also focused upon morale and social functioning, with the intention of constructing a multidimensional profile of 'psychological well-being' for each respondent. This research forms part of a longitudinal project the principal aim of which is to evaluate relationships between levels of customary physical activity and well-being in old age. Assessments of mental competence, depression, life-satisfaction, and social functioning were accomplished using rating scales administered in the course of a structured interview. Standardised instruments were used wherever possible, and psychometric ratings of mental competence and mood were subsequently validated against diagnostic ratings made by experienced psychogeriatricians. In this paper, we present evidence for the reliability and validity of the brief assessment scales and describe (a) the prevalence of psychiatric disorders, and (b) variations in psychological wellbeing and social functioning within representative samples of 'young' old and very old elderly individuals living at home.

Method

Instruments

Mental competence was assessed using the 12-item Information/Orientation scale from the Clifton Assessment Procedures for the Elderly (CAPE: Pattie & Gilleard, 1979). Although originally developed for use in institutional settings (Pattie & Gilleard, 1975, 1976) this scale has been successfully employed in surveys of the elderly at home (Clarke *et al*, 1984). To improve social acceptability in the present study, items 1-6 of the scale (e.g. name, address, date of birth) were presented at the beginning of the interview, while the remaining items (e.g. name of the British Prime Minister, name of the US President) were presented later, when a rapport between interviewer and respondent had developed. If any of the first six items were incorrectly answered, however, the interviewer was instructed to continue immediately with items 7-12. The scale yields a maximum score of 12. Scores of 7 and below are associated with dementia or acute organic brain syndrome (Pattie & Gilleard, 1979). If, after appropriate prompting, the respondent failed to achieve a minimum Information/Orientation score of 8 and, in the opinion of the interviewer, was unlikely to respond reliably to the remaining questionnaire items, the interview was discontinued.

The Symptoms of Anxiety and Depression scale (SAD: Bedford *et al*, 1976) was used to assess functional mental disorders. Derived from the Delusions, Symptoms and States Inventory (Foulds & Bedford, 1979), the SAD scale focuses exclusively on recent symptomatology and comprises two subscales of seven items relating to depression and anxiety respectively. Items are scored 0, 1, 2 and 3 according to the degree of personal disturbance reported for each (i.e. none, a little, a lot, and unbearable respectively). In non-elderly populations, Bedford *et al* (1976) suggest that an overall score of 6 or more indicates psychiatric illness, while scores of 4 or more on either the depression or anxiety subscales indicate membership of that set. The SAD scale has previously been used as a screening instrument for functional disorders among the very elderly (McNab & Philip, 1980).

Measurements of morale were provided by Wood *et al*'s (1969) 13-item version of Neugarten *et al*'s (1961) Life Satisfaction Index (the LSIZ). To improve comprehension of this American scale in a British sample, the word form of some of the items was, in the present study, slightly modified (for example item 2 "I have gotten more of the breaks in life than most of the people I know" was changed to "I have had more chances in life than most of the people I know"). Scores of 2 for a 'right' answer, 0 for a 'wrong' answer, and 1 for a 'don't know' were assigned to each item (see Wood *et al*, 1969).

Of particular interest in the present study was the degree to which elderly individuals engage actively (e.g. voting, going on holiday) or symbolically (e.g. watching television, listening to the radio) in the social milieu. In the absence of a standardised instrument for assessing social functioning a Social Engagement Scale was developed as follows. Items judged relevant to the assessment of social involvement were included in the structured interview. Of these items 13 were derived from a prototype scale the validity and reliability of which is described elsewhere (Morgan *et al*, 1985). All items were dichotomously scored, 1 for a positive response and 0 for a negative response. Items were then removed from the scale (a) if positive answers were obtained from less than 2% of the survey population (i.e. if that item showed too little variance) and (b) if it correlated less than 0.2 with the sum of the remaining items, and its removal substantially increased the value of the reliability coefficient alpha (Cronbach, 1951). This procedure resulted in the 20-item scale shown in Table I.

TABLE I
Social Engagement Scale items (abbreviated)

1. Has access to a telephone
2. Has made a personal telephone call in the last week
3. Reads a newspaper or magazine
4. Attends religious services, gatherings, or meetings
5. Voted in the last general/local/European election
6. Has been away on holiday in the last year
7. Is planning to go on holiday within the next year
8. Uses public library
9. Attends meetings of clubs, societies etc.
10. Has senior citizen's rail card
11. Has access to a car
12. Has television and radio
13. Is employed or engaged in voluntary work
14. Has sufficient contact with family and friends
15. Shares accommodation
16. Is mobile (ambulant/non-ambulant)
17. Gets out and about as much as desired
18. Has one or more friends in district
19. Is infrequently lonely
20. Knows at least one person to approach for help

The sample

The survey was conducted in three geographically separate districts of Nottingham each within the psychogeriatric catchment area of the University Department of Health Care of the Elderly. Prior demographic analyses had established that the age, sex, and social class structure, and the proportion of the elderly individuals living alone within the survey area as a whole showed no significant departure from the national pattern as described by the 1981 census (OPCS, 1983). With the consent and cooperation of general practitioners a register of elderly persons living within the survey area was compiled from patient records maintained by the Nottinghamshire Family Practitioner Committee. All general practitioners with surgeries in the three survey areas cooperated. In this way a total population of 8409 individuals aged 65 years and over (4856 aged 65-74 years; 3553 aged 75+ years) was registered, representing the combined patients of 25 general practitioners in nine practices. While practice and census ward boundaries do not necessarily coincide, the number of elderly individuals identified in the survey area closely approximated the number provided by the 1981 census. Equal probability

Interviewed sample	507	535	406	636	1042

target samples were then selected from the old (i.e. those aged 65–74 years) and the very old (i.e. those aged 75 years and over) subpopulations. Those in institutional care were excluded from the target sample. As the intention was to interview approximately 500 individuals from both subpopulations, the samples drawn were large enough to accommodate losses due to deaths, migration, etc.

Procedure

Interviews were conducted between 7 May and 24 September 1985 by ten women aged 27–56 years. Each interviewer received 2 weeks of intensive classroom based training, and a further 2 weeks of close supervision in the field. Before being interviewed respondents were first contacted by letter and invited to participate in the survey. After a minimum of 3 clear days, each was then visited by an interviewer. The structured questionnaire contained a total of 318 items covering aspects of health and lifestyle and with the consent of the respondent, was followed by measurements of right and left handgrip strength, weight, shoulder flexibility, and stature. Previous experience had shown that interviews could be completed in 30–90 minutes.

Validation of dementia and depression ratings

In order specifically to assess the accuracy of psychometric classification in the present study, and generally to assess the value of the Information/Orientation and SAD scales as screening instruments, selected ratings of dementia and depression were subsequently validated against clinical diagnoses. On completion of the survey respondents were classified as (a) Cognitively Impaired, (b) Borderline Impaired, (c) Depressed, or (d) Normal. Classification was as follows:

(a) Using the cut-off point recommended by Pattie & Gilleard (1979) for identifying cases of dementia, respondents with an Information/Orientation score of $\leqslant 7$ were classified as Cognitively Impaired.

(b) Respondents with Information/Orientation scores of 8 or 9, and who were not rated as depressed (see below) were classified as Borderline Impaired. These Information/Orientation scores fall between the thresholds for impairment ($\leqslant 7$) and non-impairment (>10) suggested by Pattie & Gilleard (1979).

(c) Using the cut-off points suggested by Bedford *et al* (1976), respondents with a total SAD score of $\geqslant 6$, and a depression subscale score of $\geqslant 4$, and who were not rated as Borderline Impaired, were classified as Depressed. Effectively, this procedure identified those who showed significant personal disturbance characterised by symptoms of depression, but who were cognitively intact (fourteen respondents whose scores indicated both Depression *and* Borderline Impairment were unclassified. These individuals will be considered in a separate report.)

(d) Those with Information/Orientation scores of 10, 11 or 12, and who were not rated as depressed were classified as Normal.

Groups were then randomly selected to represent the Cognitively Impaired, Borderline Impaired, and Depressed classes. For the Normal (control) group, individuals were matched for age (+ or − 5 years) and sex with the Impaired group. Respondents thus selected were visited at home and clinically assessed by an experienced psychogeriatrician who was 'blind' to the survey classifications. Evidence for dementia or depression respectively was rated by each clinician on a 4-part scale as follows: 0 – No Evidence; 1 – A Little Evidence; 2 – A Lot of Evidence; 3 – Outstanding Evidence. If appropriate, ratings of severity were then completed and scored: 1 – Mild (dementia/depression); 2 – Moderate; 3 – Severe. Wherever possible clinical diagnostic assessments were carried out within 12 weeks of the original survey interview.

Results

The sample

Losses from the original target sample of 1599, mostly due to deaths and changes of address totalled 300, resulting in an effective target sample of 1299 individuals (see Table II). Of these, 1042 (507 aged 65–74 years; and 535 aged 75 years and over) were interviewed – a response rate of 80.3%. The age and sex structure of the interviewed sample is also shown in Table II.

Internal consistency of the assessment scales

All four brief assessment scales showed acceptable levels of internal consistency. α-Coefficients (Cronbach, 1951), and the number of respondents completing each scale were as follows: 12-item Information/Orientation Scale, $n=1022$, $\alpha=0.84$; 14 item SAD scale, $n=979$, $\alpha=0.85$; 13-item LSIZ, $n=986$, $\alpha=0.74$; 20-item Social Engagement Scale, $n=971$, $\alpha=0.70$.

Criterion validity of dementia and depression ratings

Clinical diagnostic ratings were obtained for 20 respondents classified as Cognitively Impaired, 14 classified as Borderline Impaired, 25 classified as Depressed, and 20 classified as Normal. The smallest group – Borderline Impaired – included all the respondents thus classified. The correspondence between survey classifications of Cognitive Impairment and Depression, and clinical ratings of

Cognitively Impaired (demented)	18 (0.28)	0	2 (0.03)
Depressed	3 (0.05)	16 (0.25)	6 (0.09)
Normal	0	1 (0.02)	19 (0.29)

Total $n = 65$

Overall agreement = 81.5%; $\kappa = 0.73$, $P < 0.001$

1. Mild, moderate, or severe

dementia (mild, moderate or severe) and depression (mild, moderate or severe) was assessed using the κ statistic (Cohen, 1960). Table III shows an overall level of agreement of 81.5% with a κ-coefficient of 0.73 ($P < 0.001$). Ratings of dementia and depression were then considered individually by collapsing these data into fourfold tables comparing the dichotomous categories of dementia/not dementia and depression/not depression. For dementia ratings, the analysis showed an overall agreement of 92.3% with a κ-coefficient of 0.83 ($P < 0.001$). Preliminary analyses of the survey and clinical ratings of depression showed that the cut-off scores suggested by Bedford *et al* (1976) possibly overestimate psychiatric morbidity in the elderly (see Table III). A higher cut-off score was therefore selected to reduce total misclassifications, namely, a total SAD score of $\geqslant 8$ with a depression subscale score of $\geqslant 6$. Using this adjusted threshold, clinical and survey ratings showed an overall agreement of 84.6% with a κ-coefficient of 0.66 ($P < 0.001$).

Rank order correlation coefficients showed a highly significant association between Information/Orientation scores in the combined Cognitively Impaired and Borderline Impaired groups, and clinical ratings of evidence for ($n = 34$, $\rho = 0.60$, $P < 0.001$) and severity of ($n = 34$, $\rho = 0.61$, $P < 0.001$) dementia. Within the Depressed group, survey scale scores and clinical ratings were less consistently associated. While a weak correlation obtained between overall SAD scores and clinical ratings of evidence for depression ($n = 25$, $\rho = 0.43$, $P < 0.05$), the correlation between SAD scores and ratings of the severity of depression failed to reach significance ($n = 25$, $\rho = 0.32$, $P = 0.08$).

Prevalence of dementia and depression

When, for the purposes of statistical description, the old and the very old subgroups were combined, the older subgroup was appropriately weighted so that the age structure of the combined subgroups approximated that of a true (i.e. non-stratified) random sample. The weighted distribution of Information/Orientation scores is shown in Table IV. Evidence of significant cognitive impairment, as defined by a scale score of 7 or less was present in 3.2% of the weighted sample. The distribution of Information/Orientation scores above and below this cut-off point according to age and sex is shown in Table V.

The distributions of SAD anxiety and depression subscale scores are shown in Table VI and VII respectively. Combining both age groups, 9.8% of the weighted sample met the survey criteria for a psychometric classification of depression (a total SAD score of $\geqslant 6$, and a depression subscale score of $\geqslant 4$). Within the older and younger subgroups 10.0% of those aged 65–74 years, and 9.5% of those aged 75+ were classified as depressed. Using the more conservative criteria which had maximised agreement between clinical and survey ratings (namely a total SAD score of $\geqslant 8$, with a depression subscale score of $\geqslant 6$), 4.9% of the weighted sample were classified as depressed – 4.5% of those aged 65–74 years, and 5.5% of those aged 75 years and over. Total SAD scores for the older and younger subgroups, compared using the Mann-Whitney statistic (Siegel, 1956), showed no significant difference ($Z = 0.94$, $P = 0.34$).

*$P<0.05$; **$P<0.001$

−0.39 respectively). Nevertheless, while scores tended to cluster at the higher end of the distribution (i.e. greater Life Satisfaction and more Social Engagement) the Life Satisfaction Index was active throughout its range, and scores on the Social Engagement Scale ranged from 2 to maximum. Total scale scores for the age subgroups 65–74 and 75 years and over were compared using the Mann-Whitney statistic. For both Life Satisfaction ($Z=2.18$, $P<0.05$) and Social Engagement ($Z=9.12$, $P<0.001$) scores were significantly higher in the younger subgroup (Table VIII). As regards Life Satisfaction, Table VIII also provides normative data for a British sample for this variant of the widely used Life Satisfaction Index.

Relatively strong correlations obtained between Life Satisfaction and Social Engagement scores ($\varrho=0.49$, $P<0.001$), and also between Life Satisfaction and SAD scores ($\varrho=-0.49$, $P<0.001$). While significant, the correlation between engagement and SAD scores was rather modest ($\varrho=-0.27$, $P<0.001$).

Discussion

Satisfactory response rates, calculated as a percentage of the effective sample (see Table II) were achieved for both the old (80.1%) and the very old (80.5%) subgroups. Of the 257 individuals who refused to be interviewed 108 (42%) returned short postal questionnaires which had requested information on their marital status, health status, occupation (or husband's occupation) before retirement, and reasons for refusing. Insufficient time, a desire for privacy, and lack of interest were the most frequently expressed reasons for not wishing to participate in the study. Overall, results from these postal questionnaires provided no evidence that the cognitively or physically impaired were over-represented among the interview refusals.

All four psychometric scales displayed levels of internal consistency consonant with their use as survey instruments. Both the Information/Orientation and SAD scale classifications showed significant levels of agreement with clinical ratings of dementia/not dementia and depression/not depression respectively. Concordance between survey and clinical ratings of Cognitive Impairment-Dementia were particularly high. Only two of the 20 individuals in the Cognitively Impaired class were rated 'not demented' by the clinicians (see Table III). Of these two, one, a man aged 71, was described by the psychogeriatrician as 'educationally subnormal'. The only other misclassification was a woman aged 83 with an Information/Orientation score of 7. Fourteen individuals were classified as Borderline Impaired and of these, nine (64.3%) were subsequently rated as demented (eight as 'mild' and one as 'severe') by the clinicians. A high level of dementia in this class was not unexpected. The Borderline Impaired group included those individuals for whom, on the basis of their Information/Orientation scores, serial re-assessment is recommended in order to "... clarify diagnostic uncertainty" (Pattie & Gilleard, 1979). Our findings support this recommendation. The relationships shown here between survey classifications of Cognitive/Borderline Impairment and clinical ratings of dementia indicate that the 12-item Information/Orientation scale can effectively identify cases and probable cases of dementia among the elderly living at home.

Relatively lower levels of agreement were found between survey classification and clinical ratings of depression. In part, this may have been due to the sometimes lengthy interval between the administration of the SAD scale, with its emphasis on recent symptomatology, and subsequent clinical assessments. While most of the clinical assessments were conducted within 3 months of the original survey interview, a minority were conducted some 4 months later. There was evidence in the present study that concordance between survey and clinical ratings of depression was related to the degree of personal disturbance originally reported, suggesting that the stability of depressive states over time may be related to severity. Overall SAD scores among those for whom survey and clinical ratings of depression were concordant ($n=16$, mean SAD score $=16.8$) were significantly higher than those for whom survey and clinical ratings were discordant ($n=9$, mean SAD score $=12.3$; Mann-Whitney $Z=1.93$, $P=0.05$). Nevertheless, the scale used in the manner described here identified clinically significant depression in this elderly community sample with a probability well above chance.

Table V shows a weighted overall prevalence rate of cognitive impairment/dementia of 3.2%. Given that 64.3% of those with borderline Information/Orientation scores of 8 or 9 were subsequently rated as demented by psychogeriatricians, the 'true' prevalence of dementia falls within the score range 7–9 which, in the present study, includes between 3.2% and 5.0% of the sample (see Table IV). Adding the Borderline Impaired individuals who were clinically rated as demented ($n=9$ to those whose Information/Orientation score was $\leqslant 7$ yields a weighted overall prevalence estimate of 4.3% (2.4% of the men, and 5.5% of the women). This estimate falls between the rates of 'pervasive dementia' reported by Gurland *et al* (1983) for similar samples of elderly people living at home in London (2.3%) and New York (4.9%). In both age subgroups the present data show a higher prevalence of impairment among females. While this may result from selective institutionalisation, future clinical studies will examine the possibility of a genuine sex difference in prevalence.

The overall weighted prevalence of depression (9.8%) found in the present study also approaches the rates of 'pervasive depression' reported by Gurland *et al* (1983) for their London (12.4%) and New York (13.0%) samples. In contrast with the findings of Kay *et al* (1985) for a community sample in Hobart, Tasmania, we found little difference in the prevalence of depression between the younger and older subgroups. However, when the SAD cut-off points were raised to include only those (presumably more severe cases) with a total score of $\geqslant 8$ with a depression subscale score of $\geqslant 6$, a greater prevalence among those aged 75+ did emerge (4.5% versus 5.5%).

While the old and the very old subgroups showed similar levels of depression, anxiety, and overall 'disturbance', life satisfaction was significantly lower among those aged 75+. Nevertheless, the significant correlation between SAD and LSIZ scores does indicate that the scales assess some common aspects of well-being. Levels of social engagement were also significantly lower among the older subgroup. It is interesting to note that the strong correlation between social engagement and LSIZ scores is consistent with an activity-affect relationship in old age. That the correlation between the engagement and total SAD scores was relatively weaker further suggests that the influence of this relationship does not extend equally to all domains of psychological well-being. As expected, increasing levels of psychiatric disturbance (as measured by the total SAD scores) were associated with decreasing levels of morale.

The present study has demonstrated the usefulness of four brief assessment scales in providing a profile of psychological well-being in the old and the very old living at home. In addition the survey, conducted within a defined psychogeriatric catchment area, provided information of immediate value to the clinical department of Health Care of the Elderly. Two cases of severe dementia with no previous contact with primary care services were referred to general practitioners following research clinical assessment by psychogeriatricians. A further two cases of depression were similarly referred. Thus, the present study illustrates the value of screening elderly populations and also emphasises the benefits of combining clinical and research interests in screening programmes.

Acknowledgements

Thanks are due to Dr E. Joan Bassey, Ann Terry, and Ursula Harries for their assistance in piloting the questionnaire. The Activity and Ageing Research Group is supported by the Grand Charity. Copies of the Life Satisfaction Index and the Social Engagement Scale used in this study are available on request.

Comparison of the Sensitivity of Three Instruments for the Detection of Cognitive Decline in Elderly Living at Home

A. LITTLE, D. HEMSLEY, K. BERGMANN, J. VOLANS and R. LEVY

We followed up 181 elderly living at home over 2 years. The changes shown on a brief dementia rating scale (the Abbreviated Mental Test Score (AMTS)) were monitored. At follow-up, subjects were classified as organic or non-organic by three potential screening tools – a screening questionnaire (the Psychogeriatric Assessment Schedule), a psychometric test (the Inglis' Paired Associate Learning Test) and a dementia scale (the AMTS). The value of these as screening tools for community samples was considered as a function of their sensitivity to cognitive decline. The classifications made by each were significantly related to previous cognitive change, but all were conservative, missing many subjects who had declined. Of the three, the AMTS appeared the most useful as a predictor of previous change on the AMTS. It remains to be seen whether it is equally useful with different samples and with different measures of outcome.

There is a pressing need for an economical and acceptable screening tool to identify elderly living in the community who have senile dementia (Cooper & Bickel, 1984; Henderson & Huppert, 1984). Kay *et al* (1964) established that most demented elderly live outside hospital or residential care, and the alarmingly high prevalence of this disorder among the community elderly has been confirmed by most studies (Kay & Bergmann, 1980; Henderson & Kay, 1984). Unfortunately these cases may be poorly recognised (Williamson *et al* 1964; Parsons, 1965; Williams *et al*, 1972) and often relatives/friends bear the brunt of care with inadequate support from the services (Gilhooly, 1984). Bergmann (1979) suggests that more timely identification and support might enable the community to accommodate the demented person for longer and thus reduce demands on over-stretched services.

Recognition of senile dementia at an early stage is a difficult undertaking. The demented patient shows changes in cognition, affect and behaviour which are hard to differentiate from those observed in normal ageing or other age-related conditions. There appears no obvious boundary between normal and abnormal ageing. Kral (1962) proposed that not all cognitively impaired elderly show 'malignant' (i.e. progressive) change, although his concept of 'benign senescent forgetfulness' has yet to be validated. Furthermore, physical and affective illness and non-progressive organic brain disease can produce changes in the elderly similar to those observed in dementia although very different in outcome. Cases of dementia may be best distinguished by the rate of changes shown (Whitehead, 1976). Thus, within clinical samples, the diagnostic sensitivity of psychometric tests is improved with repeated assessment over brief time intervals (e.g. Walton, 1958).

Serial assessment is an expensive undertaking, so for community screening, cases will have to be identified on the basis of current levels of function, from which previous deterioration is presumed. Most community studies have relied upon clinical interviews (structured or unstructured) to identify cases. This is expensive and may be of dubious validity. Recent community studies following up clinically diagnosed cases suggest that many show outcomes inconsistent with the original diagnosis (Gurland *et al*, 1982, 1984). This is particularly true for early cases (Bergmann *et al*, 1971). Studies have reported problems in applying the diagnostic criteria developed to establish differential diagnosis within clinical samples to case-identification in the community (Cooper & Schwarz, 1982; Gurland *et al*, 1982).

Alternative, less expensive methods of case-identification have been developed and used. These can be employed by non-medical personnel to identify possible cases which require clinical confirmation. These include structured screening interviews assessing several areas of function (e.g. Gurland *et al*, 1977–1978), dementia scales briefly quantifying mental status (e.g. Pattie, 1981) and informant ratings of self-care impairment and behavioural disturbance (e.g. Pattie, 1981). Other studies have employed psychometric tests developed to measure specific cognitive functions in clinical samples (e.g. Williamson *et al*, 1964).

There have been few attempts to establish or compare the sensitivities of these screening methods (cf. Milne *et al*, 1972). Most tools have been validated against clinical diagnosis only, often in situations where direct or indirect contamination could operate (Shapiro *et al*, 1956). This is unacceptable, given the problems of establishing diagnosis in community cases. Some have been validated only in clinical samples, despite important differences between community and hospital cases (Bergmann *et al*, 1979). The ultimate test of these tools is their ability to identify as cases those elderly showing the type and rate of changes characteristic of dementia.

The present study was undertaken to compare the sensitivity of three possible screening tools – a semi-structured screening interview (the Psychogeriatric Assessment Schedule (PAS) (Bergmann *et al*, 1975)), a dementia scale (the Abbreviated Mental Test Score (AMTS) (Hodkinson, 1972)) and a psychometric test of verbal learning and memory impairment (the Inglis' Paired Associate Learning Test (IPALT) (Inglis, 1958, 1959)). The PAS was developed for community screening. The AMTS was developed for screening geriatric in-patient samples but has been used with samples in residential care (e.g. Brocklehurst *et al*, 1978). The IPALT is not a screening tool as such but has been used to quantify cognitive impairment in community studies (e.g. Williamson *et al*, 1964). (No informant-assessment was included because of the difficulties of finding reliable informants in elderly community samples (Kay, 1977)). The sample collected (elderly subjects living at home, identified from their general practitioners' lists) is representative of community populations that researchers or clinicians might wish to screen. The sensitivity and specificity of these tools were examined with regard to the cognitive changes shown over the preceding 2 years by the subjects. Sensitivity was defined as the proportion of subjects showing marked cognitive decline correctly identified as probably organic, specificity as the proportion of those showing no decline (or slight decline) correctly identified as probably non-organic.

Method

Tests used to classify subjects

Three different classifications of organic/non-organic were made: the PAS, the AMTS and the IPALT.

Psychogeriatric Assessment Schedule

The PAS is a semi-structured interview developed for use by non-medically qualified personnel to screen elderly samples. The interview used is a modification of an earlier schedule (Bergmann *et al*, 1975) and further details can be obtained from Dr Bergmann. Subjects are classified as probably normal, organic or functional. The organic classification is made in two stages. Firstly, subjects who rate their ability to care for themselves as poor and/or show impaired comprehension during the interview are given nine questions assessing memory and orientation, and rated from direct observation by the interviewer on three scales measuring behaviour indicative of organic impairment (impaired comprehension, puzzled appearance and lack of expression (Bergmann & Eastham, 1974)). Secondly, subjects who score below a validated cut-off point on these questions and ratings are classified as organic. Subjects classified as normal or functional were considered as non-organic for this study. This interview takes (on average) 15 minutes to complete.

Abbreviated Mental Test Score

The AMTS is a ten-item questionnaire assessing memory for recent and remote events, and orientation, developed by Hodkinson (1972) from a longer questionnaire based on that of Blessed *et al* (1968). Scores on the longer test are related concurrently to clinical diagnosis and prospectively to neuropathological and neurochemical indices of dementia (Blessed *et al*, 1968; Perry *et al*, 1978). Scores on the AMTS agree well with those on the longer questionnaire, and a validated cut-off score has been established by Hodkinson (1972) to classify subjects as organic/non-organic. Three items of the AMTS are identical to those included in the PAS. This test takes (on average) 5 minutes to complete.

Inglis' Paired Associate Learning Test

The IPALT provides a sensitive measure of verbal learning ability which is significantly related to clinical diagnosis in elderly psychiatric and geriatric patients (e.g. Inglis, 1958; Isaacs, 1962), and in clinical samples to outcome over periods of up to 5 years (e.g. Whitehead & Hunt, 1982). Subjects were required to learn the associations between three pairs of words (cup–plate; cat–milk; gold–lead) taken from the mediate pairs of Inglis (1959). Up to ten trials were given, and correct responses scored from 0 to 30 according to Whitehead (1971). There is no validated cut-off score for this test, so one was established from the present sample by taking all subjects with complete data (PAS, AMTS, IPALT) at follow-up ($n = 181$) and estimating the base rate of organic impairment from their PAS and AMTS scores. These tests identified 18% and 14% respectively of the sample as organic. The IPALT score giving the most similar proportion of organics was selected as the cut-off point. A score of 23 or less gave 18% of the sample as organic. This cut-off point was cross-validated by consideration of a second sample ($n = 147$) living in residential care. Using the same score, 28% of subjects were classified as organic, which agrees well with the 31% and 27% given as organic by the PAS and AMTS.

The IPALT takes (on average) 10 minutes to administer.

Assessments

All measures were gathered in the same interview (lasting around 30 minutes in most cases). Tests were always given in the order PAS, AMTS and IPALT. The three different interviewers (two State Registered Nurses and a clinical psychologist) were trained together and achieved perfect agreement at the end of training. No further assessment of inter-rater reliability was made.

Sample

This sample was gathered as part of a larger study examining the incidence and prevalence of cognitive impairment in the elderly living at home, for which all patients aged over 65 registered with a GP practice in South London were approached. There were 893 patients located, of whom 81 (9%) refused to be interviewed and 8 (1%) were too physically ill. The remaining 804 subjects were given the PAS and the AMTS and 746 (93%) finished the interview. A random sample of those classified as normal at interview by the PAS and all those classified as organic or functional were followed up 2 years later. The non-random follow-up was undertaken to ensure sufficient numbers of cases for statistical comparison. At follow-up 21 could not be traced and of the remaining 283, 59 (21%) were dead, 37 (13%) refused to be re-interviewed at all and 6 (2%) refused the AMTS or IPALT. This left 181 surviving subjects with complete data at follow-up.

At baseline these subjects were aged (± one standard deviation) 74.45 (± 6.34), and 69% were female, 31% male. Most were living with others (38% with spouses, 17% with family and 2% with friends). Of those living on their own the majority (74%) were in regular contact with friends or family. They scored (± one standard deviation) 7.76 (± 1.37) on the AMTS. Scores on this test ranged from 3 to 10.

Validation criteria

The classifications made by the three tests at follow-up were validated against the cognitive decline shown over the preceding 2 years. Cognitive decline was established from the change in performance on the AMTS from baseline. Since some cognitive decline might result from non-pathological age-related changes or from chance fluctuation in performance (attributable to imperfect reliability of the measure), an arbitrary cut-off was selected to classify subjects on the basis of change scores. A decline in score of one-fifth or more of the range of the test (scored 0 to 10) was taken as indicating a significant decline in performance. Thus those subjects whose scores had declined by 2 or more points during follow-up were classified as showing decline. All subjects scored over 2 at baseline, so no subject was unable to show decline because of floor effect. A check was made of this arbitrary cut-off by estimating the standard error of measurement of the AMTS using the equation of Payne and Jones (1957); that is, standard error of measurement = standard deviation $\times \sqrt{(1-r)}$, where r is a reliability coefficient of the test. The test–retest reliability coefficient over a 2-week period of 0.92 reported by Quershi & Hodkinson (1974) was substituted in this equation, together with the standard deviation of baseline scores from the present sample. This gave a standard error of measurement of ± 0.38. The cut-off change score selected (−2) falls outside the 99% confidence limits for scores on the test and so it most unlikely to occur by chance (presuming a normal distribution of change scores).

Results

At follow-up, the 181 subjects with complete data scored (± one standard deviation) 7.34 (± 2.27) on the AMTS and 25.07 (± 9.11) on the IPALT. Thirty-two (18%) were classified as organic by the PAS and 149 (82%) as non-organic. The intercorrelations between the three tests used to classify subjects are given in Table I. All correlations were significant, indicating that the three measures share variance.

TABLE I

Intercorrelations (Pearson-R) between the three tests used to classify subjects at follow-up

	Coefficient r^1		
	Entire sample (n = 181)	*Subjects showing no decline on the AMTS (n = 151)*	*Subjects showing decline on the AMTS (n = 28)*
PAS × AMTS	0.66	0.40	0.84
PAS × IPALT	0.54	0.35	0.54
AMTS × IPALT	0.77	0.65	0.70

1. All coefficients significant at $P \leqslant 0.001$.

Only 179 of these subjects had AMTS scores at baseline. The average change shown on the AMTS was (± one standard deviation) a decline of 0.39 (± 1.47); the change ranged from a decline of 6 points to an improvement of 2 points during follow-up. Comparing baseline and follow-up performance on this test, overall the sample showed a significant decline ($T = 3.51$; d.f. 178; $P \leqslant 0.001$). Twenty-eight subjects (16%) showed a decline of 2 or more points, the remaining 151 (84%) showed little change or an improvement in performance.

Classification of subjects as organic non-organic

Similar proportions of subjects were classified as organic by each of the three tests. Despite this, rather different subjects were identified as cases by each (Fig. 1). (Because of the small numbers in some cells the Venn diagram shown in Fig. 1 has not been drawn proportionately.) The three tests agreed in 82% of cases (all three classifying 73% of subjects as non-organic and 9% as organic). In the remaining 18% of cases the classifications made by one test disagreed with those made by the other two.

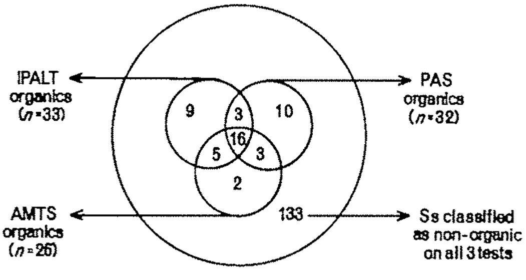

FIG. 1 Overlap of classifications made by the three tests at follow-up (Ss = subjects).

Sensitivity of each of the three tools to cognitive decline

When subjects classified as organic and non-organic at follow-up were compared, substantially more subjects in the organic group had declined over the previous 2 years (Table II). However, whereas only 20% of subjects classified as organic on the AMTS had not declined, about half of the PAS and IPALT organics showed no previous decline.

TABLE II
Relationship between classifications and cognitive change over the preceding 2 years

	Percentage showing decline on AMTS	*χ^2 (d.f. 1)*[1]
PAS organics	48%	27.54*
PAS non-organics	8%	
AMTS organics	80%	85.63*
AMTS non-organics	5%	
IPALT organics	53%	38.10*
IPALT non-organics	8%	

1. χ^2 (corrected for continuity) comparing the outcomes of organics and non-organics.
*$P \leq 0.001$.

The sensitivity and specificity of test classifications were examined with regard to the cognitive changes shown since baseline (Table III). Although specific (correctly identifying 89–97% of those who had not declined as non-organic), the tests missed many subjects who had declined (correctly identifying 54–71% as organic). The AMTS is the most sensitive and specific of the three. When the overall misclassification rates were considered (Goldberg, 1972), only 7% of the sample showed previous cognitive change inconsistent with their AMTS classifications. This figure rises to 15% and 17% for the IPALT and PAS respectively. The hits positive rate (Meehl & Rosen, 1955) represents the probability of previous cognitive decline for subjects classified as organic, taking into account the prevalence of decline in the sample. This is considerably higher for the AMTS (P = 0.82) than for either of the other two tests (P = c.0.50).

TABLE III
Sensitivity and specificity of classifications with regard to cognitive change over the preceding 2 years

	AMTS changes			
Test	*Sensitivity*[1]	*Specificity*[2]	*Overall mis-classification rate*[3]	*Hits positive rate*[4]
PAS	0.54	0.89	0.17	0.48
AMTS	0.71	0.97	0.07	0.82
IPALT	0.61	0.90	0.15	0.54

1. Proportion of subjects showing decline classified as organic.
2. Proportion of subjects showing no decline classified as non-organic.
3. Proportion of 'false positives' (i.e. subjects showing no decline classified as organic) plus proportion of 'false negatives' (i.e. subjects showing decline classified as non-organic).
4. Probability of having declined given a classification of organic.

TABLE IV
Cognitive change over the preceding 2 years shown by subjects classified as organic on all, some or none of the tests

	AMTS	
	Average change (±1 s.d.)	*Percentage showing decline*
Subjects classified as organic on all three tests	−3.73 ± 1.79	80
Subjects classified as organic on some tests	−0.78 ± 1.13	31
Subjects classified as organic on no tests	+0.09 ± 0.86	4
ANOVA[1]	F = 98.57 (d.f. 2, 76)	$P \leq 0.001$
χ^2[2]	χ^2 = 65.31 (d.f. 2)	$P \leq 0.001$

1. ANOVA comparing the average changes shown by the three groups.
2. χ^2 comparing the outcomes of the three groups.

TABLE V
Sensitivity and specificity of the organic classifications in combination to cognitive change over the preceding 2 years

	Sensitivity	*Specificity*
Subjects classified as organic on all three tests	0.43	—
Subjects classified as organic on at least one test	0.79	—
Subjects classified as organic on no tests	—	0.83

Validity of the organic classifications considered in conjunction

Given the considerable disagreements between the classifications made by the different tests (Fig. 1), the classifications made by the three in conjunction were considered. The sample was split into three groups: subjects whom all three tests classified as non-organic, those whom all three classified as organic and those for whom inconsistent classifications were made (i.e. whom only one or two of the tests classified as organic). There were insufficient numbers of subjects classified as organic by only some of the tests ($n = 32$) to break this group down further. The sensitivity and specificity of these combinations of classifications to cognitive decline were examined.

Those classified as organic by all three tests showed substantially more decline on the AMTS than those classified as organic by only some tests. The group classified as non-organic by all three tests showed almost no change during follow-up (Table IV). The group classified as organic by no test accounted for 83% of all subjects who had not declined, whereas those classified as organic by all three tests included only 43% of the subjects who had declined. The sensitivity to previous change was increased to 79% when subjects classified as organic by one or more tests were considered (i.e. when subjects classified as organic by some and by all tests were pooled (Table V)). Considering as cases those classified as organic by one or more tests and as non-cases those classified as non-organic by all three tests gave an overall misclassification rate of 48% and a hits positive rate of 0.47.

Discussion

The value of a screening tool can be considered as a function of its sensitivity (i.e. the proportion of those with a disorder classified as cases) and specificity (i.e. the proportion of those without a disorder classified as non-cases) (Goldberg, 1972). If screening is a two-stage process, with possible cases confirmed by subsequent examination, then sensitivity is of more importance than specificity since it is better to be overinclusive than to miss true cases. In the present study, three tools with established diagnostic validity were examined as possible first-stage screening tools for senile dementia: a screening interview (the PAS), a dementia scale (the AMTS) and a psychometric test (the IPALT). Their value as possible tools for elderly living at home was considered a function of their ability to classify subjects correctly on the basis of the cognitive changes shown on the AMTS over the previous 2 years. A useful first-stage screening tool would be one which identified as possible cases those who had shown a significant decline in cognitive function (i.e. a decline unlikely to have occurred by chance). This would not by itself establish the diagnostic validity of the tool. Some of these possible cases would not be dementing since their decline might be attributable to benign age-related change or to other pathologies (physical or affective illness or non-progressive organic pathology). This can only be established by careful examination, ideally supplemented by follow-up to establish outcome. However, it is unlikely that those with dementia will have shown no decline, unless floor effects were operating (which was not the case here since no subject scored less than 2 at baseline on the measure of change).

As first-stage screening tools all three were quick and easy to administer. They seemed reasonably acceptable, with refusal rates of 9% at baseline and 15% at follow-up. The interviewers all considered the IPALT to be the least acceptable, but since this test was given last this may be confounded with fatigue. Subjects classified as organic by each test were significantly more likely to have declined than were those classified as non-organic (Table II). However, the sensitivity and specificity of the three tools differed (Table III). The overall misclassification rates ranged from 7% (for the AMTS) to 17% (for the PAS). Each was unduly conservative, with acceptable specificity (ranging from 0.89 for the PAS to 0.97 for the AMTS) but poor sensitivity (ranging from 0.54 for the PAS to 0.71 for the AMTS). As first-stage screening tools all might be improved by less conservative cut-offs to classify subjects as organic, given that sensitivity is of more concern than specificity. The AMTS emerges as the most sensitive and specific.

The power of these tools to identify cases has to be considered with regard to the base rate of disorder in the sample. Goldberg (1972) claims that for decisions made on the basis of screening tools to be of use, two conditions should be satisfied: (a) the base rate of disorder < specificity of tool ÷ (specificity + false negative rate); (b) the base rate of non-disorder < sensitivity of tool ÷ (sensitivity + false positive rate).

In the present sample the base rate of 'disorder' (considered here as cognitive decline) was 16%. This is higher than the prevalence of dementia within community samples (Kay & Bergmann, 1980; Henderson & Kay, 1984), but the present follow-up sample was not randomly drawn and was deliberately weighted towards pathology. Furthermore, cognitive decline is not equivalent to dementia. The prevalence of decline was considerably less than the index of test specificity and the false negative rate for each test (which ranged from 0.66 for the PAS to 0.77 for the AMTS). The prevalence of non-decline (84%) was similar to the index of test sensitivity and the false positive rate for the PAS (0.83) and IPALT (0.86) but considerably less than that for the

AMTS (0.96). For each test the probability of subjects classified as organic having declined was substantially higher than the base rate of decline (Table III). Thus some useful decisions can be made on the basis of all three tools, but those made on the basis of the AMTS are clearly the best.

The value of these tests as screening tools should be compared with that of conventional methods of case-identification used within similar samples. Three studies have examined how well clinically identified cases are recognised as dementing by their general practitioners, and report detection rates of 13% (Williamson *et al*, 1964), 38% (Williams *et al*, 1972) and 75% (Parsons, 1965). Even the rather low sensitivities here represent an improvement upon the detection rates reported in the first two studies. Furthermore, the value of clinical interview and diagnosis for detecting community cases has been questioned by Gurland *et al* (1982, 1984) who found that almost half of their 'cases' had outcomes inconsistent with dementia. This casts doubt upon the specificity of clinical case detection; its sensitivity has not been examined.

Given the different content of the three tools it is not surprising that they classified rather different groups of subjects as organic (Fig. 1). Twice as many subjects were classified as organic by some tests (18%) than were classified as organic by all (9%). In spite of the fact that the PAS and AMTS classified different individuals as organic, they gave similar overall prevalence rates (18% and 14% respectively). (The prevalence rate from the IPALT was fixed from those of the other tests.) This suggests caution when examining epidemiological surveys which use different tools to identify cases. It is incorrect to presume that because studies report similar prevalence rates they are considering equivalent groups. Although the tests identified different groups as organic, there is little value in considering the tests in combination (Table V). The sensitivity to decline of combinations of tests was slightly higher than that of the most sensitive individual test (the AMTS), but this gain was at the expense of reduced specificity, and the overall misclassification and hits positive rates were less satisfactory than those of the AMTS. This is surprising, given the improved diagnostic sensitivity gained by combining tests of different functions (e.g. Irving *et al*, 1970; Haglund & Schuckitt, 1976).

From the present results, although all three tests appear economical, acceptable and valid, the AMTS is clearly the most useful screening tool. There is little to choose between the PAS and the IPALT, although the former may be more acceptable. Several studies report that, as diagnostic discriminators, brief dementia scales are as good as (or better than) longer scales or detailed psychometric tests (Hodkinson, 1972; Haglund & Schuckitt, 1976; Kuriansky *et al*, 1976). This may be true for prediction of cognitive change as well. However, it must be noted that all three tests were validated against change on the AMTS. Given that generally reliability coefficients for individual tests are higher than the correlations between different tests, follow-up scores on a test may agree better with changes shown on the same test than do follow-up scores on different tests. A decline of 2 points on the AMTS (the validation criteria) would necessarily bring subjects closer to the organic cut-off score on this test. Possibly with different measures of change the AMTS may be less useful. Furthermore, sensitivity to previous decline is only one of the criteria which screening tools must satisfy. A more stringent test of the tool may be its ability to predict future change. The present sample is one of several samples being followed up to examine the ability of the three tools to predict several measures of outcome.

Range of Mental Illness Among the Elderly in the Community

Prevalence in Liverpool Using the GMS-AGECAT Package

J. R. M. COPELAND, M. E. DEWEY, N. WOOD, R. SEARLE, I. A. DAVIDSON and C. McWILLIAM

A sample of 1070 elderly persons aged over 65 living in the Liverpool community was interviewed using the community version of the Geriatric Mental State (GMS) and the findings processed to provide a computerised diagnosis by AGECAT. Levels of organic disorder, probably dementia, reached 5.2%, intermediate between those of London and New York derived from previous studies. Levels for depressive illness overall were below those of other studies at 11.3% while levels for neurotic disorder were much the same at 2.4%. The rise in the prevalence of dementia with age was further confirmed. The GMS AGECAT Package provides a method for standardising both the collection of data and the diagnostic process for comparative epidemiological studies and other research.

Reviews by Kay & Bergmann (1980) and Henderson & Kay (1984) of the prevalence of mental illness in community studies of the elderly show that figures for mild and severe mental illness vary considerably between such studies. The use of diverse techniques has made it difficult to interpret the cause of these differences. The importance of standardised methods for collecting data has been stressed and such instruments are now in use. However, to improve accuracy further it is necessary to standardise two more stages, the decision on diagnosis, and the definition of case levels of illness, particularly of minor illness, in a reliable manner.

In the US/UK Cross-National (Diagnostic) Study of the elderly in the cities of New York and London, Gurland *et al* (1983) used the CARE interview developed from the Geriatric Mental State (GMS) (Copeland *et al*, 1976; Gurland *et al*, 1976). They also developed a method for identifying levels of 'pervasive dementia' and 'pervasive depression'. The Diagnostic and Statistical Manual, (DSM-III) of the American Psychiatric Association (1980) also sets forward criteria for the diagnosis of both dementia and depression, and the Research Diagnostic Criteria (Spitzer *et al*, 1978) for depression. Although representing advances in technique, these methods still allow too much individual interpretation of the criteria, (Jorm & Henderson, 1985; Copeland & Gurland, 1985). We consider it necessary for psychiatric epidemiology, to standardise the diagnostic and case-selection processes by using as reliable a method as possible if the comparative studies of populations are to be interpretable. Copeland *et al* (1987*a*), recently re-examined the New York/London community study of the elderly and applied the computerised diagnostic system AGECAT to the data. In two large studies (Copeland *et al*, 1986; Copeland *et al*, 1987*b* AGECAT diagnosis has been shown to approximate reasonably closely to the diagnosis of psychiatrists trained in the British tradition. A computer method of diagnosis has the disadvantage that it must await input of the data to the computer, but it has the advantage of consistency, can take into consideration a wider range of unusual combinations of symptoms, can reliably categorise subcase as well as case levels, and can provide symptom profiles and scale scores.

The study reported here was undertaken as part of a pilot longitudinal study aimed at examining the early detection of dementia in the community elderly. The sample therefore excludes those elderly resident in institutions.

Method

Interviewing techniques: GMS and AGECAT

The development of the GMS has been described in detail elsewhere (Copeland *et al*, 1976; Gurland *et al*, 1976).

GMSA, the shortened version of the GMS for use in the community, was developed specially for this study by selecting those GMS items derived from a series of discriminant function analyses applied to data from the London community sample (Copeland *et al* 1987*a*), aimed at distinguishing between depression and dementia; depression, dementia and other psychiatric diagnoses; all psychiatric diagnoses and non-cases. It covers the important symptom areas for the psychotic and neurotic disorders likely to be encountered in the community and AGECAT can be applied to it. This interview is also a syndrome case finding instrument. A not dissimilar interview (GMS6) was derived independently by Henderson and his colleagues in Canberra by an intuitive selection of items, but unfortunately

AGECAT has only limited application to this version for the identification of subcases.

AGECAT (Copeland *et al*, 1986; Dewey & Copeland, 1986; Copeland *et al*, 1987*b*) consists of a computer program derived from a theoretical model which was subsequently tested against psychiatric diagnosis. It groups the items of the GMS and related interviews into 157 symptom components. These components are gathered under eight diagnostic 'clusters' and allocated to groups according to their importance for establishing the certainty of diagnosis for that diagnostic cluster. For example, in the organic cluster the groups concern 'mild memory disturbance'; 'moderate memory disturbance and time disorientation'; and 'place/person disorientation and organic thought disorder'. While those for depression represent 'depressive mood'; 'non-specific symptoms of depression'; 'symptoms characteristic of neurotic, reactive depression or dysthymic mood'; 'symptoms denoting severity'; 'symptoms characteristic of psychotic, endogenous depression or major affective disorder'; and 'mood congruent hallucinations and delusions'. Each subject is awarded a level from 0–5 for most diagnostic clusters according to the certainty 'of diagnosis' on that cluster. All levels on each cluster are then compared across clusters, one with another, according to a hierarchy of illness starting with organic and proceeding to schizophrenic, manic, depressive (psychosis and neurosis), obsessional, hypochondriacal, phobic and anxiety. The subject emerges with a main diagnosis and a subsidiary or alternative diagnosis if appropriate, the levels on all eight diagnostic clusters, the routes by which these levels are achieved, a symptom profile, a decision on whether or not the condition reaches the 'syndrome case' stage, organic and depressive scale scores and an Organic/Depression Index (Copeland *et al*, 1986*b*, 1987*a*).

A 'syndrome case' is reached when a psychiatrist recognises that a subject's symptoms have formed a recognisable diagnostic pattern. In practice, this usually implies the need for professional intervention. Bereavement reaching syndrome case level on the depressive cluster is an example of an exception. Syndrome cases may therefore be further defined, as requiring or not requiring such intervention. A subject may reach case level on several syndromes. AGECAT will select one of these as the overall diagnosis. We then refer to this as a 'diagnostic syndrome case of ——'. Most studies will require additional case criteria tailored to the aims of the study. We have called cases so selected, 'criterion cases'. In this study we report levels of illness at the 'syndrome case' and 'diagnostic syndrome case' stage.

The agreement between AGECAT and psychiatrists' diagnoses was compared in an initial study (Copeland *et al*, 1986*a*) and in a replication study (Copeland *et al*, 1987*b*). For 396 community-based subjects in the initial study the κ value for overall agreement was 0.74, for cases of depression 0.80, for organic cases 0.88 and for non-cases 0.74. For the replication study, diagnostic concordance was reached on 89% of 647 community subjects, giving a value for Cohen's κ overall of 0.71, for depression 0.73, and for organic disorder 0.77. The last was complicated by the introduction of a third category of 'borderline organic' case. Where the decision was case/non-case, κ reached 0.89 for organic disorders. These studies and others show that psychiatrists trained in different centres appear to agree with AGECAT diagnoses for both institutionally based and community based subjects.

The sample

The 360 General Practitioners forming the Liverpool Family Practitioners' Committee were randomly sampled to provide 58 names. These GPs were approached by a letter explaining the study and requesting permission to interview their patients. Three refused permission at this stage, leaving 55 who were randomly allocated to 11 subsamples of five practitioners each. Each subsample formed a random sample in its own right. Failure to complete one subsample would not have invalidated the random nature of the total sample, and separate subsamples were available for individual studies.

The potential pool of subjects was 12 909. In order to provide approximately 1000 subjects, 2425 or 19% of the available pool were selected from cards held by the Family Practitioner Committee. In the event, only nine of these subsamples were required.

Each subject was sent an individually signed letter describing the project, accompanied by a letter of introduction from the GP. The explanatory letter stressed the random selection of the subjects, the nature of the health survey, that it was not 'an official survey' and that there was no obligation to take part. An address and telephone number for contact were also given. Written or verbal refusals were accepted without question, otherwise subjects were visited up to four times if necessary, whether or not they replied to the letter. To a small number of subjects who objected to being approached in this way a personal letter of explanation was sent.

Interviewers

Six interviewers participated in the project, three full-time and three part-time. Two of the full-time interviewers possessed first degrees in psychology and the third was an ex-ward sister (SRN) with geriatric experience. Two of the part-time interviewers had degrees in psychology and one an HNC in medical subjects.

Training on the GMS was undertaken using videotaped and live interviews in the usual manner. A short pre-pilot study was undertaken in a geriatric day hospital to test the confidence of the interviewers when confronted with patients with mental and physical illness. Inter-rater reliability was assessed using 19 videotaped interviews of community residents. Each of the six non-medical interviewers recorded two or three interviews while the three medically qualified raters who participated in the follow-up study (see below) each recorded two. All raters subsequently viewed and scored each other's interviws. The results are to be reported (Forshaw *et al*, in prep.). Satisfactory agreement between trained non-medical and medical raters for the Present State Examination has been demonstrated (Cooper *et al*, 1977) and there is little reason to suppose that this can not be achieved for older age

TABLE I
Liverpool: Comparison of mean organic scores and subject's mean age for each rater

Rater	*Organic mean score*	*s.d.*	*Mean age*	*s.d.*
1	2.6	3.3	73.3	7.1
2	2.4	3.1	75.1	6.9
3	2.4	3.7	72.6	5.9
4	2.4	2.9	73.5	6.8
5	3.1	3.4	74.5	6.1
6	3.1	4.6	73.2	6.2

Organic score $F=0.44$ (NS); Age $F=1.62$ (NS).

subjects. Meanwhile, Table I shows a comparison of subjects' organic mean scores and age for each rater. The organic score was made up of those items which best discriminated between organic disorders and other mental illness, and between organic disorders and non-cases, using a series of linear discriminant function analyses. The rating of organic symptoms was particularly important for the study as a whole. The variation between raters is not great for the overall organic mean score nor for the mean age of subjects seen. Standard deviations are similar and differences are not statistically significant.

Initial test battery

All subjects, at the initial interview lasting 50–90 minutes, received: a first blood pressure reading; a health questionnaire; a social information questionnaire; a number of psychological tests including the SET Test, the National Adult Reading Test, and the Mill Hill Vocabulary Test; the second blood pressure reading; the GMSA; and the third blood pressure reading. The Stockton Behaviour Rating Scale was abandoned early in the study as unsuitable for a community population of comparatively well subjects.

A subsample of dementing subjects had a physical examination, computed tomographic scan, biochemical investigations and an interview by a psychiatrist using the GMSA.

Results

Table II shows the overall response rate. As expected, the GPs lists were inaccurate. Although places of residence were repeatedly visited where necessary and attempts made to gather additional information, a proportion of subjects was not accounted for. One GP refused access to his patients after the interviewing started. In all, 1070 or 72% of the eligible sample were interviewed. Although the procedure in Liverpool was similar to that used in our London studies the response rate was 9% lower, only a little above that found in New York. We discuss this further below.

Table III shows the distribution of the sample by age divided into half decades. The proportions of male and female subjects are not significantly different from either those found in the 1981 census for Liverpool city or in the study in London. The mean age of 74 years is similar to that of both the London and New York samples. The low proportion of male subjects aged between 80 and 84 is probably a result of the First World War. Both subjects who refused interview and those who were not traced have a similar age distribution to the full sample.

TABLE II
Liverpool: Random sample of subjects aged 65 and over living in the community of Liverpool city: response rate

Total estimated subjects available aged 65 and over: 12 909		
Selected from GPs' list	2425	(19%)
Discovered already dead	114	
Discovered already moved away	270	
Subsamples drawn but not used, not traced or GP refused	555	
Sample eligible for study	1486	
Refused interview	416	(28%)
Sample interviewed	1070	

Response rate 72%

Table IV shows some of the other demographic features of the sample. They differ little from the census statistics where these are available, and apart from 'race', are similar to those found in the previous London and New York studies.

Prevalence

Table V shows the male and female distribution of the major psychiatric syndromes. AGECAT diagnostic confidence levels of 3 or above are used to define 'syndrome cases'. It was our experience based on the London and New York studies that acute organic states are rarely diagnosed in community samples. Therefore, subjects with AGECAT diagnostic organic disorders quoted here are likely to be suffering from dementia (overall 5.2%).

The total proportion of cases of all diagnoses is 19.3%. The proportions of subjects with no AGECAT level on any of the syndrome clusters is 47% for males and 37% for females. Thus over one-third of the population had no important psychiatric symptoms.

Organic disorders

Table VI shows the distribution of AGECAT diagnostic syndrome cases and subcases of organic disorders according to levels of confidence of diagnosis. AGECAT organic levels which are associated with diagnostic cases of other conditions are not included. There are some 14 'routes' by which subjects may be allocated to organic confidence levels. In general, to achieve level 01 there must be a score of at least 2 on symptoms of mild memory disturbance, such as failing to remember the interviewer's name, miscalculating the length of time at the present address, the rater's opinion that the memory defect is a problem for the subject, etc, while for level 02 a higher proportion of such symptoms is required or others of moderate memory disturbance, inability to calculate age, failing to recall the

interviewer's name on the second occasion or misidentifying objects. Case level 03 is reached when a substantial number of such symptoms is recorded often accompanied by time disorientation. Higher levels, 04 and 05 (the community version of the GMS did not provide for these levels at that time) require the presence of severe disorientation in place and person as well as organic thought disorder.

A higher proportion of female subjects is evident at the case level but not at the subcase level ($P < 0.001$). If, as anticipated, subcase levels 01 and 02 mainly represent minor acute confusional states there is no reason to suppose that these would be more common in female patients. They would also be expected to include early cases of dementia but these would be comparatively rare. Subjects achieving any kind of AGECAT organic level represent 9.3% of male and 10.6% of female subjects. The difference is not statistically significant.

Figure 1 shows the distribution of AGECAT 'diagnostic syndrome cases' (03 and above) of organic disorder by age and sex. There is a linear relationship between age and the logit of the proportion of demented subjects ($P < 0.001$). The fall after age 90 is a less certain finding because of the

few subjects in this age group. The proportion aged over 80 with organic disorder is only 12.1%, rather below the often quoted figure of 20% (this sample does not include the comparatively small proportion of institutionalised subjects).

Depressive illness

Table VII shows the distribution of AGECAT diagnostic syndrome cases and subcases of depressive disorders by levels of diagnostic confidence. The table excludes those levels of depression associated with diagnostic cases of other conditions. There are over 60 'routes' for achieving levels of confidence on the depressive cluster. As a rough guide, level D1 is achieved by subjects with minor mood symptoms and some symptoms of non-specific depression, such as loss of concentration, interest, lack of enjoyment, lack of energy, etc., D2 requires a higher proportion of such symptoms. Case levels of depressive neurosis (DN3) must have characteristic symptoms in addition, such as, depression worse in the evening, difficulty getting off to sleep, depersonalisation, feelings of loneliness, etc. in the absence of more psychotic symptoms. Level DN4 is achieved if more severe symptoms (group D) are also prominent, such as, the future appearing bleak, wishing to be dead, feeling worthless, having conceived a suicidal plan or attempted to carry it out. Case levels of depressive psychosis (DP) require symptoms such as, depressive mood worse in the morning, being unable to cry, slowness in the morning, early morning wakening, retardation on examination, muddled thinking and a combination of appetite and weight loss. Level 4 of depressive psychosis depends on the prominence of group D symptoms and level 5 on the presence of mood congruent delusions and/or hallucinations.

There is a consistent tendency for there to be a higher proportion of female subjects at each depressive level of diagnostic confidence ($P < 0.05$). In all, 17.3% of males and 24.9% of females are nominated as either diagnostic syndrome depression subcases or cases. For the full sample with the sexes combined, 10.7% of subjects achieve diagnostic syndrome subcase level and 11.3% case level, making a total proportion of 22.0%. The overall prevalence of diagnostic syndrome cases of depressive psychosis is 3.0%.

TABLE VII

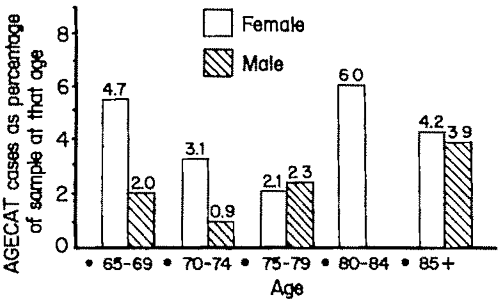

FIG. 2 Distribution of AGECAT diagnostic syndrome cases of depressive psychosis (DP) by age and sex. (Full sample: males n = 410, females n = 660.)

Figure 2 shows the distribution of AGECAT 'diagnostic syndrome cases' of depressive psychosis by age and sex. Subcase levels are excluded from this figure. Again, there appears to be a preponderance of female subjects at all half decades except one.

Figure 3 shows the distribution of 'diagnostic syndrome cases' of depressive neurosis by age and sex. Again, a higher proportion of female patients is evident at each half decade.

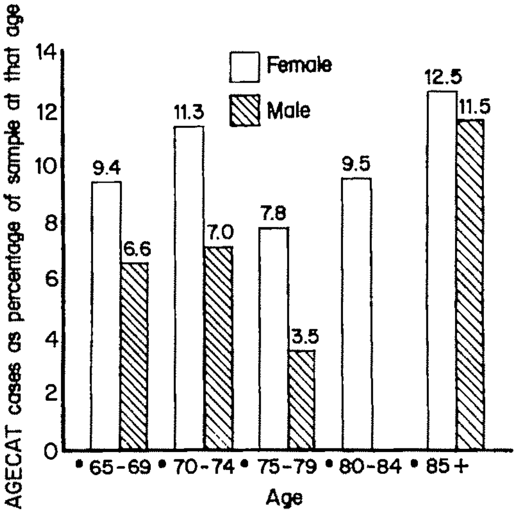

FIG. 3 Distribution of AGECAT diagnostic syndrome cases of depressive neurosis (DN) by age and sex. (Full sample: males n = 410, Females n = 660.)

Neurotic disorders

Table VIII shows the distribution of AGECAT diagnostic syndrome cases and subcases of neurotic disorders by levels of confidence of diagnosis and by sex. The table excludes those neurotic levels associated with diagnostic cases of other conditions. For the three conditions obsessive, phobic and anxiety neurosis there is a tendency for rather higher proportions of subjects to be found at level 2 than at the case levels.

Whether or not a subject achieves syndrome case levels on the hypochondriasis cluster largely depends on whether he or she shows undue preoccupation with physical symptoms for which there is no apparent cause. For subjects on the obsessional cluster to reach syndrome case levels the symptoms must interfere with daily living. Subjects at level OB2 have genuine obsessional symptoms in so far as they have rituals or compulsive thoughts which they attempt to resist. For subjects to achieve syndrome case level on the phobic cluster there must be evidence of active avoidance or in more extreme cases the subject must be housebound. To achieve syndrome case levels on the anxiety cluster subjects must complain of or show evidence of somatic symptoms or symptoms of tension.

TABLE VIII

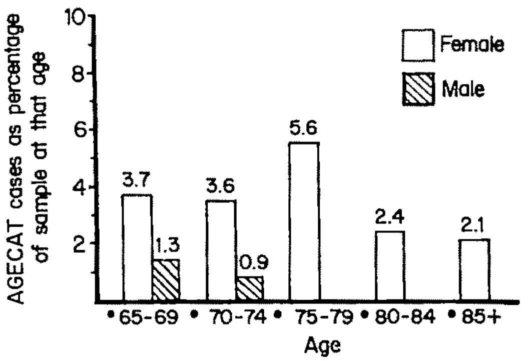

FIG. 4 Distribution of AGECAT diagnostic syndrome cases of neurotic disorders by age and sex. (Full sample: males $n = 410$, females $n = 660$.)

Table VIII shows that although neurotic syndrome 'case' levels as defined here are rare in these age groups, high proportions of neurotic symptoms, particularly anxiety, are often present. On the evidence of previous studies, confidence levels 4 and 5 for anxiety are uncommon, unless associated with diagnostic cases of depression, dementia or schizophrenia. The overall prevalence of diagnostic syndrome cases of neurosis is 2.4% (males 0.3%, females 2.1%). However, if those subjects with diagnostic subcase level 2 are included with the cases on the grounds that this level represents substantial neurotic symptoms (although they may not interfere with daily living), and because case/non-case distinctions are somewhat 'arbitrarily' chosen for neurotic conditions, the overall prevalence rises to 24.6% (males 8.6%, females 16%, NS). If all diagnostic syndrome cases and subcases of neurotic disorders are included, the overall prevalence is 26.7%. Only levels of phobic symptoms are significantly different between the sexes with females having rather more symptoms than males ($P < 0.05$).

Figure 4 shows the distribution of AGECAT diagnostic syndrome cases of neurosis by age and sex. The higher proportion of female cases is evident, ($P < 0.003$). The apparent decline with age is not significant.

Discussion

Response rate

Although the same procedures were used in both Liverpool and London, the response rate was lower in Liverpool. It is similar to the response rate in New York and a little below that achieved by Kay *et al* (1985) when both their younger and older samples of the elderly in Hobart are combined. The reasons why subjects refuse to take part in a study are varied but it is our impression that a substantial proportion of refusals are caused by misinterpretations of the study's aims and a failure to appreciate its importance in terms either of the usefulness of its results or in its financial outlay. Even when attempts are made by letter to explain the importance of interviewing both the well and the ill, this may still not be truly appreciated by the subject. We have found in subsequent studies that a substantial improvement in response rate occurs, if a preliminary visitor calls at the house to explain in person the nature of the project. Such a procedure increases the overall expense of the project but can also save interviewer's time if the preliminary visitor arranges precise appointments.

As there were no significant differences in age distribution between those who were interviewed and those who refused interview, we do not expect to have lost a higher proportion of cases than non-cases, although this always remains a possibility in such studies.

Prevalence

Organic disorders

The level of 5.2% for diagnostic syndrome cases of organic disorder (probably mostly dementia) compares with 4.3% for London and 8.3% for New York. All prevalence figures for the New York and London studies quoted here are those given by Copeland *et al* (1987*a*) derived from the application of AGECAT to the New York and London CARE data. Mental state item differences between the CARE Schedule and the GMSA are small and, in any case, diluted by the pooling of items to form the symptom components. It is unlikely, therefore, that differences in prevalence can be ascribed to differences in the technique used.

The age distribution in the Liverpool sample is similar to that in the London sample. The prevalence of organic disorders in males in Liverpool is similar to that in London, while that in females lies midway between the New York and London figures. The overall proportion of organic syndrome subcases lies between the London and New York figures. The combined proportions of subcases and cases of 10.1% and the proportion for cases of 5.2% are remarkably similar to the findings of the original Newcastle studies (Kay *et al*, 1964) of approximately 10% for both mild and severe organic brain syndromes and 4.9% for severe alone.

Depression

The overall prevalence figure of 11.3% for diagnostic syndrome cases of depressive disorders is somewhat below that for either New York 16.2%, or London 19.4%. It is accounted for by a lower proportion of cases (also subcases) of depressive neurosis, while the overall prevalence for cases of depressive psychosis of 3.0% is slightly above that for either New York or London. The City of Liverpool is noted for its high level of social problems, particularly unemployment, crime and drug dependence. However, it had been anticipated in the London/New York studies, that the prevalence of depression would be higher in New York than in London because of the additional social problems in that city, the presence of which were amply documented by the study. Nevertheless, the proportions of depression found in London and New York were similar. It therefore cannot be assumed that the level of depressive illness or depressive symptoms in a community will bear a direct positive relationship to the level of social disturbance. This may be related to the well-known finding that certain types of psychiatric morbidity are negatively correlated with social disturbances such as war. As for the affective disorders as a whole, if the diagnostic syndrome subcase levels of 10.7% and the case levels of 11.3% are added together to equal 22.0%, this figure is not far short of the 26.2% for mild-to-severe levels of affective disorder given in the Newcastle studies. The Liverpool diagnostic case level of 11.3% is close to the figure of 10.0% for moderate/severe affective disorders, found in Newcastle. The Liverpool figure of 3.0% for psychotic depression is close to the figure of 3.7% found by Blazer & Williams (1980) using DSM-III criteria for major affective disorder in a community sample aged over 65 years.

Neurotic disorders

The overall prevalence for diagnostic syndrome cases of neurosis in Liverpool of 2.4% may be compared with 1.4% in New York and 2.0% in London. There are no important differences in syndrome case levels for any of the individual neurotic disorders between the three cities. If all diagnostic syndrome levels for obsessional disorders are taken together (cases and subcases) the prevalence is 1.7% for the Liverpool sample, close to the 0.7% for the New York sample, but much lower than the figures for London of 9.8%. 2.4% is also remarkably close to 2.6% for 'other' functional diagnoses found by the Newcastle study after the removal of cases of schizophrenia, paranoid illness and affective disorders.

There are few differences between the sexes for the neurotic disorders and there is no consistent preponderance of males across the age-span as was evident in the combined London and New York samples. Neurotic symptoms may fail to reach case level because elderly people may have a lifestyle which allows them to avoid contact with provoking factors.

The measures

The GMS-AGECAT Package offers a method for undertaking comparative studies of elderly populations. It introduces a degree of standardisation not only into the collection and recording of symptoms but also into the selection of diagnosis. A range of information is provided about each subject including the identification of case and subcase levels of diagnostic confidence.

In the study described here the diagnoses were made in terms of eight diagnostic clusters. Historical data were not available at the time. If more exact distinctions are to be made between, for example, dementia and acute confusional states; and between types of dementia, other chronic organic conditions and pre-existing mental subnormality; historical data will be essential. The History and Aetiology Schedule is being used in the follow-up studies now being undertaken. Data from this interview pass into the next stage of AGECAT which aims to divide the eight diagnostic clusters into subgroups. It provides information on the form of onset and development of the illness, family history, previous illnesses, head injury and alcohol and drug abuse.

Acknowledgements

The authors would like to acknowledge the help they received with the interviewing from Mary Heary, Josephine Silcock, Colleen Hensey, and Jenny Wood and to give their thanks to Michael Kayodi for his work on the computer, to Barbara Ackerley for calculating the proportion of subjects not contacted and Arthur Pugh for preparing the diagrams. They also wish to express their gratitude to the General Practitioners in Liverpool for their help, and the community residents who gave up their time to be interviewed. The study was supported by a major competitive award from the Wellcome Trust, and the World Health Organisation.

Detention in Broadmoor
Factors in Length of Stay

S. DELL, G. ROBERTSON and E. PARKER

When the length of stay of restricted patients admitted to Broadmoor under the legal category of psychopathic disorder was examined, the factor found to be of primary importance was the gravity of the admission offence. If the men's offences did not cause personal injury, they had a good chance of early release. Patients convicted of violent or sexual offences, and particularly those who attacked strangers, made up the great majority of the long-term group. For the mentally ill there was no relationship between length of stay and admission offence: instead the data suggested that severity and chronicity of illness were the main relevant factors.

The Special Hospital Case Register was set up in 1972 and since the beginning of that year, the Special Hospitals Research Unit have been recording particulars about all patients entering the special hospitals. The information is obtained by interview and from the official records. Data about the patient's progress or treatment in hospital are not collected, but there is information about his psychiatric history, social background, criminal record, and diagnosis on admission. It was possible to use these data for the purpose of seeing whether admissions to Broadmoor had changed over the years since 1972, and also for examining the characteristics of different groups of patients, and seeing how long they were held in the hospital. Information about all the male admissions between 1972 and 1984 were made available to us.

Table I shows Broadmoor's annual figures by legal category of male admissions with a Mental Health Act classification of psychopathic disorder (PD) or mental illness.

It is clear from the table that Broadmoor's intake has fallen substantially over the years, with admissions of PD patients decreasing more than those of the mentally ill. The data were examined to see whether, within each of these Mental Health Act classifications, there was any pattern to the decline, i.e. whether receptions of certain types of patients or offenders decreased more than others. No such patterns emerged, but it is probable that there were trends in the fall of a kind not recorded in the Case Register data. There has, for example, been increasing scepticism about the treatability of psychopaths, and increasing insistence by the DHSS that mentally ill patients, however serious their offences, should not be admitted to special hospitals unless they need maximum security (Dell, 1984).

How long do patients stay in Broadmoor? The case register showed the date of discharges and transfers up to December 1982, so for patients admitted in the early 1970s some picture on the

length of stay was ascertainable. We decided therefore to look at patients admitted in the years 1972–1974, for whom at least 8 years had elapsed by the time the release date was collected in 1982.

Psychopathic disorder patients

Table I showed that there were 106 men with a MHA classification of psychopathic disorder admitted in the years 1972–1974. The great majority were sent to Broadmoor by the courts on restricted hospital orders, and we confined our length of stay analysis to this group, since very different considerations are involved in the discharge of other groups, for example, of transferred prisoners who are liable to be returned to prison.

There were 81 PD patients admitted from the courts on restricted hospital orders in the years 1972–1974. For the purpose of looking at length of stay, we excluded two men who died in Broadmoor and another three who were sent to prison after committing further serious offences in Broadmoor. This left us with 76 men, and the length of time they stayed in Broadmoor (or if they moved to one, in another special hospital) is shown in Table II.

TABLE II
Section 60/65 Patients admitted 1972–1974: Length of stay

	Psychopaths (*n* = 76)		*Mentally ill* (*n* = 111)	
Length of stay	*n*	%	*n*	%
2 years or less	6	8	21	19
over 2–3 years	2	3	12	11
over 3–4 years	10	13	13	12
over 4–5 years	7	9	7	6
over 5–6 years	6	8	3	3
over 6–8 years	5	7	8	7
over 8 years	40	53	47	42

It will be seen that 25% of the men were released within the first 4 years, but that 53% were held more than 8 years. In the light of these figures we decided to divide the 76 cases into three groups: the early releases (the 18 men who were held 48 months or less), the 40 long-termers who stayed over 8 years, and the intermediate group of 18 men, who were held between 4 and 8 years. These three groups were then compared over the variables collected for the Case Register to see what, if anything, distinguished them.

Comparisons on the historical and demographic data revealed little of interest – the groups were not different on items such as age, early family history, social class or previous psychiatric hospitalisation. Criminal history distinguished the groups only in respect of previous sexual offences: 6% of the short-stay men compared with 29% of others had such convictions ($P<0.12$).

There were major differences between the groups as regards the offences for which the men had been sent to Broadmoor: Table III shows the position.

It can be seen that the long-stay group was made up largely of men who had committed offences of violence against the person, sexual or otherwise, while the men whose offences did not physically injure other people accounted for the majority of the short-stay group. The figures in Table III, showing how long different kinds of offenders were detained, have something of the air of a tariff. Long-term confinement followed 76% of homicides, 62% of non-fatal attacks, 55% of sex offences and 25% of arson cases.

TABLE III
Psychopaths admitted 1972–1974: Offence, victim and length of stay

Other	2	11.1	1	5.6	7	17.5

1. Long-stay vs others for homicide/wounding, sex/arson, other offences: χ^2 10.84 2 d.f., $P<0.001$.
2. χ^2 15.34 6 d.f., $P<0.018$.

When offender/patients are admitted to the special hospitals, the consultants are asked to provide the Case Register with a diagnosis, and also with an assessment of the motive for the offence (e.g. self defence, revenge, sex, etc.). Some of these motive and diagnostic ratings proved to be related to the patient's length of stay. First when a sexual motive had been attributed to the offence (and this was done in 45% of cases) the patient was very unlikely to be in the short-stay group. Of 34 such men, only two (6%) fell into this group, whereas for 42 offenders to whom sexual motives were not attributed, 16 (38%) were released in their first 4 years ($\chi^2 = 11.07$ d.f., $P<0.004$).

Another type of motive assessment that was significantly related to length of stay was when the consultant had at admission recorded the offence as being 'apparently motiveless'. Of the 15 men so categorised, 13 (87%) fell into the long-stay group ($\chi^2 = 8.68$ 2 d.f., $P<0.013$).

Taking the long-stay group as a whole, 85% were men whose offences had been regarded as either 'motiveless' or sexually motivated, whereas only 17% of the short-term group came into this category.

Two other ratings were also found to be associated with length of stay. One was the attribution of the offence to motives of 'jealousy or revenge'. This rating was given to 22 men, and they were significantly over represented in the short-term group: more than half (56%) of the patients in this group had their offences attributed to this motive (χ^2 9,28 2 d.f., $P<0.01$). Further analysis showed that arsonists had more often ($P<0.01$) than other men had their offences ascribed to jealousy. Also, we found that men who were regarded as having committed their offences out of motives of jealousy were more often than others ($P<0.03$) given the diagnosis of 'transient situational reaction'. This diagnosis was made for seven men (9%) and five of them fell into the short-stay group ($P<0.007$). From these findings it seemed that shorter lengths of stay were associated with offences which caused no personal injury and which the doctors regarded as 'one-off' cases arising in temporary circumstances. In terms of common sense expectation, the results are unsurprising, but they do raise the question of whether some of these offenders should ever have been committed to Broadmoor as suffering from psychopathic disorder: it is not easy to see how offences which, on admission, are ascribed to a transient situational reaction can have been the result of "a persistent disorder or disability of mind" (section 4(4) MHA, 1959).

Mentally ill men

Table I showed that these men came to Broadmoor under a wider range of legal categories than did the psychopathic. How long the mentally ill men in the various legal categories were held was clearly of interest, and Table IV divides the men admitted between 1972 and 1974 into the three length of stay groupings.

It will be seen that the civil patients (S.26 in the table) tended to stay longer than offenders admitted under hospital orders. Two factors were probably relevant here. First, the civil patients had come to Broadmoor from psychiatric hospitals where they had proved difficult to manage (in over a third of cases they had attacked hospital staff), and it was therefore likely to have been difficult to return them. Secondly, there was evidence in the data that these men were on admission more severely and chronically ill than the patients who had committed serious offences: they had more often been hospitalised before.

Different considerations govern the release from Broadmoor of patients in the various legal categories. As far as hospital order cases are concerned, the release of restricted patients who are subject to statutory aftercare and supervision is obviously approached differently from the release of unrestricted offenders to whom these provisions do not apply. For these reasons, length of stay needs to be examined separately for each legal category. However, only in the case of restricted hospital order cases were our numbers large enough to permit comparisons to be made between the short- and longer-stay men. Our analyses were therefore confined to this group. It comprised all men subject to restricted hospital orders who were admitted from the courts between 1972 and 1974 with a MHA classification of mental illness. Excluding a few men who died in Broadmoor or were sent to prison after committing further offences in the hospital, the group comprised 111 men, 75% of whom had been diagnosed as schizophrenic on admission. Table II shows how long these patients were held.

As with the PD men, we divided the mentally ill into three categories: those released in the first 4 years (46 men, 41%), those held 8 years or more (47 men, 42%), and those in the intermediate group (18 men, 16%). Comparisons were then made between the three groups on the variables available, to see what distinguished the longer from the shorter stay mentally ill patients.

These comparisons revealed no significant differences in age, nor in the data regarding early family history, though there was a trend to suggest that the short-stay men were less likely than others to have suffered disruption in their upbringing. The criminal histories showed that men who had previous convictions for serious offences (violence or arson) were somewhat less likely ($P<0.07$) than others to fall into the short-stay group. Only 27% of the men (compared with 47% of the psychopaths) had such convictions on their records.

Among the PD patients, it was the data relating to the admission offence which distinguished the long- from the short-term groups, but this was not the case among the mentally ill. Table V shows the type of offence committed and what victims, if any, there were; neither of these items was significantly related to length of stay.

Only one factor relating to the offence appeared among the mentally ill to be significantly related to length of stay; this was the consultant's assessment, made on admission, of whether the offence had been sexually motivated. Fifteen men were positively rated in this way, and 11 of them (73%) fell into the long-term group (χ^2 8.49 d.f. 2, $P<0.014$). With this exception, data about their offences did not relate to the length of time that mentally ill patients were held in Broadmoor. Factors relating to the seriousness and chronicity of their illnesses appear to have been more relevant. Since the Case Register does not contain information about the patient's stay in hospital, information about mental state was not available. There were however indications in the data to suggest that length of stay was related to a severity of illness. For example, more of the long-term group (64%) than of the other men (44%) were recorded as being deluded or hallucinated on admission ($P<0.13$), and more of the short-term group (24% compared with 11%) had an admission diagnosis of paranoid state ($P<0.15$). But the previous hospital

2. χ^2 6.59 6 d.f., NS.

experience of the men was perhaps the most telling factor, as representing the seriousness and intractability of their illnesses. Of 77 men who had previously been psychiatric in-patients, 49% fell into the long-term group, whereas of the 31 who had no such history only 23% were detained for more than 8 years ($\chi^2=6.88$ 2 d.f., $P<0.033$).

Discussion

Our analyses were based on the patient's MHA classification on admission to Broadmoor. In fact, many men who are admitted to Broadmoor under the PD classification are, or become, mentally ill. When two of us carried out research in Broadmoor in 1982–1984 (Dell & Robertson 1986), we found that 17% of the resident men who were classified as PD under the Act were diagnosed by their doctors as being mentally ill. Conversely, about 8% of the men classified as mentally ill under restriction orders were said by their doctors not to be suffering from mental illness. It was not usual for cases like these to be reclassified under the Act.

Analyses based on MHA classifications are thus bound to be somewhat misleading. Nevertheless the data did point to a major difference between the detention of PD and mentally ill offenders: length of stay for the former, but not for the latter, was related to the seriousness of their offences. Table III, which shows how long PD men were detained for different kinds of offences has something of the appearance of a tariff; Table V (detention of mentally ill men) does not.

How is this difference to be explained? In our view, it arises from the fundamental differences between the two groups. The mentally ill offender in Broadmoor suffers from disorders (mainly schizophrenic) about which there is an established body of psychiatric knowledge: doctors in the main agree about the recognition and treatment of the symptoms concerned. The patient is seen as having offended in the context of his illness, and if it responds satisfactorily to treatment, transfer to a less secure environment will be envisaged, whatever the offence. The course of the illness, rather than the nature of the original offence, is the dominant consideration in discharge decisions about mentally ill offenders.

For the PD men, the situation is very different. Their offences have not been committed in the context of illness. Had they not committed their crimes, few of them would have been said by doctors to require psychiatric detention. Once in hospital, the course of the disorder attributed to them cannot be monitored by the doctors in the same way as can the course of mental illness: questions of treatment, too, are more uncertain (Home Office, DHSS 1975). An offender admitted to Broadmoor with a schizophrenic illness will receive for it the standard type of drug treatment. The extent to which the illness is controlled by this treatment can then be systematically assessed by mental state examinations. For the PD offender the choice of treatment is seldom so clear, and it is certainly more difficult to establish whether change that is relevant has occurred. It is therefore not surprising to find that in this uncertain territory the seriousness of the patient's offence evidently assumes considerable importance: it is one of the few hard pieces of data available to the discharge decision makers. However, that the length of detention in a hospital should mirror the gravity of the patient's offence does raise fundamental questions about the whole process of committing offenders who are not mentally ill into indefinite psychiatric detention.

Acknowledgements

This work was carried out in the Forensic Psychiatry Unit at the Institute of Psychiatry. We are very grateful to the DHSS for the grant which made the study possible, to Dr John Hamilton and Professor John Gunn who proposed the work, and to Mrs Maureen Bartholomew for secretarial help.

Psychiatric Disorder in the Community and the General Health Questionnaire

P. G. SURTEES

Goodchild & Duncan-Jones (1985) have proposed a new scoring method for Goldberg's General Health Questionnaire (GHQ) in which increased weight is given to item responses considered to indicate current (but chronic) affective disorders. This report examines both their revised and the conventional scoring of the GHQ in the context of a longitudinal general population study of psychiatric disorder among women. Sensitivity estimates based upon advised cut-points were found to be higher for the revised than for the conventional scoring scheme, and this difference remained when allowance was made for the duration for which disorders had been present prior to assessment with the GHQ. However, Relative Operating Characteristic (ROC) analysis revealed that while both forms of scoring the GHQ discriminated affective conditions (with or without allowance for their duration) there was no significant difference in their ability to do so. The justification therefore for the post-hoc interpretation of certain item responses as indicators of enduring affective states remains controversial and an issue for future research.

The General Health Questionnaire (GHQ) was developed to facilitate the detection of cases of affective disorder among community and primary care samples (e.g. Goldberg & Blackwell, 1970; Goldberg, 1972, 1978, 1981). Since its introduction, it has been subject to a number of validity studies, used for prevalence estimation, applied in a variety of cultures and languages and evaluated in relation to prescriptive screening (e.g. see Tarnopolsky *et al*, 1979; Henderson *et al*, 1981; Benjamin *et al*, 1982; Radovanovic & Eric, 1983; Banks, 1983*a*; Chan & Chan, 1983; Skuse & Williams, 1984). In addition, several forms of the GHQ have been produced, ranging in length from 12 to 60 items to suit a variety of research needs, but Goldberg has suggested that, where possible, the longer forms of the questionnaire are to be preferred to ensure maximal sensitivity and specificity.

The years since the GHQ was first published have seen the development of a number of semi- or fully structured psychiatric assessment interviews designed to provide current symptom state profiles, to enable diagnoses to be assigned according to a variety of schemes, and to strengthen the basis for aetiological and cross-cultural studies. The availability of these diagnostic methods, with their increasing emphasis on classifying *episodes* of psychiatric disorder rather than health state during particular pre-interview periods, has enabled estimates to be made of the timing of clinical changes, and of how long given symptom states have persisted, and enabled times of remission from illness to be documented. Such information, allied to that obtained from the GHQ, provides the basis for an examination of the recurrent issue of whether this questionnaire fails to detect *chronic* affective conditions (Finlay-Jones & Murphy, 1979; Benjamin *et al*, 1982; Williams 1983; Banks, 1983*b*; Skuse & Williams, 1984). As such disorders are usually found to represent about half of those contributing to point prevalence estimates in both general population and primary care settings (e.g. see Goldberg & Huxley, 1980; Brown *et al*, 1985; Surtees *et al*, 1986), clarification of the relationship is required.

In a largely exploratory study, Goodchild & Duncan-Jones (1985) proposed a new scoring of the GHQ motivated by reports that the questionnaire frequently failed to detect chronic disorders. They challenged Goldberg's (1978) assertion that 'as usual' responses to items on the questionnaire only indicated normal functioning; believing that such responses could understandably be elicited from those chronically impaired at the time of assessment. On this basis therefore, Goodchild & Duncan-Jones divided the 30-item GHQ into equal item sets distinguished by whether or not an 'as usual' type of response could be a 'potential indicator of chronic difficulty or illness'. The revised scoring provided improved estimates of sensitivity and specificity, showed greater stability in repeated use over time and was psychometrically more satisfactory than the conventional method of scoring the GHQ (results from a general population sample incorporating a longitudinal design; Henderson *et al*, 1981). However, their research design made only limited use of a semi-structured psychiatric interview to assess present state, no attempt being made to determine either onset or remission of identified disorders. Chronic disorders meeting diagnostic criteria could not therefore be distinguished from acute disorders in the assessment of the modified scoring scheme. It is clear then that further investigations of the revised scoring scheme on new data are warranted, but such investigations must incorporate diagnostic information which allow clear case status designation. The findings would then be helpful in enabling a choice to be made between the two scoring methods. The present report therefore presents results obtained from contrasting the revised with the conventional scoring of the GHQ in the context of a longitudinal general population study of psychiatric disorder among women.

The research had the following specific aims in relation to the usual and the revised scoring of the questionnaire:

(a) to examine the psychometric properties of the two scoring methods, particularly in repeated use over time;
(b) to estimate sensitivity and specificity associated with each scoring method and to examine change in such estimates with time;
(c) to investigate the relationship between case status (with or without allowance for chronicity) at each of two interviews 6 months apart and that accorded by the two GHQ scoring methods.

These aims represent an attempt to repeat aspects of the procedure reported by Goodchild & Duncan-Jones (1985) and additionally to assess, through the specific examination of chronic conditions, whether there is any justification for adopting a modified scoring of the GHQ.

Method

The community study was undertaken in a geographically discrete area of Edinburgh and based upon a random sample of 576 women aged 18–65 years. A subsample of those women initially interviewed were approached for re-interview 6 months and 1 year later. Details of the design and methodology of the initial survey, of the follow-up and of response rates are provided in two earlier reports (Surtees *et al*, 1983, 1986). Briefly, two groups of women were selected for follow-up. In sample A were those who met *either* the Research Diagnostic Criteria (RDC; Spitzer *et al*, 1978) *or* the diagnostic scheme allied to the Present State Examination (PSE; Wing *et al*, 1974; Wing & Sturt, 1978) for a current psychiatric disorder. In sample B were those who were currently free of psychiatric disorder but had one or more of a set of putative vulnerability factors being recorded as present; *or* were included in a 40% random sample of those women who were both currently well and had none of the factors recorded as present. The ten factors chosen were (a) none or very poor relationship with a confidant, (b) none or very little diffuse support, (c) living alone, (d) reporting a poor relationship with one or more household members, (e) living with three or more children aged <14 years, (f) loss through death of one or both parents before age 11 years, (g) separation from either or both parents for ⩾1 year before age 11 years, (h) unemployment of spouse/cohabitee, (i) prior contact with health services for 'nerves', (j) low self-confidence.

At each interview, the subject's psychiatric status was evaluated using a semi-structured clinical interview, the Psychiatric Assessment Schedule (PAS). This was based on the first 40 items of the PSE and selected items from the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978). The PAS provided a detailed assessment of each respondent's psychiatric status for the month preceding each interview, and in addition sought information about her clinical state during the inter-interview time periods in order to establish accurately when the onset and remission of any illness episode had occurred. Further details describing the PAS are given in an earlier report (Dean *et al*, 1983).

The validation procedures adopted for all the interviewers' assessments completed during the follow-up were identical to those applied in the first stage of the study and reported elsewhere (Surtees *et al*, 1983). In brief, if after checking interview material, evidence of psychiatric illness was found, then the audiotape of the interview was listened to and re-rated by staff. Consensus symptom ratings were then established by joint discussion between interviewer and a staff rater.

Where respondents had provided interview information from two or three assessments, then two staff examined all available clinical material obtained from the interviews. The objectives were to re-evaluate all clinical change points, to date them in relation to each respondent's last interview and to apply the RDC scheme to all available symptom data.

At each follow-up, respondents completed the 30-item GHQ which was scored according to the conventional and, for this paper, also the revised method. Full details of the revised scoring procedure are given in Goodchild & Duncan-Jones (1985) and are therefore not repeated here. To facilitate comparison with that work, this paper will adopt an identical method of score designation. Those 15 GHQ items considered to be potential indicators of chronic illness were defined as set N, with the remainder set P. The four GHQ response categories ('not at all' (code 1); 'no more than usual' (code 2); 'rather more than usual' (code 3); and 'much more than usual' (code 4)) were then conventionally scored, with codes 1 and 2 being scored 0 and codes 3 and 4 scored 1. Under the revised scoring, all set P items were similarly scored, but set N items with assigned codes 2, 3, or 4 were scored 1.

Results

For most of the analysis the distinction was retained between those women re-interviewed who met the RDC for a psychiatric disorder at initial interview, sample A, and those also selected for follow-up but who were assessed as 'well' at initial interview, sample B. As no significant difference in case inception rates was found between the two subsamples comprising sample B (Surtees *et al*, 1986), for present purposes they were treated as one group.

Table I displays the distribution of responses to set N and set P items by sample and follow-up (F1 and F2 indicate first and second follow-up respectively). As with the Canberra study, these results reveal the 'as usual' responses

TABLE I

Distribution of responses (averaged %) within each set, for each follow-up of each sample

	Sample A		*Sample B*	
	F1 (*n*=*61*)	*F2* (*n*=*59*)	*F1* (*n*=*313*)	*F2* (*n*=*283*)
N items

Codes 3 and 4	32	21	10	10
P items				
Code 1	13	23	19	15
Code 2	62	61	73	76
Codes 3 and 4	25	16	8	9

(code 2) to be more frequently found among the set of P items than among the N set, particularly among sample B.

Table II shows the mean GHQ (conventional scoring) and CGHQ (revised scoring) scores by sample and follow-up. Also indicated is the proportion of women with score values at or above the appropriate scale cut-points at each follow-up. In accordance with expectations, the proportions of women above the cut-points (on both scales) drops between first and second follow-up assessments for sample A (those all with RDC diagnoses at the start of the study), but not sample B. However, the change can be seen to be proportionately greater for the conventional scoring (GHQ) than for the revised scoring of the questionnaire (CGHQ).

A further indication of the consequence of adopting the revised rather than the conventional scoring is revealed by comparing the cumulative distributions of respondents with given scale scores. The results for samples A and B are shown in Figs 1 and 2 respectively. In Fig. 1, with the conventional scoring of the GHQ, just over 20% of sample A respondents at first follow-up and almost 40% at second follow-up obtain a zero score, in marked contrast to the results obtained with the revised method. The difference in this respect is particularly pronounced in Fig. 2, where the analysis is based upon a sample more representative of the general population. The almost linear increase in the CGHQ cumulative distribution may be an advantageous psychometric property for future research application, as it more closely approximates a normal distribution than that based upon conventional GHQ scoring.

TABLE II

GHQ and CGHQ scores

	Sample A		*Sample B*

Percentage scoring $\geqslant 13$	67.2	52.5	18.5	26.1
Mean	14.9	12.8	8.0	8.4
Mean/mean F1	1.0	0.9	1.0	1.1

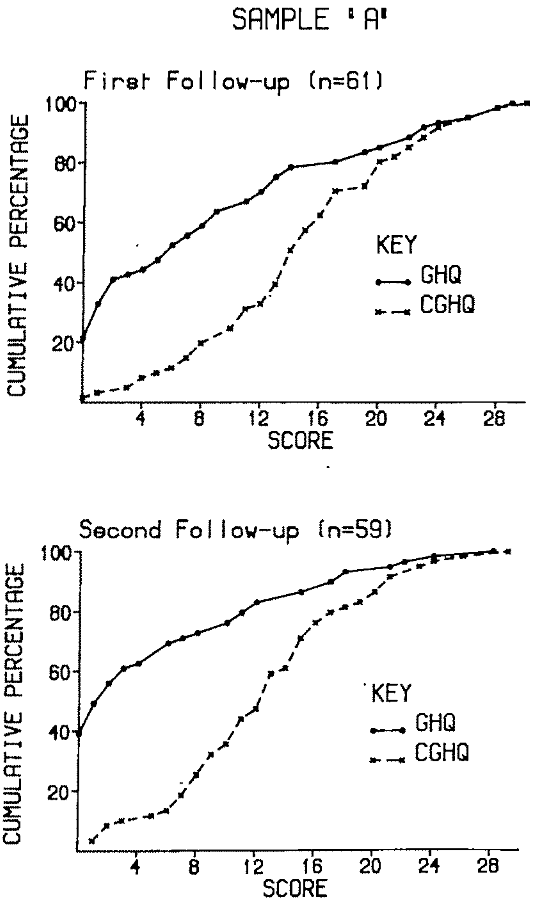

FIG. 1 Cumulative distribution of women in sample A by their GHQ and CGHQ score values at each follow-up.

Estimates of sensitivity (proportion of 'true' cases correctly identified) and specificity (proportion of 'true' normals correctly identified) associated with the advised cut-points on the GHQ and CGHQ scales were determined next. Analyses were undertaken for the samples separately and when combined. The results are shown in Table III.

The indices are intended primarily to provide a basis for comparison between the two scoring methods and not as precise estimates in view of the deliberate sampling biases adopted in this study. The results reveal that the sensitivity estimates based on the CGHQ equal or more usually exceed those determined from the GHQ. The difference is particularly marked at the second follow-up for sample A

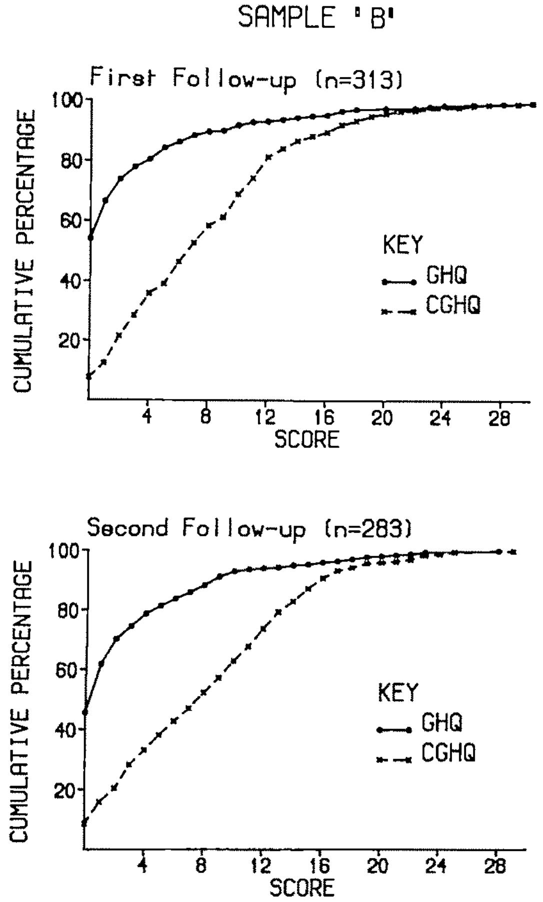

FIG. 2 Cumulative distribution of women in sample B by their GHQ and CGHQ score values at each follow-up.

where, for many, the duration of continuing RDC disorders will have already exceeded one year. While there appears to be a price in terms of specificity, these results do suggest that *perhaps* the modified scoring of the GHQ enhances detection of chronic disorders.

Table III additionally shows the percentage of each sample within an episode of RDC disorder at the time of GHQ assessment. For comparison, the percentage of women at or above the cut-points on the two GHQ scoring methods was shown in Table II. These results taken together reveal somewhat paradoxical findings. While there are a number of reports which have found prevalence estimates of psychiatric disorder to fall with repeated assessment (e.g. Henderson *et al*, 1981; Tennant *et al*, 1981; Robins, 1985), there is no obvious explanation for the phenomenon (see Henderson *et al* (1981) for a discussion of some alternatives). These results clearly show that, unlike the Canberra findings, the GHQ-based prevalence estimates in this study (sample B) remain stable or indeed increase based upon the revised scoring.

Also shown in Table III are the values of Y (Yules' coefficient of colligation) associated with each case/cut-point analysis. It has been suggested recently (Spitznagel & Helzer, 1985) that this measure has particular advantages over the more usually determined κ statistic for certain investigations of reliability and validity. In particular, for studies of validity the measure Y is totally independent of prevalence. The Y values in Table III were determined from smoothed pseudo-Bayes estimates of the cell probabilities (Bishop *et al*, 1975, equations 12.7–18 and 12.7–19), a procedure considered to be superior to that based upon raw cell values. In addition, the method enables Y estimates to be calculated from 2×2 contingency tables containing zero counts. As can be seen, the Y estimates in Table III suggest an advantage (if only marginal) in adopting the revised over the conventional scoring of the GHQ.

The results presented so far are based upon the advised or working cut-points usually adopted for estimating validity coefficients associated with the scales. An alternative method is to examine the variation in true

positive (sensitivity) and false positive (complement of specificity) proportions with changes in GHQ and CGHQ scale cut-points. This procedure, known as Relative Operating Characteristic (ROC) analysis, was originally used for research into signal detection using radar, but has subsequently been adopted in a variety of research areas where indices of comparative accuracy are required. The method has enabled, for instance, an evaluation of two diagnostic imaging techniques, computed tomography and radionuclide scanning (Swets *et al*, 1979). The application of the method to epidemiological studies is only very recent (Erdreich & Lee, 1981) and particularly so to psychiatric epidemiology (Mari & Williams, 1985).

The ROC method was applied to the GHQ and CGHQ scores obtained in this study, using a computer program developed by Dorfman & Alf (1969), but modified by Metz *et al* (1984; ROCFIT). The program provides fitted (maximum-likelihood) estimates of both sensitivity and false positive rate for all chosen scale cut-off points. ROC curves can then be plotted to these estimates. The area under each curve is used as an index of the detectability of a scale and varies between 0.5 (discrimination no better than chance) and 1.0 (scale with perfect discrimination). The ROCFIT program provides the area under the fitted curve and its standard deviation as part of the output.

Table IV shows the area estimates (and that of their associated variance) obtained for the conventional and modified scaling of the GHQ by sample and by follow-up. A two-sample Z test was applied to each pair of area estimates to establish whether they were significantly different (Erdreich & Lee, 1981). None of the analyses revealed significant differences in area estimates, and in these terms therefore both scales were found to be equally good, but indistinguishable from each other, as discriminators of women with RDC disorder.

The nature of the relationship between the fitted ROC curves for the two scales is shown in Figs 3 and 4 (for samples A and B respectively). These figures show the extent to which each ROC curve deviates from a linear ascending diagonal, and therefore the degree to which discrimination exceeds chance. The figures underpin the results shown in Table III, in that the detection of case status among sample A is clearly less successful than among sample B.

To examine the relationship between the two GHQ scoring methods and case detection further, women were classified according to their RDC case status at *each* of the two follow-ups. The percentage correct case status allocation by the advised cut-points on the two scoring methods was then determined. The results are shown in Table V. Due to missing values at either follow-up, the database available for analysis was reduced below that reported on in previous tables.

Of particular interest was the relative success with which the conventional as opposed to the revised scoring identified those women fulfilling the RDC at *both* follow-ups. Table V shows that the CGHQ was more successful than the GHQ in correctly allocating such women, and as Table III hinted, this appeared particularly so among those with enduring disorders in sample A. However, so far neither those analyses based upon advised cut-points nor those using ROC analysis have included any specific allowance for the *duration* of RDC disorders. To assess claims that a revised scoring of a widely used screening instrument will enhance detection of chronic conditions, allowance should be made for episode duration. This was attempted in the following analyses.

For sample A a chronicity criterion of two or more years was adopted, while because of constraints imposed by the limited follow-up period, when both samples were combined this was reduced to six or more months. Those women with RDC disorders but not meeting the chronicity criteria were regarded as 'acutes'. Analyses then determined the success with which the advised cut-points on the two GHQ scoring methods correctly identified the various subgroups of women. The results are displayed in Table VI.

The results, although based on relatively small numbers, suggest that adopting the revised scoring of the CGHQ increases the percentage of women identified with chronic RDC conditions. It would appear also that there is neither a compensatory loss of those women identified with acute conditions nor a substantial increase in false positives.

As before, these analyses were complemented by adopting the ROC procedure with the chronicity criteria varied as in Table VI and with scale discrimination being assessed in relation to those women with and without chronic RDC conditions. The results in terms of the areas (and their variance) under the resulting ROC curves are shown in

Table VII. Analyses revealed no significant differences between any of the area values (e.g. for the second follow-up, combined samples $Z = 0.97$).

Discussion

The attempt to screen successfully for affective conditions with only limited use of self-report questioning methods, while desirable from a multitude of standpoints, is necessarily hazardous. Perhaps of primary significance is that validation of the screening measure is absolutely dependent upon what Robins (1985) has called the 'erratic standard' of the clinician's interview; that is, the psychiatric assessment has to be assumed to be correct (also, see Williams, 1986). Additionally, variations in the diagnostic criteria of different schemes and differences in the conceptualisation of episodes of psychiatric disorder contribute to difficulties in understanding what may be a changing validity criterion. A further compounding factor is of course that the questionnaire-based screening method transfers responsibility to the respondent for interpreting the meaning of items; severity of and change in affective state therefore have no common reference. These issues are well known, but it is relatively difficult to investigate their specific effects.

The suggested revised scoring of the GHQ proposed by Goodchild & Duncan-Jones (1985) reinterprets certain responses to particular scale items. However, the Canberra investigation, through only limited adoption of a standardised psychiatric assessment method, did not contrast the conventional with the revised scoring method in detecting long-term as opposed to short-term affective conditions. The scoring methods were only examined in relation to psychiatric state at each interview. As Table V in this

study showed, such analyses do not correspond to an examination of the detection of chronic conditions. The results shown in Table VI, with allowance for chronicity criteria, do lend some support to the revised scoring method.

However, the ROC analyses revealed that the conventional and the revised scoring of the GHQ were indistinguishable in their ability to discriminate between those women with and those without RDC disorders, regardless of whether or not allowance was made for the duration of illness episodes preceding GHQ assessment. These analyses, of course, took account of the full scale ranges. In many circumstances the practical application of a screening instrument for detecting psychiatric morbidity rests upon use of a specific advised cut-point. The results of this study have suggested that where the advised cut-points are adopted, there appears to be a marginal advantage in favour of using the revised scoring. However, the assumption underpinning the revised scoring of the GHQ remains controversial and not specifically addressed by this study. The extent to which it is justified must remain an issue for further research.

Background and acknowledgements

The community study described in this article was designed and completed by the following staff members of the MRC Unit for Epidemiological Studies in Psychiatry, Edinburgh, Scotland: J. G. Ingham, N. B. Kreitman, P. McC. Miller, S. P. Sashidharan and P. G. Surtees, together with C. Dean, who is now at the Department of Psychiatry, Manchester Royal Infirmary. Statistical advice concerning pseudo-Bayes estimation was provided by J. C. Duffy, Department of Statistics, University of Edinburgh. The ROCFIT program (written by C. E. Metz) was kindly provided by P. Williams of the General Practice Research Unit, Institute of Psychiatry, London.

Long-stay Patients in a Psychiatric Day Hospital
A Case Note Review

G. McGRATH and D. TANTAM

The case notes of all non-psychogeriatric patients attending the Psychiatric Day Hospital at the University Hospital of South Manchester during one week in October 1982 were reviewed. Clinical, demographic, social and occupational data were gathered for all patients, and their attendance at the day hospital monitored for the year following the census period. No significant differences between patients could be found on any of the factors that it was predicted would distinguish short from long-stay patients. The best predictor of length of day hospital attendance in the current admission was the total quantity of previous hospital treatment whether as an in-patient or a day-patient. It is concluded that in the day hospital studied all patients had similar characteristics, and the majority could be seen as 'new long-stay' patients. The implications of this finding are discussed.

The Government White Paper (DHSS, 1975) on day care for the mentally ill endorsed the policy of dividing day care into two sectors; acute treatment to be provided by District Health Authorities with local Social Services providing social care for the chronically disabled. This philosophy of community rather than hospital care reflected the aim of closing large mental institutions and replacing them with psychiatric units attached to District General Hospitals. Recently both the philosophy and the practice of psychiatric day care has been called into question (Royal College of Psychiatrists, 1980; Bender, 1983; Vaughan, 1983*a*,*b*; 1985; Wilkinson, 1984).

A number of studies have highlighted the difficulties in pursuing the government's expressed aims. Edwards & Carter (1979) found in a national survey of day units that over 30% of users of day hospitals had been attending over 1 year compared with 50% in day centres, and that these patients did not make full use of the facilities offered. Pryce referred to the expanding 'stage army' of new long-stay day patients, noting the trend for the psychiatric day patients increasingly to have been in contact with day services for over a year (Pryce, 1982; Pryce *et al*, 1983). These authors doubt the adequacy of service provision for long-stay patients at day hospitals. There are also doubts as to whether day care provides any effective treatment for these patients (Herz *et al*, 1971, 1976, 1977; Vaughan, 1983*a*, 1985).

In a series of papers published in the early 1970s, Gath, Hassal, and Cross (Cross *et al*, 1972; Hassal *et al*, 1972; Gath *et al*, 1973) reported on a study of patients at seven day hospitals in Birmingham, four in traditional mental hospitals and three relatively new units attached to District General Hospitals (DGH units). They found that the two types of hospital day units served two radically different patient populations. Patients attending the day hospitals in traditional large mental institutions were older, had more severe mental illnesses, showed greater morbidity in terms of their past psychiatric history, were more likely to have been attending for long periods before the census and were much more likely to be still attending at the end of the one year follow-up period.

This distinction between the patient populations of traditional and newer DGH day units was felt to be highly relevant to planning of day services. Gath *et al* concluded that it was ill-advised to close down mental hospitals until other provision was proved to be better.

The study in this paper to some extent repeats that of Gath and his colleagues, but in a Psychiatric Day Hospital attached to a District General Hospital in a Health District where there is no large mental institution and no other Health Service provision for day care of psychiatric patients. The prediction was that the two radically different patient populations identified in the Birmingham study could be identified in one DGH unit, with implications for the kind of service provided.

Present study

The day hospital used in the study occupies part of the Department of Psychiatry in the University Hospital of South Manchester providing 80 places per day for psychiatric patients (0.3/1000 resident population). There is no alternative health service facility such as a local mental hospital for the treatment of mental illness in the South Manchester district. There are five clinical teams admitting to the day hospital, totalling nine consultants and ten junior doctors, each team having one full-time nurse. These teams each continue to look after their own patients and thus effectively operate individual services within the day hospital. A full range of occupational, social and recreational activities is offered, and there are wood and metal workshops and an industrial therapy unit.

There are no other health service day facilities for the mentally ill in South Manchester. There is one local authority-funded day centre in the district, plus two day centres in adjoining districts which accept a limited number of patients from South Manchester. There are a few places available in sheltered employment, primarily in Cheadle Royal Industries. All day places are shared with other health districts of Manchester, so the number of day places available for after care from the day hospital varies with demand from other areas.

It was predicted that if patients attending the psychiatric day hospital are divided into subgroups on the basis of their length of stay and rate of discharge then these groups will be distinguishable on a number of variables relating to severity of illness, social and demographic factors, employment before and after discharge and associated physical ill-health.

Method

The study included all 109 patients recorded in the day hospital attendance roll at any time in the week beginning 1 October 1982, excluding those under the care of the psychogeriatric services.

The case notes of all patients were reviewed and the following data collected:

(a) Demographic – age; sex; marital status; recent and past occupations; length of time in work; housing; family.

(b) Clinical – current diagnosis; past psychiatric history; current treatment; date of admission; date of day hospital enrolment and frequency of attendance.

In addition, case notes and other records were perused for the 1-year period following the census to obtain the following information:

(c) Attendance – weekly attendance was obtained from day hospital records for the year following the census week.

(d) Discharge – for those patients discharged information was collected on occupation, housing and disposal following discharge.

Results

Length of stay

Of these patients, 39 (36%) continued on the roll of the day hospital throughout the year of the follow-up period. The 'length of stay' refers to the time from the date of enrolment in the day hospital to the date of discharge or the end of the study, whichever was the longer.

The frequency of lengths of stay did not, however, bear out the prediction that there would be two separable populations of attenders; short-stay patients who were discharged in a matter of months, and long-stay patients. When the cumulative frequencies of length of stay were plotted (as the percentage of patients remaining on roll against time (Fig. 1)) there was no incisura which would have indicated the presence of two populations. The distribution of lengths of stay closely approximated to an exponential as can be seen from its linearity when plotted on a semi-log scale (Fig. 2; correlation coefficient = 0.98). There is a departure from linearity beyond 60 months, suggesting that there may be a distinct very long stay group, but the number of patients involved (five) is very small.

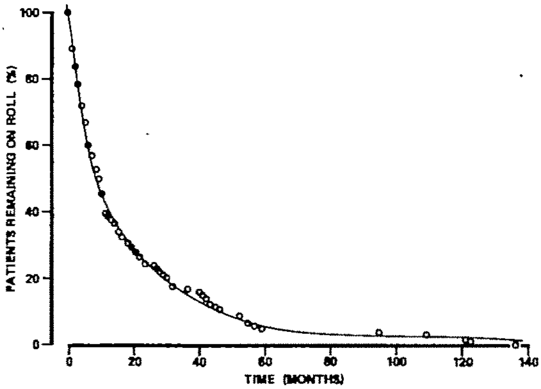

FIG. 1 Percentage of patients remaining on day hospital roll (Cumulative frequencies of months on roll during index admission) vs time from enrolment – linear scale.

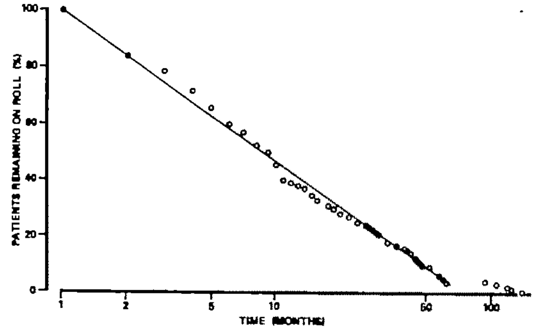

FIG. 2 Percentage of patients remaining on day hospital roll (Cumulative frequencies of months on roll during index admission) vs time from enrolment – log-linear scale.

TABLE I
Comparison of patient characteristics with length of stay

	Test	*Value*	*Significance*
Age at entry to study	R	0.156	0.052
Marital status	χ^2	8.28	NS
Last employment: months before current admission	R	0.328	0.001
Accommodation during day-hospital attendance	χ^2	10.03	NS
Primary diagnosis	χ^2	1.83	NS
Whether sectioned in lifetime	χ^2	1.899	NS
First psychiatric contact: months before current admission	R	0.3818	0.001
Total number of previous in-patient admissions	R	0.399	0.001
Total length of previous in-patient stay	R	0.227	0.01
Total number of previous day-hospital admissions	R	0.47	<0.001
Total length of previous day-patient stay	R	0.521	<0.001
Prescription of four or more categories of drugs	χ^2	28.95	0.0056
Frequency of attendance: days per week	R	0.257	0.003
Occupation after discharge	χ^2	16.18	0.04

Discrete variables analysed using χ^2 with short, medium and long-stay groups. Continuous variables compared using correlation with length of stay.

In the absence of two naturally defined groups, the 109 patients were arbitrarily divided, for the purposes of further data analysis, into the same three groups used in the study of Gath *et al* (1973); short-stay (length of stay $<=3$ months), medium stay (4–9 months) and long-stay (>9 months). Statistical analyses were performed to generate χ^2 for discrete variables and Pearson correlation coefficients for continuous variables.

Demographic and clinical factors

There were almost twice as many women (71) as men (38) attending the day hospital, but the proportion of men to women was the same in all variables subjected to analysis, so the results are presented for the whole population (Table I).

The majority (nearly 60%) of patients attending the day hospital were admitted during the transition between in-patient care and discharge. There was relatively little use of day care as the primary treatment strategy. Of all patients, 62% had diagnoses of schizophrenia or manic-depressive psychosis. It was anticipated that factors related to the severity of the illness would distinguish short-stay from long-stay patients and these factors would include diagnosis, duration of illness and the history of medical intervention, including history of involuntary admission. In fact, no significant differences were found between groups. Nor were the long-stay patients more likely to be single or living alone.

Several factors related to previous psychiatric contact correlated significantly with length of stay. These were: duration of treatment (time between the first recorded contact with psychiatric services and the current admission), number of previous in-patient admissions and total previous in-patient stay, number of previous day-hospital admission and total duration of previous day hospital attendance. Whether a day patient remains on the day hospital roll for a long period thus seems to be most closely related to previous contact with the hospital.

There was a weaker positive correlation between age and length of stay, and this may have been a confounding factor. In order to check this, and determine the relative contributions of the different variables to the overall variance, multiple regression analysis was performed. Length of previous day-hospital stay accounted for 37% of the observed variance, and overall less than half the variance was accounted for by the variables measured in this study. Age, when forced through first in the analysis, accounted for approximately 4% of observed variance and the contribution of other variables was reduced proportionally. Thus age does seem to be a confounding variable, but its contribution is small.

There were no significant differences between the groups on whether or not they were prescribed neuroleptics (oral or depot), anxiolytics, lithium, ECT or antidepressants during the period of the study. The long-stay group were significantly more likely to have received hypnotics ($P=0.01$) and drugs for physical complaints ($P<0.001$) and were more likely to have received four or more different kinds of treatment than the short-stay group. Exactly half the patients in all groups were given an antidepressant in the course of the study, despite the major diagnostic group being schizophrenia.

Much of the treatment provided in a day hospital is social and occupational. However, although an attempt was made to elicit information about non-drug treatments given to patients, these were insufficiently well recorded for this to be possible. For example it was rare for either clinical notes or nursing records to detail occupational or social therapy programmes, and the occupational therapy department was unable to provide this information.

The frequency of attendance during the follow-up period was also recorded. It might be expected that the short-stay group, receiving intensive brief treatment would attend more frequently than the long-stay group, but in fact the reverse proved to be true. Nearly 50% of the long-stay group were attending over 3 days per week whereas nearly

70% of the short-stay group attended 3 days or less. There is a statistically significant correlation between months on the day hospital roll and the frequency of attendance.

During the follow-up period 70 patients were discharged (seven were discharged twice), 15 were readmitted (two twice). Of the patients who were discharged in the follow-up period, three were discharged to in-patient care and two to supervised accommodation, the rest to their own or their family home. Out-patient appointments (usually with a junior doctor on a rotational training scheme), were offered to 61 (88%) of those patient discharged: four (6%) referred back to the care of their General Practitioner and one was followed up by a community nurse. Four patients had no disposal arrangements recorded.

Only five patients (7%) returned to open employment after discharge. 15 (22%) were accommodated at day centres or industrial rehabilitation units and four (13%) were doing voluntary work. The great majority of patients (46; 66%) had no occupation at discharge. The short- and long-stay groups differ significantly in that the short-stay group are more likely to return to open employment ($P<0.01$), but if those patients attending rehabilitation units or involved in voluntary work are classed as 'employed' this difference disappears.

Discussion

Contrary to the original hypothesis, it was not possible to separate, using social or clinical characteristics, two distinct groups of patients with different lengths of stay in the psychiatric day hospital. It may be that the measures used in this study were too insensitive to distinguish these populations, but in fact they are consistent with those that clearly distinguished the two populations in the Birmingham study of Gath *et al.* An alternative explanation is that to all intents and purposes the patients in this study represent a single population. This is supported by the lack of clear differences between long- and short-stay populations, and also by the close similarities between the patients in this study and those described by Gath *et al* (1973) and Pryce *et al* (1982, 1983) as being typical of the long-stay day-hospital patient population.

Length of stay in the day hospital was significantly related to age, duration of illness, length of time unemployed before admission and the amount of hospital treatment received by patients prior to the current day hospital admission. This latter relationship holds both for number of admissions and total duration of stay, whether as an in-patient or a day-patient, although the correlation is strongest with previous day care, which alone accounted for 37% of the variance. These factors may simply reflect the severity of the illnesses suffered by the patients. However, length of stay is not related to differences in other clinical or social factors that might be related to the severity of the illness, such as diagnosis or the use of compulsory orders.

There are other possible explanations of this finding. First, it could be that the majority of patients being referred for day care are those with chronic disabilities. As the day hospital under study is operated by nine different consultants it is not the case that it constitutes a special unit with a defined policy of care for long-stay patients. Second, it is possible that the environment of the day hospital encourages dependency on the service such that patients become institutionalised, and makes it increasingly unlikely that they will be able to find acceptable alternatives. This proposition could be tested by relating the numerical order of previous admissions to the duration of each admission, when the length of stay should increase with successive admissions. Third the average length of in-patient stay in UHSM is relatively short (29.8 days; North West Regional Health Authority, 1986), raising the possibility that with the rapid turnover of in-patient beds the day hospital is increasingly being used for more disabled chronic patients who have gradually replaced the neurotic patients. It is not possible from our data to distinguish between these alternative explanations.

It may be that what determines whether a patient is discharged from the day hospital is the availability of alternative suitable occupation such as employment or a day centre, or some other opportunity arises that provides a more appropriate way of life, such as acceptance at a rehabilitation hostel or group home. There is a significant correlation between the duration of previous unemployment and day hospital stay. In addition two-thirds of patients are discharged to no employment at all. Although there was no difference in the proportions of patients in the artificial short and long stay groups who were in open employment at the time of admission, those who returned to work were all in the short-stay group. The majority of patients were living alone or with other family members and very few (7/109 by the end of the study period) had been in sheltered hostel accommodation. These findings imply that the day hospital setting is not providing the kinds of social and occupational treatments necessary for the effective rehabilitation of long-stay patients. This is supported by the absence from the medical and nursing records of a clear description of non-physical treatments being offered to patients. On the other hand, length of stay is significantly related to the number of different categories of physical treatments given, especially the addition of hypnotics or drugs for physical illnesses to regular psychotropic medication. The lack of adequate records of non-drug treatments and non-medical disposal and the poor recording of social and occupational histories implies that medical staff in ward rounds place comparatively more weight on the medical interventions that may well have the least to offer in the long-term management of such patients.

The implications of these findings are that if day hospitals similar to the one in this study are to be effective then the model of short-term care for acutely ill patients is not an appropriate one. If these patients are only attending the day hospital for lack of suitable day centres or occupational training in the community then there is an urgent need for more alternatives to hospital for such patients. If they are generally too ill or too disabled to function adequately in such alternative settings then a coordinated programme organised toward long-term rehabilitation is required.

Mania Following Head Injury

A Report of Two Cases and a Review of the Literature

A. F. CLARK and K. DAVISON

Secondary mania has been described in association with a variety of physical conditions. While there have been a number of reports of mania occurring in individuals with intracranial cerebral lesions, there have been few reporting its occurrence in association with non-penetrating cerebral trauma. Two further cases of mania following non-penetrating head injury and the efficacy of ECT in its management are reported, and a brief review of the literature relating to the subject is given.

Krauthammer & Klerman (1978) reviewed the literature on the occurrence of mania in association with physical illness and drugs. Their criteria for a diagnosis of mania were at least 1 week of elated or irritable mood, and at least 2 of hyperactivity, 'push of speech', flight of ideas, grandiosity, decreased sleep, distractibility and lack of judgement. A previous history of affective disorder or the presence of confusion excluded the diagnosis of secondary mania being made. In their search they found cases of mania thought to be secondary to drug use, metabolic disorders, infections, intracranial neoplasms and epilepsy. Further reports have since added cerebrovascular disease to the list of physical conditions reported (Jampala & Abrams, 1983) and have extended the range of drugs implicated (Stasiek & Zetin, 1985).

Head injury, however, appears to be an uncommon precipitant of mania. There are some reports in the early literature (Symonds, 1937; Tennent, 1937), but these patients are also reported as having clouding of consciousness, and would therefore be excluded on the criteria suggested by Krauthammer & Klerman (1978). Certainly the latter authors were unable to find any instances of mania following head injury to include in their review of the literature; nor were Stasiek & Zetin (1985) in their review of more recently reported cases. However, Whitlock (1982) found two reports of mania occurring after head injury: Dalen (1965) reported two cases of mania in association with both epilepsy and a previous head injury, although the dual pathology and the lack of a clear temporal association make the nature of the relationship unclear, while Cohn *et al* (1977) reported manic symptoms in a 12-year-old male following multiple injuries sustained in a road traffic accident. Two large follow-up studies of patients admitted to neurological and neurosurgical units following head injuries failed to find any cases of mania as either an immediate or long-term complication (Fahy *et al*, 1967; Roberts, 1979). In his series of 1168 adult patients who had suffered head injuries, Ota (1969) reported a single case of mania, but this occurred many years after a 'very slight head injury' and was thought to be unrelated to the insult.

There have been two recent case reports associating mania and head injury. Sinanan (1984) reported a 21-year-old female who developed mania after a head injury sustained in a road traffic accident, and Khanna & Srinath (1985) also reported a case of symptomatic mania in an adolescent female following head injury. Despite a computer search of the literature we have been unable to identify any other reports. In a 6-year retrospective study of all referrals to a psychiatric unit based in the same hospital as the regional neurosurgical unit, two cases of mania closely associated with non-penetrating head injury were identified and are reported here.

Case histories

Case one

A previously fit 70-year-old male was admitted to the neurosurgical unit, Newcastle General Hospital, in October 1981 with a 6-week history of headache, nausea, vomiting and increasing confusion and disorientation. He had suffered a non-penetrating head injury 4 months previously.

Prior to this illness he had been living alone and coping well with home-help and family support. He had been retired for 5 years and widowed for 2 years. He had two daughters living close. Neither he nor any of his family had any prior history of psychiatric disorder.

On admission he was conscious but disoriented in time and place and had impaired short and long term memory.

He was noted to be hallucinating but the nature or modality of the hallucinations was not recorded. Physical examination was unremarkable but a CT scan showed bilateral subdural haematomata. These were evacuated the following day; he improved initially but began to deteriorate 2 weeks later, when a repeat scan showed reaccumulation of the haematomata, which were again drained. A week later a corrugated drain was inserted when a second reaccumulation was discovered. From this time he made an unremarkable recovery and was discharged home 6 weeks after admission, with no neurological or cognitive deficit. He was started on phenytoin, 100 mg four times daily, as a prophylactic.

In February 1982 he was readmitted with dizziness, unsteadiness of gait and a coarse tremor. His serum phenytoin level was 33.0 mg/l and a diagnosis of phenytoin toxicity was made. The phenytoin was immediately stopped and his symptoms rapidly and fully resolved.

In April 1982 he was again readmitted, having become overtalkative and overactive for the preceding 4 weeks. He was described as having become irritable and disinhibited and as behaving 'completely out of character'. He had talked of becoming a missionary. He had begun to give his money away and had ordered new cars and gold teeth, none of which he could afford. He saw no reason to stay in hospital and believed that the ward sister was in love with him. His mood was euphoric. Neurological examination and CT scan were both normal. Psychological assessment showed some impairment of visuospatial abilities but no cognitive deficits. In particular, attention, orientation and long and short-term memory were all normal.

A psychiatric opinion was requested and a diagnosis of hypomania was made. He was started on thioridazine, 25 mg twice daily, which was increased to 50 mg twice daily when he failed to respond. On this dosage he became less grandiose and disinhibited and was discharged to out-patient follow-up.

Two months later he became socially withdrawn and lost most of his interests. He felt miserable and was frightened of meeting people. His sleep and appetite were not disturbed. At interview he looked depressed and there was marked psychomotor retardation, with little spontaneous activity or conversation. His thioridazine was reduced to 25 mg twice daily, and 50 mg of amitryptiline at night was added. This was increased to 100 mg at night as there was only a partial response.

Two months later he was thought to be fully recovered, with no evidence of mood disturbance. He was again coping well at home with home-help and family support. In November 1982 he was discharged to the care of his general practitioner, while still maintained on amitryptiline, 100 mg at night, and thioridazine, 25 mg twice daily.

Case two

A 60-year-old male Punjabi bus-driver was admitted to the neurosurgical unit, Newcastle General Hospital, after a fall in which he had struck his head and been unconscious for 10 minutes. On admission he was oriented in place and person but not in time. He was unable to give a coherent personal history. He could move all his limbs, although there was mild left-sided weakness. There was also some left-sided sensory inattention. A CT scan showed a diffuse area of low density in the right parietal region, consistent with an old infarct. His family subsequently confirmed that he had suffered a left hemiparesis 3 years previously but had made a good recovery, with little residual weakness. There was no other past medical history nor was there any personal or family history of psychiatric disorder.

He was observed in the neurosurgical unit for a fortnight, during which time his conscious level returned to normal. When discharged he was fully oriented with no intellectual defect, although his mild left-sided weakness persisted.

Two months later he became overactive, elated and overtalkative. He began telephoning the Pakistani High Commission in London late at night and became irritable if prevented from doing so. On one occasion he threw his son out of his house following a minor disagreement. During this period he was fully oriented, with no apparent memory impairment. A diagnosis of acute mania was made and admission to the local psychiatric unit arranged, where he was prescribed major tranquillisers. An EEG performed shortly after admission showed an area of delta activity in the right temporal region, which was thought to be related to his previous infarct. An ECG showed him to be in atrial flutter with variable block. Other investigations were normal. In view of his abnormal ECG and EEG findings he was seen by both a cardiologist and a neurosurgeon. Neither felt that they had anything to offer to his immediate management, although an M-mode echocardiogram was arranged, to exclude a cardiomyopathy as a cause of an embolic cerebral infarct. After 2 weeks' treatment he was thought to have settled sufficiently to be managed as an out-patient, but had to be readmitted within a week after again becoming extremely overactive and irritable.

On readmission he was extremely disruptive, with unprovoked outbursts of verbal and physical aggression. He was disinhibited in behaviour and would freely enter other patients' rooms, becoming irritable if intercepted. At no stage during this behaviour was there any evidence of disorientation nor of clouding of consciousness. His dosage of major tranquillisers was increased.

A second EEG showed increased asymmetry compared with his initial record; there was increased delta activity on the right side anteriorly and decreased delta activity on the right side posteriorly. Therefore, a second CT scan was performed, which showed a new area of low density in the left frontal region in addition to the previously noted area in the right parietal region. There was also a mild degree of cerebral atrophy.

As large dosages of major tranquillisers were failing to control his behaviour, an attempt was made to start him on lithium. However, he would not comply with regular oral medication and therefore adequate serum levels were not obtained. Finally a course of bilateral ECT was prescribed. After two treatments he had improved dramatically, and although still elated was much less irritable and overactive and would co-operate with medical and nursing staff in his management. After four treatments he was eating and sleeping normally and was only mildly overcheerful. ECT was then discontinued, but he rapidly became irritable, overactive and restless again. Two further ECTs were given, with the same dramatic improvement.

He was now also complying with oral medication, and adequate serum lithium levels were obtained.

In view of his maintained improvement he was discharged home to continue out-patient treatment. He was seen regularly in the out-patient department over the next 6 months, during which time he remained asymptomatic and his serum lithium levels remained within the therapeutic range (0.4–0.9 mmol/litre). His echocardiogram performed in this interval showed no abnormality. After 6 months he developed a further episode of hypomania and required readmission. He was treated with a course of four ECTs and with oral neuroleptics, and made a good improvement. He was discharged after 1 month. His lithium was withdrawn during this period when he became confused. For the next year he was regularly reviewed as an out-patient and remained well. He was recently readmitted with a third episode of hypomania. The results of all investigations performed during this last admission, including CT scan and EEG, were no different from those previously obtained.

Discussion

Both these cases fulfil the criteria for secondary mania in association with non-penetrating head injury. However, each patient also had other specific intracranial pathology. It is therefore necessary to consider whether these may have contributed to the development of their manic episodes.

The psychiatric sequelae of subdural haematomata have been studied by Fleiss (1945) and by Black (1984). Fleiss reported a single case of recurrent mania associated with recurrent subdural haematoma formation. The manic episodes occurred only when the haematoma had reaccumulated, and responded to either conventional psychiatric treatment of mania or to the tapping of the subdural collection. In a follow-up study of 79 patients, Black reported three cases of depressive illness but none of mania. In our Case 1 the presence of significant subdural collection at the time of the manic episode had been excluded by CT scan. It is therefore unlikely that the presenting symptomatology was associated with the subdural haematomata rather than the head injury *per se*.

Case 2 suffered from cerebrovascular disease in addition to his head injury and developed a new left frontal infarct during the course of his illness. Whereas it is conceivable that this event was the cause of the fall precipitating his head injury, it seems insufficient to account for his subsequent illness and behaviour. However, there are two possible associations between his frontal infarct and his subsequent illness which first need to be addressed. The first is that he may have suffered an organic personality change. The organic personality changes associated with frontal lobe damage are well described by Lishman (1978), and there are many similarities between his description and our patient's presentation. However, the rapid and dramatic improvement that occurred following his courses of ECT make this diagnosis extremely unlikely. A second possibility is that his mania was secondary to the infarct itself. Secondary mania in association with cerebrovascular disease has been described (Jampala & Abrams, 1983). However, in a review of the site and nature of intracerebral lesions which have been reported in association with secondary mania, Cummings & Mendez (1984) could find none sited in the left frontal region, nearly all being right-sided. The old right parietal infarct is unlikely to be significant in this respect, and the most probable explanation of our patient's mania is that it is associated with his preceding head injury.

The pathogenesis of secondary mania is unknown and, in view of the variety of conditions with which it has been associated, probably heterogeneous. In contrast with primary mania, there does not appear to be a major genetic component; both reviews of secondary mania highlight the absence of a family history of affective disorder as a diagnostic pointer towards an underlying organic condition (Krauthammer & Klerman, 1978; Stasiek & Zetin, 1985). Both reviews also comment that it appears to be more common in the elderly, and stress that a careful search for other treatable conditions should be made in elderly patients presenting with a first episode of mania. These two cases support both these observations. It is of interest that both previously reported cases of mania associated with head injury have occurred in younger patients (Sinanan, 1984; Khanna & Srinath, 1985).

Krauthammer & Klerman (1978) suggested that the initial treatment of choice for secondary mania should be that specific to the underlying condition. Only if that led to an inadequate clinical response did they advocate the use of psychotropic medication. Others have since argued similarly and have reported short-lived episodes of secondary mania which have resolved spontaneously (Cummings & Mendez, 1984). If there is no treatment specific to the primary disorder or if such treatment fails to adequately control the manic episode, then conventional treatment of acute mania is instituted. There are a number of reports demonstrating the efficacy of lithium treatment in secondary mania (Rosenbaum & Barry, 1975; Wiesert & Hendrie, 1977; Young *et al*, 1977; Oyewumi & Lapierre, 1981; Cummings & Mendez, 1984), and some suggesting that it should be used as a first choice treatment in preference to neuroleptic medication (Gregersen & Hagen, 1983).

Both our cases developed their manic episodes at a time when there were no treatable primary conditions. Both required urgent psychiatric treatment. Case 1 responded well to neuroleptic treatment and, despite subsequently suffering a minor depressive episode, made a full recovery. Case 2 proved much more resistant to treatment. Initially unresponsive to neuroleptic therapy, he was then treated with lithium. However, this also proved ineffective, due to a lack of compliance, a problem which has not previously been reported in connection with treatment of secondary mania. ECT has long been held to be effective in primary mania, although is rarely prescribed now, with the advent of alternative treatments in the neuroleptic drugs and lithium. Therefore, a course of six ECTs was given, with dramatic effect. When the patient relapsed 6 months later a further course of four ECTs was given, with similar therapeutic effect. This appears to be the first usage of ECT in a case of secondary mania. These cases suggest that non-penetrating head injury may precipitate secondary mania, and add ECT to the treatments known to be effective in its symptomatic management.

Ethanol Retards Desensitisation of Simple Phobias in Non-alcoholics

O. G. CAMERON, M. R. LIEPMAN, G. C. CURTIS and B. A. THYER

Twenty non-alcoholic patients with DSM-III defined simple phobias for small animals received behavioural approach tests and exposure therapy while under the influence of a moderately intoxicating dose of ethanol or after placebo administration. Ethanol did not demonstrate any acute anti-anxiety effect, but retarded the rate of behavioural *in vivo* desensitisation, without changing the final treatment outcome. State-dependent effects of ethanol on anxiety were not demonstrated. This study supports prior research indicating no anti-anxiety or 'tension-reducing' effects of ethanol for simple phobias.

Ethyl alcohol is the oldest and most widely used psychoactive substance (Goodwin & Guze, 1979). Pharmacologically, ethanol is classified as a sedative-hypnotic drug (Hoffman, 1983), and is considered to have potential 'tension-reducing' or anxiolytic properties (Cappell & Herman, 1972; Hodgson *et al*, 1979; Lipscomb *et al*, 1980; Pohorecky, 1981; Thyer & Curtis, 1984). This is supported by research suggesting that many ethanol-abusers appear to have pre-existing anxiety disorders, and that these abusers often started their ethanol use as an attempt to reduce the anxious symptoms (Quitkin *et al*, 1972; Mullaney & Trippett, 1979; Bowen *et al*, 1984; Smail *et al*, 1984; Stockwell *et al*, 1984; Thyer *et al*, 1986). However, the DSM-III defines several different anxiety disorders (Task Force on Nomenclature and Statistics, 1980), which might have different pathophysiologies and therefore different responses to psychopharmacological agents (Klein, 1964). In a prior study, two of us demonstrated that ethanol did not reduce the acute anxiety or avoidance associated with exposure to the phobic object in non-alcoholic simple phobics with small-animal phobias (Thyer & Curtis, 1984). Other investigators (Rimm *et al*, 1981) found that ethanol intoxication reduced subjective phobic anxiety but had no effect on phobic avoidance behaviour. The purpose of the present study was to replicate these observations, and to determine if ethanol intoxication influenced the course of *in vivo* exposure treatment in a separate group of non-alcoholic small-animal phobics.

Method

Subjects

Two experiments were performed. Twenty adults (3 male, 17 female; mean age 30.9 ± 8.0 (s.d.) years) were studied. All had discrete simple phobias for small animals as defined by DSM-III. The phobic objects included spiders, snakes, worms, dogs, cats, bees, wasps, fish and birds. The average duration was 23.8 ± 9.4 years. The diagnostic pretreatment evaluation included an extensive interview with an experienced clinician who made the DSM-III diagnosis of simple phobia. Any patient with a history of present or prior substance abuse was excluded. All patients completed several self-rated questionnaires prior to Experiment 1, including the Hopkins Symptom Checklist-90-Revised (Derogatis *et al*, 1973), the Spielberger State-Trait Anxiety Inventory (Spielberger *et al*, 1970) and the Fear Survey Schedule (Wolpe & Lang, 1969). All subjects participated in the first experiment; a subgroup of these ($n = 12$) participated in the second. All subjects gave written informed consent, and the protocol was approved by the University of Michigan Hospitals' Human Use Committee. Pregnant women were excluded.

Procedure

The study was designed to determine if moderate ethanol intoxication during *in vivo* exposure altered the course of desensitisation, and also to determine if state-dependent effects of ethanol on the desensitisation process occurred. State-dependent effects would be demonstrated if subjects showed a greater response to treatment when tested under the condition under which they had been treated than when tested under the opposite condition (i.e. ethanol versus placebo).

The design of Experiment 1 included (a) two behavioural approach test assessments (A1 and A2) before treatment, one while intoxicated and one after a placebo; (b) an assessment immediately after 2 hours of behavioural treatment in the same condition as the treatment session (ethanol or placebo) (A3); and (c) a subsequent assessment under the opposite condition (A4). All sessions were separated by at least 24 hours. Sessions A1 and A2 were counterbalanced so that half of the subjects had A1 under ethanol and A2 under placebo, with the other subjects in the reverse order; subjects were randomly assigned to one order or the other. After A2, each subject was then randomly assigned to ethanol or placebo treatment, which thus dictated the conditions for A3 and A4. All 20 subjects completed Experimental 1 (A1 to A4).

A subgroup of subjects ($n = 12$) participated in Experiment 2. These subjects were treated with exposure therapy in 2-hour sessions until either they calmly permitted unlimited contact with the phobic object or until 20 hours of treatment were completed. All subjects continued to be treated under the same drug condition as that of the first treatment session; seven were ethanol patients and five placebo. At the completion of treatment, subjects were evaluated under both conditions (A5 and A6), in a counterbalanced order. Finally, 10 of these 12 subjects had two further assessments at 6 months post-treatment, and at 12 months, again in counterbalanced order.

Behavioural *in vivo* desensitisation treatment of simple phobias has been described in detail elsewhere (Curtis *et al*, 1976; Marks, 1981). Prior to both assessment and treatment sessions, ethanol or placebo was administered, with monitoring of blood alcohol level using an Alcosensor II portable 'breathalyser'. Ethanol dose was based on body weight, with a goal of obtaining a blood alcohol level of approximately 0.10 g/dl, a moderate level usually associated with some intoxication in inexperienced users of ethanol, and legally associated with intoxication in most states. Ethanol was administered as vodka mixed in iced orange juice. Placebo was approximately 7.5 ml of vodka layered on top of iced orange juice. Ethanol administration, desensitisation treatment, and behavioural assessment were always performed by different staff, who were blind to the outcomes of the other activities. Patients were also procedurally blind to drug condition.

Assessment of therapeutic outcome was evaluated with a behavioural approach test (BAT; described in detail in Thyer & Curtis, 1984). Subjective units of distress (SUDs), rated from 0 (none) to 100 (most ever), and latency of approach (0–20 s) were rated at eight points: (a) outside the room where the phobic object was present, (b) 3 m from the object, with it in sight, (c) 1 m, (d) 0.3 m, (e) indirect contact with the object, (f) brief direct contact, (g) holding the object, and (h) unlimited direct contact. These tests, as well as treatment, were always performed with a live specimen of each subject's phobic object. The BAT was stopped when a subject could not reach the next step within 20 seconds of being requested to proceed. The point of maximum approach (rated 0–100) was used as the third BAT variable. For any step not reached, a SUDs score of 100 and a latency of 20 s were assigned, and average scores for SUDs and latency at the eight points, as well as the maximum approach score, were used as data to be analysed for each BAT.

Data analysis

Analyses were performed separately for SUDs, latency and maximum approach measures. Subjects given ethanol were compared with those given placebo at A1, and A1 was compared with A2 for all subjects. Because ethanol versus placebo condition and order are confounded for A3 and A4, the effects of 2 hours of treatment while intoxicated versus while sober were determined by comparing the two treatment groups for the mean of A1 plus A2 versus the mean of A3 plus A4. Means of A5 plus A6, A7 plus A8, and A9 plus A10 were also used for further comparisons. When appropriate, comparisons were performed only after initial differences had been removed with covariance analyses. Because of the confounding of order and condition, state-dependent effects could not be evaluated at A3 or A4; therefore, these were studied only at A5 and A6, and thereafter. Analysis of state-dependent effects involved determining for the two treatment groups whether subjects showed less phobic avoidance when tested in the same drug condition as treatment versus the opposite drug condition. Duration of treatment to reach therapeutic criterion was compared for the two groups, and finally scores on pretreatment self-rating scales as potential predictors of therapeutic outcome were investigated. Analyses included t-tests, analyses of covariance, and correlation coefficients. All significance levels were $P > 0.05$ for two-tailed tests.

Results

As expected, blood alcohol levels were 0.00 g/dl after placebo administration. After ethanol, levels were in the range 0.08–0.12 g/dl; thus, the goal of 0.10 g/dl was well approximated. During treatment sessions, small further amounts of ethanol, administered in the same way, were sometimes required to maintain these levels. Although some subjects showed signs of intoxication, no subject was ever unable to participate co-operatively in the assessment or treatment. The assessor was occasionally unblinded by the subject's behaviour, but usually could not differentiate reliably between drug verus placebo administration.

There were no significant differences at A1 between subjects given drug and those given placebo on SUDs, latency or approach; there was a tendency for subjects given placebo to approach the phobic object more closely than those given ethanol, and subjects given ethanol showed somewhat larger SUDs scores and longer latencies (Fig. 1). Thus, as in our prior study (Thyer & Curtis, 1984), acute administration of moderate doses of ethanol did not reduce acute phobic anxiety in non-alcoholics. For all subjects there was a significant decrease from A1 to A2 in SUDs ($P < 0.02$) and latency ($P < 0.005$), and a significant increase in approach ($P < 0.04$).

Even though significant differences between groups were not present prior to treatment, non-significant differences were present, especially for approach (Fig. 1). Therefore, comparison of the ethanol group with the placebo group after 2 hours of treatment (mean of A1 plus A2 versus mean of A3 plus A4) was done with an analysis of covariance in which the initial differences were the covariates removed. With these analyses, the placebo group showed a significantly greater reduction of SUDs ($P < 0.02$) and latency ($P < 0.04$), and a weak trend toward significantly more approach ($P < 0.31$). Thus, Experiment 1 demonstrated that intoxication retarded behaviour treatment as measured by SUDs and latency scores (Fig. 1).

Twelve subjects completed treatment in Experiment 2. The average number of hours required for patients receiving placebo to calmly permit unlimited contact with the phobic object was 5.85, while for the ethanol group it was 9.37. Because of much variation from subject to subject this difference was not significant; it might have been with a

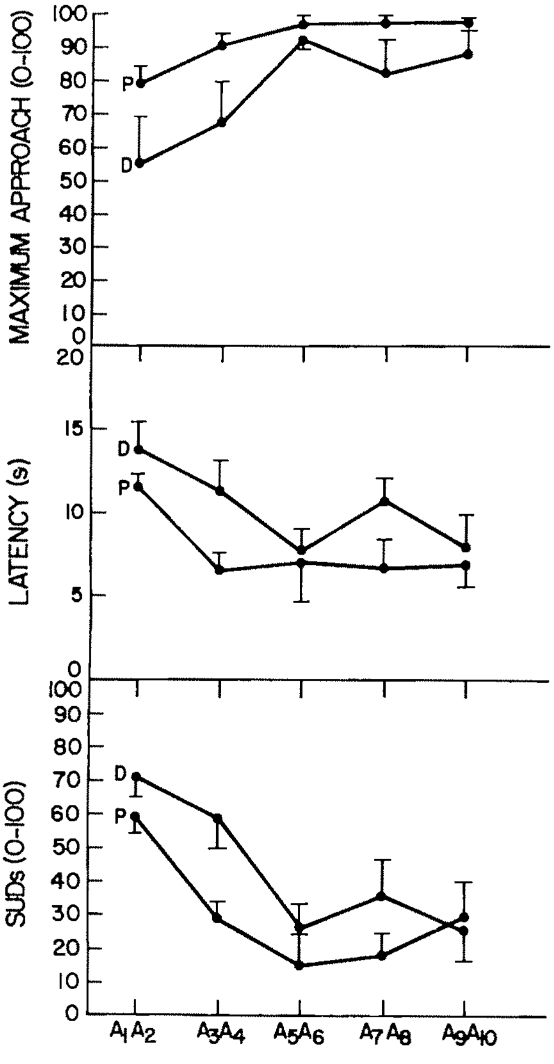

FIG. 1 Means ± s.e.m. for patients treated under drug (D) and for those treated under placebo (P), separately for subjective units of distress (SUDs), latency to approach the phobic object, and maximum approach, represented as mean of A1 plus A2, A3 plus A4, A5 plus A6, A7 plus A8, and A9 plus A10; A1A2 is assessment prior to treatment, A3A4 is after 2 hours of treatment, A5A6 is after completion on all treatment, and A7A8 and A9A10 are 6-month and 12-month post-treatment evaluations.

larger group of patients. This difference is consistent with the finding of Experiment 1 that ethanol retarded treatment progress.

No significant differences in final therapeutic outcomes on any of the three measures could be demonstrated at the completion of treatment, or at the 6-month or 12-month follow-ups (Fig. 1), and no consistent state-dependent effects could be demonstrated. No differences between patients treated with ethanol and those with placebo were observed on any of the pretreatment rating scales. Nevertheless, the State–Trait anxiety measures tended to predict outcome of treatment; higher scores were associated with poorer outcomes. Furthermore, removal of the effects of the State and Trait measures by analysis of covariance diminished the difference in latency between groups after 2 hours of treatment ($P = 0.10$ and 0.12, instead of 0.04, for State and Trait measures, respectively) and also reduced the weak trend in maximum approach ($P = 0.44$ and 0.48 instead of 0.31). However, the difference in SUDs was unchanged. Other potential pretreatment predictors were not useful.

Discussion

The results of this study replicate the prior finding that ethanol in a mildly-to-moderately intoxicating dose does not reduce avoidance behaviour or acute phobic anxiety ('tension') in non-alcoholic simple phobics. Results might be different in alcoholic patients. Furthermore, ethanol appears to slow the progress of behavioural desensitisation exposure therapy, but apparently does not impair the final outcome if extra treatment is administered. It is possible that a different dose might have a different effect. For example, the very common use of ethanol as an intoxicant in people with flying phobias in order to tolerate flying might contribute to the lack of desensitisation often observed in these individuals, especially if moderate-to-severe intoxication slows desensitisation more than a less intoxicating dose, or even totally prevents it.

Several issues in these results are important. First, even with counterbalancing of order of initial assessments with ethanol and placebo, phobic avoidance during the second assessment was significantly less than during the first. Thus, in naïve individuals, a behavioural approach test alone appears to provide some therapeutic benefit, which is probably due to both the exposure involved and the reduction in uncertainty associated with completion of the first assessment. Secondly, latency scores may have been influenced directly by the motoric impairment effects of acute intoxication; this should not, however, influence the effects seen on subjective distress or the similar trend in maximum approach. Thirdly, state-dependent effects were not demonstrated. This may reflect either a lack of state-dependent effects of ethanol in this paradigm despite its effects in other circumstances (Goodwin *et al*, 1969; Overton, 1972; Crow & Ball, 1975; Weingartner *et al*, 1976; Barry & Krimmer, 1978; Schechter, 1978), or an inability to demonstrate them despite their presence because other competing effects were more potent and masked the state-dependent effects. The fact that, under some conditions, not only were the effects not demonstrated but trends were in the opposite direction suggests that masked effects were not present. Fourthly, despite the disruption by ethanol observed in rate of treatment progress, treatment was effective for both groups, and the observed improvement was relatively stable for a year. Finally, the effects of pretreatment anxiety level (as measured by the State–Trait Inventory) on latency and maximum approach after 2 hours of treatment suggest that behavioural phobic severity (avoidance) may be an aspect of simple phobias which is less sensitive to the retarding effects of ethanol on desensitisation. However, pretreatment anxiety level did not modify the retarding effects of ethanol on reduction in subjective phobic anxiety (SUDs).

These results may or may not be generalisable to other sedative–hypnotic drugs or different anxiety disorders. In a similar study of acute phobic anxiety (Whitehead *et al*, 1978), diazepam did increase approach to simple phobic objects, suggesting that ethanol and benzodiazepines have different modes of action in the simple phobia paradigm. Further, ethanol may be an effective anxiolytic drug for other anxiety disorders (Quitkin *et al*, 1972) such as panic disorder, social phobia or generalised anxiety. If true, this finding would imply pathophysiological differences between these different anxiety states.

Our results are congruent with a number of experiments employing animal models of avoidance behaviour which have found that ethanol intoxication retards extinction of avoidance responses (Baum, 1969, 1970, 1971; Skurdal *et al*, 1975). The effects of ethanol intoxication on animal learning of avoidance or extinction are probably due to the CNS depressant effects of the drug, as opposed to the actions of its metabolites such as acetaldehyde (Snell & Harris, 1980). Thus, ethanol may be producing the effects seen in this study by slowing the 'learning' process in desensitisation.

Clinically it has been shown that the concomittant use of diazepam and exposure therapy adds little or no benefit to treatment outcomes with phobic patients, compared with exposure therapy alone or exposure plus placebo (Hafner & Marks, 1976; Bernhardt *et al*, 1980), and that diazepam does not reduce the subjective anxiety experienced by patients during the desensitisation process (Marks *et al*, 1972). Our findings with ethanol and exposure therapy are consistent with those obtained combining another CNS depressant, diazepam, with exposure. Overall our data do not support the hypothesis that ethanol intoxication reduces the anxiety associated with simple phobias in humans, and do support the clinical suggestion made by Marks (1985) that ethanol use should be curtailed by phobic patients being treated with therapeutic exposure.

Electrodermal Responding and Chlorpromazine Treatment in Schizophrenia

Skin conductance level (SCL) and skin conductance responses (SCR) to a random series of tones were measured in 25 drug-free schizophrenic patients, 15 male and 10 female, before and after standard chlorpromazine treatment. The DSM-III diagnostic criteria were used for selecting subjects. Psychopathology was measured with the Brief Psychiatric Rating Scale. After treatment, patients showed an improved psychopathology and decreased SCL. There was a transition of patients to lower response categories: the number of responders decreased twice and the number of non-responders increased three times. Responders exhibited significantly higher SCL than non-responders and fast habituators were between the two groups.

Investigators in psychophysiology of schizophrenia often face the problem that the material under study is both heterogeneous and variable. For this reason some authors think it important to divide schizophrenics into subgroups (Houlihan, 1977). In recent years, more homogenous subgroups based on autonomic arousal and response patterns have appeared feasible (Venables & Patterson, 1976).

Gruzelier & Venables (1972), using the habituation rate technique, showed that 50% of schizophrenic subjects were non-responders while 50% tended to be hyper-responders with maximal electrodermal responses and diminished habituation. Patterson & Venables (1978) reported, in addition, that a further electrodermal subgroup of patients could be distinguished, showing very fast habituation and only one, or at the most two, responses to stimuli. Gruzelier & Venables (1972, 1973) also found that non-responders have a lower skin conductance level than schizophrenic or normal responders. The above data indicate that schizophrenics may be found in the two extreme poles of somatic arousal.

Other investigators (Zahn, 1976; Frith *et al*, 1979) found only a low proportion of non-responders among schizophrenic patients. Therefore, various views have been expressed on electrodermal responding in schizophrenia, with some investigators claiming non-responding to be a true finding, specific for schizophrenic disorder (Patterson & Venables, 1978; Venables, 1978; Straube, 1979), and some others insisting that this is an artifact due to various factors relevant to the technique of measurement or neuroleptic medication (Lader, 1975; Zahn, 1978). It is true that the majority of studies presenting high proportions of non-responders in schizophrenia used subjects receiving medication.

In this study we investigate the electrodermal responding of a group of schizophrenic patients before and after chlorpromazine treatment.

Method

Subjects

Schizophrenic in-patients admitted to Aeginition University Psychiatric Clinic who had been drug-free for at least 15 days were used for the study. Patients were fully informed about the experimental procedures and consent was obtained before participation in the study. The whole experiment was approved by the Hospital Committee. The diagnostic evaluation of subjects was performed by two experienced psychiatrists who used the DSM-III criteria for schizophrenia. Their diagnosis was based on standard clinical interviews and patients' records. Initially, 38 patients were considered. Six of these did not meet the DSM-III criteria. Four were very disturbed and the staff used medication to treat them before they could be included in the study. Three refused to participate. The remaining 25 patients, 15 male and 10 female, were all able to co-operate for the habituation procedure. Of these, 16 patients were first admissions. The mean age was 26.44 ± 7.71 years, the mean duration of illness was 3.66 ± 3.58 years and the mean duration of school education was 10.48 ± 3.47 years. Diagnostic categories according to DSM-III criteria were: eight undifferentiated, five disorganised, two residual and ten paranoid.

Measures

Psychophysiological and clinical measures were taken before and after treatment with a standard dose of 300 mg of chlorpromazine daily for 2 weeks. Two parameters of electrodermal activity, skin conductance response and skin conductance level, were studied in relation to treatment. The habituation rate to a random series of tones was also recorded. The degree of psychopathology was measured using the Brief Psychiatric Rating Scale (BPRS).

A Lafayette 76406 system was used and the skin resistance level and galvanic skin response were recorded (in kohms) from the palmar surface of the left hand. The standard silver–silver chloride electrodes provided by Lafayette and an electrolyte medium containing sodium chloride were applied at the distal phalanges of the first and third fingers. The skin resistance values were transformed to skin conductance values. Electrodermal response was calculated as a change in log conductance.

Electrodermal responses to tape-recorded simple tones were used for the habituation procedure. Patients were divided according to the number of responses into three subgroups: 1) non-responders, the patients who did not respond to the first three tones, 2) fast habituators, those who responded to the first or two first stimuli only, and 3) responders, the patients who responded to the tones and habituated the orienting response in three to fifteen trials. The criteria for the above subdivision have been used by other investigators (Gruzelier & Venables, 1972; Patterson & Venables, 1978).

An electrodermal response was counted only if it occurred between 1 and 5 seconds after the onset of stimulus, and was defined as a change in log skin conductance greater than 0.003 log μmhos. Following the procedure of Gruzelier & Venables (1972) the orienting stimuli were 15 one-second, 1000 Hz, 85 dB tones, presented at random intervals ranging between 30 and 60 s. The total duration of tone series was 11 minutes. The tones were presented binaurally through headphones after a 6-minute rest period during which a 'white' noise (25 dB) was heard from the tape.

Two values of skin conductance level were taken as measures of background activity, one just before the onset of auditory stimuli and the other one immediately after the end of auditory stimuli.

Psychopathology was assessed before psychophysiological measurements were taken, by two psychiatrists in a common interview. The patients were given standard information and instructions which were read out as follows: "You will be submitted to a laboratory examination with medical instruments. These instruments demonstrate the various functions of body organs as heart, eye, brain etc. During the test you must try to avoid purposeless movements. You will hear a series of sounds without any special meaning through headphones. When you hear the sounds do not do anything but listen to them as quietly as possible". The experiment took place in a psychophysiology laboratory; the room and conditions were standardised.

Results

As stated in Method, the patients were divided in three electrodermal groups. Before treatment, the highest percentage of subjects belonged to the group of responders, but after the standard CPZ treatment a one way movement of patients towards groups of decreased electrodermal responding appeared. Responders decreased from 19 (76%) to nine (36%), fast habituators increased from two (8%) to four (16%) and non-responders increased from four (16%) to 12 (48%). Table I illustrates the transition of patients to different response categories as a function of time and medication.

After treatment the skin conductance level of subjects decreased significantly and psychopathology improved significantly. Prestimulus SCL was 25.03 μmhos (s.d. = 16.37) before treatment and 17.49 μmhos (s.d. = 13.15) after treatment (paired t-test, $t = 3.39$, d.f. = 24, $P < 0.01$). Post-stimulus SCL values were 26.14 (s.d. = 18.31) and 18.37 (s.d. = 14.26) respectively (paired t-test, $t = 2.86$, d.f. = 24, $P < 0.01$). The mean BPRS score of subjects was 51.44 (s.d. = 6.98) before treatment, and 44.96 (s.d. = 9.31) after treatment; paired t-test value was 4.43, d.f. = 24, $P < 0.001$.

Before treatment, responders tended to show the higher level of autonomic arousal (as shown by skin conductance level), non-responders the lower one and fast habituators were at intermediate levels. The three groups did not differ significantly in this respect before the administration of chlorpromazine. However, the differences became significant after treatment (Table II).

No difference was observed in severity of symptoms among the three electrodermal groups. Before treatment the mean BPRS scores of non-responders was 53 (s.d. = 3.83), fast habituators 60 (s.d. = 0) and responders 50.21 (s.d. = 7.23). Values after treatment were 44.17 (s.d. = 11.08), 48.25 (s.d. = 7.80) and 44.56 (s.d. = 7.86) respectively.

Discussion

The question of high or low levels of schizophrenic physiological activity has been the subject of many discussions (Gruzelier & Venables, 1975; Tecce &

TABLE I

Transition of patients to different response categories after chlorpromazine administration

Cole, 1972). Gruzelier & Venables (1972, 1973) suggested a bimodal distribution of arousal in schizophrenics (hypo-hyperaroused/non-hyper-responders). Venables later (1978) added a third group, the fast habituators group, and insisted on the high percentages of non-responders in schizophrenia which he regarded as a real schizophrenic phenomenon and not as an artifact produced by psychotropic drugs (Patterson & Venables, 1978; Venables, 1978).

The findings of this study support the view that the high percentage of non-responders in schizophrenia is a function of medication rather than a real schizophrenic phenomenon. After the standard chlorpromazine treatment, a transition of patients to lower response categories was observed and responders decreased twice while non-responders increased three times. Apart from drugs, a number of other intervening factors have been suggested as an explanation of this phenomenon: the type of stimuli used, the composition of experimental groups, the chronicity of the illness, the different experimental methods (Flekkøy, 1975), the sensitivity of recording method and responding criterion (O'Gorman, 1978), the size and position of electrodes, and the electrolytic medium. The majority of these factors are excluded in our experimental design (by the use of standard diagnostic criteria, same subjects and same experimental methods in both measurements, etc.). A factor of probable error not excluded in this study is that the second measurement of each subject, after chlorpromazine treatment, coincided with the repetition of the experiment. However, there are other studies that exclude such a factor by alternating experimental designs or placebo (Spohn *et al*, 1971; Kugler & Gruzelier, 1980). These studies present data showing influence of phenothiazines on the number of electrodermal responses that are in agreement with our findings.

After chlorpromazine treatment a decrease of autonomic arousal and an improvement of psychopathology of schizophrenics was observed. It is known that chlorpromazine has both central and peripheral effects. Kornetsky & Mirsky (1966) support the view that improved behaviour of schizophrenics after drug treatment is relative to decrease of hyperarousal. It is also noticeable that before treatment responders tended to be more aroused than non-responders and fast habituators tended to have an intermediate position. Those differences became statistically significant only after treatment. Such a finding may lead to the interpretation that different electrodermal groups express different levels of autonomic arousal (Gruzelier & Venables, 1972; Patterson & Venables, 1978). Another possibility, which might better explain our results, is that electrodermal responses do not have any relation to levels of arousal but that a relation does appear if patients take drugs and in particular chlorpromazine (Spohn *et al*, 1971). However, it should be noted that some groups have a small number of subjects and, statistically, this is a shortcoming for an ANOVA analysis.

Abnormal Intestinal Permeability

An Aetiological Factor in Chronic Psychiatric Disorders?

Abnormal intestinal absorption has been suggested as an aetiological factor in schizophrenia. A procedure for investigating intestinal permeability was carried out in a group of chronic psychiatric in-patients. A proportion of the subjects studied showed abnormal intestinal permeability which could not be attributed to established bowel disease. Patients who were receiving neuroleptic but not anticholinergic drugs were those most often showing abnormal intestinal permeability. This work is at an early stage of development but preliminary findings suggest that further investigations should be carried out to establish the circumstances in which changes in intestinal permeability may be associated with mental illness.

The relationship between schizophrenia and small intestinal mucosal abnormality is controversial (*Lancet*, 1983). Increased titres of circulating antibodies to dietary antigens have been demonstrated in patients with schizophrenia, suggesting increased antigen absorption from the gut (Sugarman *et al*, 1982; Hekkens *et al*, 1980), and the prevalence of coeliac disease is increased in schizophrenics (Dohan, 1970). Coeliac disease is also characterised by high titres of antibody to dietary antigens (Kivel *et al*, 1964), which has been ascribed to the abnormal intestinal permeability found in untreated coeliac disease. Following treatment of coeliac disease with a gluten-free diet, intestinal permeability returns to normal (Hamilton *et al*, 1982), and, in some patients, dietary gluten withdrawal has led to an improvement in the psychiatric symptoms of schizophrenia (Dohan & Grasberger, 1973; Singh & Kay, 1976), although this beneficial effect of such dietary manipulation has not been confirmed by others (Storms *et al*, 1982).

The cellobiose/mannitol test has been shown to be a reliable index of abnormal intestinal permeability in coeliac disease (Cobden *et al*, 1980), when the urinary recovery of mannitol after oral administration is decreased while recovery of collobiose is increased. Expression of the result as a ratio of urinary collobiose recovery: urinary mannitol recovery minimises the effect of extraneous factors such as gastro-intestinal transit times and renal function on the test result (Cobden *et al*, 1985), and provides good separation between normal subjects and patients with coeliac disease (Cobden *et al*, 1980). We have used this test to investigate a population of long-stay psychiatric in-patients initially diagnosed as having schizophrenia to determine whether intestinal permeability is abnormal in such patients, and have further studied a proportion of these patients to determine whether abnormalities of permeability are due to co-existing coeliac disease.

Method

Patients

Thirty-two patients in long-term residential care were studied. All had been initially diagnosed as schizophrenic, often many years before, and were interviewed at the time of study by a psychiatrist who reclassified them as having schizophrenia or non-schizophrenic psychiatric disease according to Feighner *et al*'s criteria (1972). Age, sex, duration of symptoms and admission and details of all drug treatment were recorded. All patients performed a cellobiose/mannitol test. Patients fasted overnight provided a baseline urine sample and then ingested a solution containing 2 g mannitol and 5 g cellobiose in 100 ml water, with lactose and sucrose added as osmotic fillers. Patients continued to fast over the next 5 h, during which time all urine passed was collected and cellobiose and mannitol were assayed in the 5 h urine collection as previously described (Cobden *et al*, 1980). Recovery of both cellobiose and mannitol were expressed as a percentage of the administered dose, and the collobiose/mannitol recovery ratio, the percentage recovery of cellobiose:percentage recovery of mannitol, was compared with the established normal range (Cobden *et al*, 1980).

Subsequently, 10 patients in whom the ratio was within the normal range and 10 in whom the ratio was abnormal were selected for further investigation. Each of these 20 patients underwent endoscopy and distal duodenal biopsy (using an Olympus GIFP endoscope) and metabolism and excretion of cellobiose and mannitol were studied. Each patient received an intravenous injection of 500 mg mannitol and 50 mg cellobiose, and urine was collected for 5 h. Cellobiose and mannitol were assayed as for the oral test, and urinary recovery of each expressed as a percentage of the administered dose.

This study was approved by the Hospital Medical Ethical Committee and all patients consented to inclusion.

Results

Seventeen patients were classified as having schizophrenia whilst the remaining 15 were considered to have non-schizophrenic psychiatric disease.

Intestinal permeability in patients with psychiatric disease

The cellobiose/mannitol recovery ratio in the control population ranged from 0.002–0.03.

Of the 17 patients with schizophrenia, the cellobiose/mannitol ratio was normal in 11 (65%) and was abnormally high (range 0.032–0.46) in six while in the remaining 15 patients the ratio was normal in 10 (67%) and abnormal (range 0.032–0.072) in five. Overall, the ratio was abnormal in 11 of 32 (34%) long-stay psychiatric patients. Mean mannitol recovery was 8.4 (s.d. 7.1)% in patients with an abnormal ratio and 28.0 (s.d. 24.1)% in those with a normal ratio ($P<0.001$, Wilcoxon rank sum test), while mean cellobiose recovery was 0.42 (s.d. 0.3)% in patients with an abnormal ratio and 0.21 (s.d. 0.18)% in those with a normal ratio ($P<0.05$, Wilcoxon rank sum test). Thus the abnormal ratio in this group of patients was due to both a reduced mannitol absorption and an increased cellobiose absorption, the pattern found in coeliac disease (Cobden *et al*, 1980).

Patients in whom the cellobiose/mannitol ratio was abnormal did not differ from those with a normal ratio in respect of age, sex, duration of admission or length of illness, and there was no difference between groups in treatment with phenothiazines, butyrophenones or antidepressants. Only one of the 11 patients in whom cellobiose/mannitol ratio was abnormal required anticholinergic treatment, however, compared with 14 of the 18 with normal permeability who were taking phenothiazines ($P<0.002$). No patients were treated with non-steroidal anti-inflammatory drugs.

Recovery of cellobiose and mannitol after intravenous injection

Ten patients in whom the cellobiose/mannitol ratio was abnormal (six with schizophrenia and four with non-schizophrenic psychiatric disease) and 10 (six schizophrenic and four non-schizophrenic) with a normal ration, received intravenous cellobiose and mannitol.

In the patients with an abnormal ratio, mean urinary mannitol recovery was 45 (s.d. 18)% of the injected dose in 5 h, and mean cellobiose recovery 28 (s.d. 10.8)%, while in those with a normal ratio mean mannitol recovery was 53.9 (s.d. 30.3)% and mean cellobiose recovery was 29.3 (s.d. 17.7)%. Thus there was no significant difference between these two groups of patients in the metabolism or excretion of the two probe molecules after absorption.

Small intestinal histology

Each of the 20 patients receiving intravenous cellobiose and mannitol also underwent endoscopy and distal duodenal biopsy. Small intestinal mucosal morphology was normal in all patients. In particular, there was no evidence of coeliac disease or of infestation with Giardia lamblia.

Discussion

The abnormal pattern of urinary excretion of orally administered cellobiose and mannitol demonstrated in a large subgroup (34%) of long-stay psychiatric in-patients is a manifestation of abnormal intestinal absorption of these two probe molecules since there is no evidence that either probe molecule is abnormally metabolised or excreted after intravenous injection. While the recovery of each probe molecule after injection is lower than would be anticipated in normal controls, this reflects the difficulty in obtaining complete timed urine collections in the group of patients studied, and the effect of incomplete urinary collection is to reduce the recovery of each probe molecule similarly, without affecting the cellobiose/mannitol ratio (Cobden *et al*, 1985). The metabolism and excretion of both probe molecules are similar in patients studied with an abnormal cellobiose/mannitol ratio and those in whom the ratio was normal, and there is a strong and statistically significant correlation between the recovery of mannitol and that of cellobiose after intravenous injection in both groups ($r=0.74$, $P<0.01$ for patients with an abnormal ratio, $r=0.85$, $P<0.005$ for those with normal ratio) supporting the suggestion that the low recovery is due to incomplete urine collection.

The mechanisms of abnormal intestinal permeability in psychiatric patients has not been established. While the number of patients studied is not sufficient to establish the prevalence of coeliac disease in such patients, we have failed to identify any patient with histological evidence of coeliac disease, even in the group with abnormal intestinal permeability, and there was no evidence of giardiasis. The only difference in drug ingestion identified between patients with abnormal permeability and the remainder was the reduced necessity for anticholinergics in the former group, and this difference seems unlikely to account for the observed permeability abnormalities.

Increased intestinal permeability to large molecules relative to small ones may be of relevance to the pathogenesis of chronic psychiatric disease. The findings of this study are consistent with the hypothesis that a proportion of patients with chronic psychiatric illness, including schizophrenia, have abnormal small intestinal mucosal permeability, resulting in an increased absorption of endorphin-like molecules from the intestine, which induce behavioural abnormalities, but which also protect against the development of parkinsonian side-effects of phenothiazine treatment. We believe that further investigation of the relationship between psychiatric disease and small intestinal function is indicated.

Infantile Autism in Children of Immigrant Parents

A Population-based Study from Göteborg, Sweden

A population-based study of infantile autism from western Sweden has been completed. Urban children with autism more often than age-matched children in the general population had immigrant parents from 'exotic' countries. No such trend was seen in rural children with infantile autism.

In 1979, Lena Andersson (personal communication) suggested that infantile autism (IA) might be more common in children born to immigrant parents than in children born to native parents. In 1981, she published some data from an epidemiological study of autism in southern Sweden, which tended to support her hypothesis (Andersson & Wadensjö, 1981). However, in a contemporary study of autism from western Sweden no similar trend was seen (Gillberg, 1984).

Wing (1980, 1982) also has raised the possibility that infantile autism might be more common in children born to immigrant parents. She has also hypothesised that this increase in frequency, e.g. in children born to West-Indian mothers, could be due to organic factors, such as maternal rubella infection.

Akinsola & Fryers (1986) examined all severely mentally handicapped children aged 5–19 years in the city of Manchester, UK and found an increase of 'social impairments' among children of immigrant parents.

The present study reports data as regards parental country of origin from a population-based screening of children with infantile autism.

Method

Subjects

Twenty children under age 10 years with IA (17 boys and three girls) (Rutter, 1978; American Psychiatric Association, 1980) were included in the study. These children had been detected in a screening study of IA and related conditions in Göteborg (a city of about 450 000 inhabitants) (city IA group). Fifteen further children (13 boys and two girls) with IA from the adjacent county of Bohuslän (only rural and small-town areas of about 250 000 inhabitants altogether (rural IA group) were also included. The details of the epidemiological study have been published previously (Steffenburg & Gillberg, 1986). In summary, all doctors, psychologists, social workers and teachers likely to come across autistic children completed questionnaires stating whether they knew of any autistic or autistic-like children. The 35 children detected, constituted all the autistic children living in the areas on December 31 1984, and correspond to 4.5/10 000 children in the general population (4.7/10 000 in the city and 4.2/10 000 in the rural area).

All children had been diagnosed by the same child psychiatrist as suffering from IA in accordance with the criteria of the DSM-III (APA, 1980). All the parents of the 35 children were interviewed as regards their own country of origin.

Comparison group

The numbers of children under age 10 years born to immigrant parents of various origins and living in Göteborg on December 31 1984 were detailed from the registers of the Swedish Central Bureau of Statistics. Further, the corresponding number of children under 10 years of age born to all Swedish parents was noted.

Statistical tests

The χ^2 test with Yates' correction was used for comparisons of group frequencies.

Results

Six of the 20 (30%) city children (all boys) with IA were born to immigrant parents. The parents had been born in the republic of China (1), Uruguay (1), Hungary (1), Turkey (1) and Poland (2). In all cases but one (the boy whose father was Hungarian), both parents were immigrants from that country. Two of the boys (with parents from Hungary and Turkey) were born in Sweden. The remaining four had been born in their parental country of origin.

None of the 15 rural children with IA had immigrant parents.

Altogether 25.7% of the comparison group (11 022 out of 42 886) had at least one parent who had been born abroad. The majority of immigrant parents came from Finland. The difference between the city IA group and the comparison group (30% vs 25.7%) was not statistically significant.

Only 4.6% of the comparison group had at least one parent who had been born in any one of the 'immigrant countries' of the city IA group. The difference between these two groups is statistically significant at the 0.001 level. The difference between the rural IA group and the comparison group (0% vs 4.6%) was not statistically significant.

In the rural IA group there were significantly fewer immigrant parents than in the comparison group (0% vs 25.7%, $P<0.001$).

Four of the six IA city children with immigrant parents were severely mentally retarded and belonged in the most handicapped group of IA children in the whole material. No specific aetiology common to these cases could be found.

Discussion

From these results it appears that 'exotic' immigrant parents (that is parents from other than neighbouring foreign countries) might be more common in city children with infantile autism.

The reason why we did not find a corresponding increase in our previous epidemiological study of urban autism (Gillberg & Schaumann, 1982) is possibly that at the time of that study immigrants from such countries were very few indeed in Göteborg.

In the rural areas we did not find any immigrant parents at all, the main reason for this being that immigrants are extremely rare in these rural parts of Sweden.

The findings agree with those obtained by Andersson & Wadensjö (1981) in the late 1970s in Malmöhus län in southern Sweden. Malmöhus län was possibly already at that time more of an immigrant area than Göteborg. The findings are also in accord with those of Wing in London.

The reason for our findings can only be speculative since we have no hard data to uphold any specific view. Organic factors (such as intrauterine malnutrition, infections etc.) might be important. Genetic factors with or without the combination of a bilingual family problem (that is the vulnerable child in a 'language confused' state) might also be important - or, of course, other factors, that we have no idea of at the present stage, might be important.

During 1985, that is the year after our screening had been completed, seven further children with infantile autism born in 1978–1984 and living in either of the two areas studied, have been referred for diagnosis, work-up and treatment. Five of these children were born in 1983 and 1984 and had probably been missed in the screening because they were too young to have been clearly diagnosed or suspected of suffering from infantile autism. Two children had moved to the screening areas in 1985. Of these seven children no less than six have at least one immigrant parent. All of these children except one were born in Sweden and their parents had emigrated from Spain (1), Chile (1), Sri Lanka (1), The Philippines (1), England (1) and Finland (1). Again, this 'pattern' of immigrant parents in Sweden is unusual, and the frequency is much raised as compared with age-matched population samples.

On the basis of these and other recent data, we would urge other research groups to examine or re-examine their findings with a special view to disclosing possible increases in the frequency of immigrant parents in infantile autism.

Psychiatric Vulnerability and Cerebellar Haemangioblastoma

A Case Report

A case of cerebellar haemangioblastoma in described in a middle-aged woman with a history of multiple psychiatric admissions for depressive and psychosomatic symptomatology. The diagnosis was not made until a late stage, largely because of the knowledge of her psychiatric history and its particular slant. Similar psychiatric symptoms were present at the outset, colouring the emerging neurological picture. The clinical manifestations and management of cerebellar haemangioblastoma are described.

Case report

Jane, 51, had no family history of psychiatric illness apart from her mother's suicide. She described her childhood as unhappy because her mother was too harsh. She left school at 13 and worked in factories until, at 26, she married a Post Office driver – a move her mother opposed. Her marriage was initially happy though later less so. She had the first of five miscarriages at the age of 31 and had not worked since. She always had few social contacts outside the home and was not on good terms with two siblings living locally. Jane described her life as a failure because she had produced no children. She had had extensive contact with gynaecologists and since the age of 12 had taken medication for intermittent asthma-like symptoms.

The year 1968, when Jane was 37, marked both her fourth miscarriage and her mother's suicide, and Jane said she never recovered from this latter blow. Shortly afterwards she had her first contact with psychiatrists when she claimed to have consumed bleach in a suicide attempt. In the following year she had numerous presentations with psychosomatic symptoms. She was considered to have an atypical depression (and low-normal IQ) and was given ECT during several admissions, without marked benefit. She had a further four admissions over the next 3 years and was usually given ECT. There were no further admissions over the next 8 years though her home life remained as restricted as before. A further cluster of admissions, usually of a few weeks duration, began in 1980. She complained of depression, suicidal thoughts, poor sleep and appetite ("one slice of toast a day for two years"), lack of support from her husband and of having no friends. On another admission she complained of tightness in her throat since a hysterectomy for menorrhagia a few months earlier. As before her symptoms were said to have a hypochondriacal slant and on one admission she was diagnosed as having a hysterical personality disorder. She tended to improve with in-patient support though staff often found her demanding and histrionic. In 1981 a further two admissions followed an overdose of anti-depressants and Jane complained that she was mad and should be put away. On this occasion ECT was said to have been effective. In July 1982, now 51, she presented to a casualty department with complaints of an inability to eat, drink, urinate, defaecate or breathe. She said that life was not worth living, that she was about to die and complained that her husband hit her. She was again treated with ECT, again without clear benefit.

In September 1982 she was again unable to cope at home, felt depressed and kept her curtains drawn all day in case the neighbours spied on her. One definitely new feature was the presence of involuntary movements, choreiform in nature, particularly in her face, left arm and legs. She had not been on psychotropic medication recently. These movements persisted after admission and she had a number of falls. After several weeks there was concern about memory and orientation though she was irritable and tended to co-operate poorly at interview. Her husband volunteered that her condition at that point seemed unlike all the previous episodes requiring in-hospital treatment. Transfer to a medical ward at the local General Hospital produced no new diagnostic insights though after her return she soon needed a Zimmer frame to walk. Later she became largely confined to bed. She was re-referred to the physicians and had a further 4-week stay in their care. They treated a chest infection but found no other focal pathology and the letter from the house physician which accompanied Jane back to the psychiatric ward noted her hypochondriacal style. On arrival she was found to be emaciated, slightly drowsy, irritable, disorientated and incontinent of urine. She had sluggish pupillary reflexes though no papilloedema, coarse nystagmus on left lateral glaze, involuntary movements of tongue, left side of face, left arm and leg, right facial and arm weakness with brisker reflexes, marked cogwheel rigidity and bilateral extensor plantars. She was close to death, 3½ months after admission.

Transfer to a specialist neurosurgery unit was immediately effected and an obstructive hydrocephalus was diagnosed on CT scan. A ventriculoperitoneal shunt was inserted and a further CT scan revealed a well-circumscribed mass in the left posterior fossa. A sub-occipital craniectomy allowed excision of a cerebellar tumour which proved to be a haemangioblastoma. Her post-operative recovery was fairly uneventful and she was left with a broad-based gait but minimal other cerebellar signs and was cognitively intact. She had a brief readmission for investigation of a pyrexia of unknown origin and the shunt was removed as a precaution.

More than 3 years later, now aged 54, there has been no evidence of a recurrence of tumour or of other pathology. Though for various reasons she has still not returned to the marital home, she has remained fairly stoical, though rather dependent, and has not complained of depression.

Discussion

One view of Jane's history is of a personality vulnerable to recurrent depressive and psychosomatic symptoms in the context of a life which she seems to have experienced from childhood as depriving and thwarting. Nonetheless it is noteworthy that her psychiatric history began only at 37, shortly after her mother's suicide, and it does seem that Jane struggled to free herself from the effects of this blow. In addition the successive disappointment of six miscarriages, an indifferent marriage and a lack of other social supports all took their toll. It was to psychiatrists she turned, frequently, and she seems to have been a rather trying patient to deal with. It is against a background of multiple psychiatric admissions, and of diagnostic tags like hypochondriasis and hysterical personality disorder, that the symptoms and signs of a posterior fossa tumour gradually emerged over several months, pursuing a largely classical course. That the diagnosis was not made until the patient was virtually moribund, despite several weeks on a medical ward, is a reminder of how potent a psychiatric history, particularly if it has a histrionic slant, can be in influencing the mental set of diagnosticians in other settings (Slater 1965). This effect may have been reinforced by the fact that she was already a psychiatric in-patient at the time.

Cerebellar haemangioblastoma is uncommon, representing 1–2% of all intracranial tumours. However, in adulthood, its incidence among primary tumours of the posterior fossa is 7.3% (Olivecrona, 1952) and it is thus nearly as common as meningiomas in this compartment. It tends to present in the 4th or 5th decade though at least a decade earlier in familial cases. It is composed of angioblasts which normally form foetal blood cells. It may exude xanthochromic fluid to form a cystic structure and the tumour may be a nodule in the wall of such a cyst. It is essentially non-infiltrating although malignant transformation and spread has occasionally been reported (Mohan *et al*, 1976). Almost all examples are subtentorial and cerebellar, usually single, although multiple tumours occur and in addition there can be similar tumours in the medulla or spinal cord (Morello & Bianchi, 1963).

Cerebellar haemangioblastoma can have prognostically important associations with other abnormalities, grouped as the Von Hippel-Lindau syndrome, though none have been diagnosed so far in the case above. The easiest to diagnose is a haemangioblastoma of the retina which is a small tumour situated peripherally in the retina and supplied by an enlarged artery and vein. Recognition may be hampered by secondary proliferative change or retinal detachment. Lindau's disease (Lindau, 1931) is the co-existence of other haemangioblastoma (e.g. spinal cord), cysts of pancreas or kidneys and carcinoma of kidneys. Phaeochromocytoma, sometimes bilateral, can emerge, particularly in certain families (Nibbelink *et al*, 1969). Polycythaemia occurs and may be the result of the elaboration of a factor stimulating erythropoiesis – such a factor has been found within the cyst fluid (Waldmann *et al*, 1961). Perhaps 10–20% of cases of cerebellar haemangioblastoma will ultimately produce evidence of some (usually not all) of these abnormalities though they are commoner when there is more than one tumour in cerebellum or spinal cord. In 20% of cases Lindau's disease has an autosomal dominant mode of inheritance, with variable expressivity. Nicol (1957) has reported five generations of one affected family. In most cases the cerebellar tumour is the source of initial symptoms.

Raised intracranial pressure is more marked and occurs earlier in tumours situated below the tentorium than those above though a cystic haemangioblastoma sometimes attains a large size without causing symptoms. Sub-occipital headache, clumsiness of the ipsilateral hand and a tendency to stagger towards the side of the lesion are common early symptoms. Nystagmus is marked and maximal with gaze towards the side of the lesion. The other signs of cerebellar dysfunction, particularly ataxia, will be most evident in the ipsilateral limbs. Speech is not commonly affected. Forward pressure by the tumour may impinge on cranial nerve function (particularly 5th, 6th, 7th) and pressure on pons and medulla can produce contralateral pyramidal tract signs. Tumour growth will produce obstructive hydrocephalus; papilloedema (though not present in this case) can be severe.

There was one other atypical feature. Involuntary movements are only unusually associated with cerebral tumours, particularly of the posterior fossa, and here they were present from the start. It is unclear just how they might arise in this context. However, it is worth noting that hysterical mechanisms have been considered capable of producing involuntary movements and it is certainly accepted that such mechanisms can be facilitated by underlying brain disease. More recently psychological explanations have been invoked less frequently than organic ones, not least because drugs like the phenothiazines (not implicated in the case above) have been observed to regularly produce just such movements (Merskey, 1986).

Mental disturbances are far less likely in subtentorial than supratentorial tumours and tend to emerge later than the neurological signs and symptoms (Hecaen & Ajuriaguerra, 1956). Cognitive disturbances, usually global, are generally related to the presence of raised intracranial pressure and develop insidiously. Here they were a late feature. Lability of mood, depression or irritability often accompany the advancing neurological picture though are unlikely to result specifically from organic mechanisms: emotional responses will be shaped by premorbid personality, vulnerability to psychiatric disorder and by the way doctors and nurses handle the patient. Moreover, a tumour arising 'de novo' may precipitate an episode of psychiatric breakdown whose characteristics, at least at the outset, may be little different from those of previous episodes. This patient's history suggests she was vulnerable to even modest stressors and she had already taken up familiar postures of despair and dependence at a point when the neurological picture was only just beginning to emerge.

It remains true that cerebellar haemangioblastoma invariably presents with neurological abnormalities rather than anything else and in Palmer's series (1972) this onset ranged from 3 weeks to 7 years (average 13 months) before diagnosis was made. Clearly this tumour can grow at very variable rates though, as we have seen, the interval between neurological onset and diagnosis may also reflect factors which emerge from the mental set of both patient and doctor. In the patient described above, neurological signs and symptoms, never noted during her many previous episodes of breakdown and in-hospital treatment, were present from the start of a progressive 4-month illness. It seems unlikely that a slow growing tumour could account for a much larger slice of her 14-year psychiatric history.

The most useful diagnostic aid is the CT scan, particularly in delineating the cystic component and associated hydrocephalus. Vertebral angiography may still have a role. Prognosis following resection is favourable and cure may result if resection is complete (Palmer, 1972). Recurrence may occur or haemangioblastoma at other sites may become symptomatic. The overall recurrence rate is said to be 33% after 4 years though higher (50%) in familial cases (Yamashita *et al*, 1982). A co-existing polycythaemia will be abolished by resection but can recur with renewed growth of tumour. The cerebellar haemangioblastoma itself remains the commonest cause of death. Renal cell carcinoma, arising later, may befall a patient with Lindau's disease who had successful initial treatment (Horton *et al*, 1976). Pre-symptomatic screening and genetic counselling have been recommended for families carrying Lindau's disease.

Acknowledgement

I am grateful to Dr R. S. Stern under whose care this patient was admitted, and who commented on the manuscript.

Schizophreniform Episode Following Measles Infection

A case of schizophreniform episode following measles infection in a 27-year-old woman is presented. The possibility that the clinical picture is a first description in the literature of an association between a schizophreniform episode and possible measles-induced allergic encephalitis is discussed. Other possible connections between measles infection and schizophreniform episode are also mentioned.

Acute measles encephalitis is distinct from two rare neurological complications of measles; subacute inclusion body encephalitis in immunodeficient or non-immunodeficient patients and subacute sclerosing panencephalitis (SSPE) (Kipps *et al*, 1983). The pathogenesis of the acute post-infectious encephalitis seems to be of an autoimmune nature. This is supported by the abrupt onset of the encephalitis late in the course of the exanthema or respiratory disease, the usual failure to detect virus in the brain, and the neuropathological changes which resemble those of experimental allergic encephalomyelitis (Johnson *et al*, 1984).

As there is no invasion of the central nervous system (CNS) by measles virus, it is possible to find normal protein, pressure and cell count in the cerebrospinal fluid (CSF) and no rise in measles antibody titer (Johnson *et al*, 1984). The clinical picture of such encephalitis usually involves severe neurological changes such as depressed level of consciousness, seizures, motor deficits and movement disorders (Johnson *et al*, 1984). The clinical picture of patients with brain lesions characterised by the presence of measles-like inclusive bodies is indistinguishable from these with the allergic type of brain cell damage (Kipps *et al*, 1983). To the best of our knowledge there is no description in the literature of schizophreniform episode as the only manifestation of measles post-infectious encephalitis. Therefore, we present for the first time, a case of post-infectious encephalitis presenting as a schizophreniform disorder.

Case report

Mrs S.H., a 27-year-old, woman of Jewish Ashkenazi origin was admitted to the general hospital because of behavioural changes which included agitated psychomotor activity, incoherent thinking, labile and inappropriate affect and poor judgement. She had a negative history for medical or psychiatric disease except for hormonal treatment for primary sterility for the last year. Her family history did not reveal any psychiatric disease. Ten days before her admission, the patient developed fever up to 40°C, maculopapular rash, respiratory symptoms and Koplik spots. She was diagnosed as having measles virus infection by her family doctor. She had suffered from the above behavioural changes since the eighth day and was admitted to the general hospital, was suspected of having measles encephalitis. Neurological examination and EEG were normal. Lumbar puncture technically failed. The mental status continued to deteriorate (bizarre delusions, frightening auditory hallucinations, extreme agitation and poor cooperation with the medical staff), and there was no change in her neurological status. The next day the patient was transferred to the Geha Psychiatric Hospital. On admission she was uncooperative and agitated. Her consciousness was clear with good orientation for time and place. Memory was undisturbed for all ranges. Her thinking was rapid, tangential and loosely associated, with delusions about her ability to hypnotise other people, read their thoughts, "turn them religious", and about having her thoughts read by others. The affect was euphoric and inappropriate. She had auditory hallucinations but could not describe them because "it was a secret". She lacked any insight and her judgement was poor.

Physical and neurological examinations were normal. Laboratory findings were as follows: leukocytes – 11 800 mm^3 with 60% lymphocytes; BSR – 80/110 mm which returned to normal within 2 days. Blood chemistry values and T4, vitamin B12, ANF, and LE cells were all within normal range. Measles antibody titer was 1:16–1:32, and progressed to 1:32–1:64, 6 days later. Cerebrospinal fluid findings were: clear fluid; pressure – 10 cm water; protein – 10 mg%; sugar – 66 mg%; cell count – 14/mm^3, with 98% monocytes and 2% polymorphonuclears. Bacterial and viral cultures were negative. Viral antibodies for measles, herpes simplex and rubella viruses were negative. On admission to the psychiatric department, and 4 days later, EEGs were normal as was CT scan.

Treatment was begun with levomepromazine up to 200 mg/day, and the psychosis gradually disappeared after 3 weeks. The patient was sent home in full remission, and on 8-month follow-up there were no psychiatric disturbances.

Discussion

Some CNS syndromes associated with measles virus are atypical and do not fit the classical description of either acute measles encephalitis or subacute SSPE (Kipps *et al*, 1983). We describe for the first time in the literature, a case of an association between a schizophreniform episode and possible measles-induced allergic encephalitic infection. This clinical picture developed post-measles infection and was constituted of agitated psychomotor activity, delusions, incoherent thinking, auditory hallucinations, labile and inappropriate affect and poor judgement and lacked any insight.

The anamnesis supported a measles virus infection with upper respiratory infection signs, maculopapular rash and Koplik spots. The clinical and laboratory findings of elevated BSR, leukocytosis with lymphocytic predominance, the increased measles antibody titre, and the most significant finding of 14 cells/mm^3 in CSF supported the diagnosis of measles encephalitis presented as a schizophreniform episode.

This case might be considered as an acute measles allergic encephalitis in which there was no evidence for direct invasion of the brain. Such encephalitis, which is considered allergic is essentially a demyelinating disorder which occurs primarily as a complication of measles, but also after vaccinia, varicella, and rubella infections. The lesions resemble those of neuroparalytic accidents following immunisation with rabies vaccine made from CNS grown virus and in experimental allergic encephalitis. This similarity suggests a common immunological reaction to some neural or vascular component resulting in demyelination, necrosis, vascular damage, and haemorrhage. Although viral inclusions are not found in this disorder and measles virus has not been isolated with certainty from the CSF or brain in such cases, the possible role of measles virus in the initiation of these changes cannot be excluded (Kipps *et al*, 1983). The case presented above can be included in group A described by Kipps *et al* (1983), which includes patients in whom neurological signs developed within 3–7 days of the onset of the measles rash, with short clinical illness lasting a week or less. This case is different from group A in that the virus was not isolated and there were no measles antibodies in the CSF, and it presented as a psychiatric disorder but not a neurological disorder. On two occasions the EEG of our patient was normal.

The incidence of encephalomyelitis post-measles infection is 1:1000. The encephalomyelitis is responsible for 25% of the neurological complications of post-measles infections. The mortality rate is 10–20%. Approximately 50% of the patients have severe persistent neurological defects, such as blindness, paraplegia and ataxia; 10% have seizures and many patients remain with mental deficiency. The prognosis is usually related to the duration of stupor or coma of the patient (Johnson *et al*, 1984). The proportion of cases presenting as a purely psychiatric disorder is unknown.

In such a discussion we must mention the viral hypothesis of schizophrenia, which may support the viral aetiology of the schizophreniform episode in this case report.

According to the developments in the field of virology and neurologic disease, there is preliminary evidence in support of the hypothesis that some individuals who are diagnosed as schizophrenics have a chronic brain disease, possibly acquired *in utero* or early infancy, the cause suspected as being a viral agent, according to findings in virology, clinical, epidemiological and laboratory spheres (Torrey & Peterson, 1976).

Common viruses including measles were suggested as possible aetiological factors of schizophrenia (Krauss, 1957; King *et al*, 1985). King *et al* inferred that an impaired immune response might be involved in schizophrenia. However, if the present case was an allergic encephalitis it would imply an augmentation of the immune response.

This case supports the concept that some schizophreniform-like disorders are associated with viral infection especially encephalitis (Wilson, 1976; Sobin & Ozer, 1966). Since the specific viral agent was not always identified, some of these cases might also have been due to measles.

Clonidine

An Effective Anti-manic Agent?

Three patients suffering from bipolar affective disorder, manic phase, and who were resistant to conservative treatment were successfully treated with clonidine. This would support the nor-adrenergic hyperactivity theory of mania. The rapidity of action of clonidine and its lack of relatively serious side-effects renders it a potential alternative to conventional anti-manic agents.

According to the catecholamine theory of affective disorder, increased central nor-adrenergic transmission has been implicated in the genesis of mania (Schildkraut, 1978). Clonidine is a long-established anti-hypertensive agent with presynaptic agonistic effect resulting in inhibition of the neural release of nor-adrenaline. Side-effects during treatment such as depression and sedation are well documented and have resulted in suggestions for its use as both a possible anti-manic and anxiolytic agent (Hoehn-Sarie *et al*, 1981; Lloyd, 1985). Increasing reports in recent literature suggest that clonidine is a potential adjunct in the treatment of mania (Giannini *et al*, 1983; Zubenko *et al*, 1984). We report here our experience with clonidine in the treatment of three patients. They presented with mania and with a history of bi-polar affective disorder.

Case reports

A 29-year-old male with a negative family history of affective disorder was first diagnosed as a unipolar depression in 1979. He developed his first manic episode in 1982 and has subsequently had several admissions with both manic and depressive episodes. He was maintained on lithium carbonate 1200 mg per day since June 1983 with serum lithium levels consistently ranging around 0.8 to 0.9 mmol/litre. His mania was treated at varying stages with chlorpromazine, haloperidol and lithium with only transient effect. His depressive episodes since 1982 were always post-mania and of brief duration. His last admission was in September 1982 when he was again noted to be markedly loud and vociferous with pressure of speech, flight of ideas, elation and grandiose delusion. He failed initially to respond to haloperidol in doses of 60 mg per day combined with chlorpromazine in doses of 1200 mg per day and his mood began to cycle rapidly between mania and apathetic depressive state. Because of his minimal response he was treated after one month with lithium carbonate 1600 mg per day (serum level 0.9 to 1.14 mmol/litre) for a period of 8 weeks but his mood continued to cycle rapidly as before. He was then given, in addition to lithium carbonate, clonidine 0.1 mg *b.i.d.* because of reports of its anti-manic effect. At this time his score on the Bech-Rafaelsen (BR) mania rating scale was 29. Clonidine doses were increased to 0.2 mg *b.i.d.* within 2 days. Following the increase in the dose of clonidine his BR mania rating scale score dropped to 7. His blood pressure did not alter. He was maintained on clonidine for 3 weeks and it was then withdrawn gradually over one week. Subsequently he was maintained on lithium carbonate 1200 mg per day. He was discharged and has remained asymptomatic up to the time of this report.

A 60-year-old woman with a long history of manic-depressive illness, depressed type, presented with her first episode of mania in April, 1985. She had one previous admission for the treatment of depression in 1970 and was treated on an out-patient basis for several depressive relapses up to the time of her latest admission. Her Bech-Rafaelsen mania rating scale score was 32. She was commenced on chlorpromazine 400 mg daily and chlopenthixol 40 mg daily with no effect after 1 week. At this stage haloperidol 5 mg orally with an intravenous dose of 10 mg was added on a daily basis. She failed to respond for a further 1 week. Haloperidol and chlopenthixol were discontinued and she was commenced on clonidine 0.2 mg daily. She became much more settled within 48 h and was normothymic 4 days later. Her BR mania rating scale score dropped to 5 and she was subsequently discharged on clonidine 0.2 mg daily with thioridazene 100 mg daily and has remained asymptomatic up to the time of report.

A 38-year-old married male with a negative family history of affective disorder was first diagnosed as psychotic depression in October 1983 and subsequently had several admissions for depression and mania. In February, 1985 he was again admitted with another episode of mania. His Bech-Rafaelsen mania rating scale score was 31 at the time of admission. He was commenced on chlorpromazine 300 mg daily and 100 mg intramuscular every 6 h with no improvement. After 5 days, haloperidol 10 mg intravenous daily was added to the regimen. He failed to respond for a further 4 days. Haloperidol was discontinued and he was commenced on clonidine 0.1 mg *b.i.d.* He became much settled within 3 days. The dose of chlonidine was increased to 0.2 mg *b.i.d.* and chlorpromazine was reduced to 100 mg a day. He became normothymic within 1 week. His BR mania rating scale score dropped to 6 and he was subsequently discharged on a maintenance dose of clonidine 0.2 mg daily and chlorpromazine 100 mg daily. He has also remained asymptomatic up to the time of report.

Discussion

The three case reports suggest that clonidine may have a role in the treatment of mania and are consistent with previous reports. (Giannini *et al*, 1983; Zubenko *et al*, 1984). All the three cases responded rapidly following commencement of treatment with clonidine and without apparent sedative effect. It is also worth noting that no patient developed hypotension or depression. The specific anti-manic effect appears to support the noradrenergic hyperactivity theory of mania (Schildkraut, 1978). Reports of relapse into mania following withdrawal of clonidine would also support this theory (Zubenko *et al*, 1984). Furthermore, Farsang & Kunos (1979) observed that clonidine may act as an endorphinergic agent, particularly in view of the fact that its hypotensive effectives are antagonised by naloxone, as a consequence it has been suggested that clonidine may exert its antimanic effect by stimulating central endorphins. It would appear likely that it has a dual endorphinergic and noradrenergic antagonistic mechanism. While it is preemptive to suggest that clonidine should be used as a standard treatment in mania, our study would suggest that it is worth considering in refractory cases or in patients who cannot tolerate lithium. The associated risks of neuroleptics such as anticholinergic effects, extrapyramidal symptoms and the potential risk of tardive dyskinesia are markedly more serious than those attributed to clonidine such as sedation, hypotension and less commonly depression. Our findings are consistent with other preliminary reports and the possibility of clonidine being used in place of neuroleptics and as an adjunct or substitute for lithium warrant further research.

The Role of Food Substitutes in a Token Economy System

Data from five behaviour management (token economy) units were analysed for periods of 10–20 weeks before and after the use of a food substitute (Complan®), provided when insufficient tokens had been earned to buy a full- or part-meal. The efficacy of this form of negative punishment to control disturbed and aggressive behaviour was examined. No evidence was found to suggest that the contingent use of a food substitute made any contribution to the therapeutic process.

It was demonstrated in the early 1960s that food could function as a powerful reinforcer of desirable behaviours among patients with psychotic disturbances (Ayllon, 1963; Ayllon & Haughton, 1962). Consequently, several early Token Economy Programmes (TEPs) utilised meals as one form of token-contingent reward. The techniques of behaviour modification have been a cause of ethical concern to several authorities (Wexler, 1973, 1975; Stolz, 1976; Kazdin, 1977; Innis, 1981). To support these forms of negative punishment as useful clinical procedures we need more evidence that to facilitate behavioural change, it is necessary to restrict access to certain basic amenities (Higson *et al*, 1985).

Behaviour management techniques can be divided into four basic conditions. Firstly, to increase behaviour one can (a) present something desirable (positive reinforcement) or (b) end something undesirable (negative reinforcement). Secondly, to decrease behaviour one can (c) present something undesirable (positive punishment) or (d) withhold something desirable (negative punishment). Withholding meals in lieu of the required tokens falls into this last category of negative punishment.

Higson *et al* (1985) investigated the effects of introducing meals as a 'free' item in the treatment of nine female chronic schizophrenic patients. The meals had previously been contingent upon the patients achieving a number of target behaviours in the area of self-help skills and social activities. Contrary to expectations, they found no systematic effects of meals on patients' performance on these specific target behaviours.

Two reservations may be expressed over the Higson study, however. The first is that subjects were all chronic schizophrenics. No attempt was made to investigate the effectiveness of food as a reinforcer with other types of patient treated in behaviour modification settings (e.g. those with conduct disorders, physical aggression and 'acting out'). Secondly, 'other consumables' (e.g. sweets) were available to these patients even when a meal was unavailable and food substitutes were not used.

The use of solid food as a method of reinforcement was a major feature of a behaviour management procedure at St Andrew's Hospital until March 1985. St Andrew's Hospital accepts very seriously disturbed patients for treatment in a controlled and locked setting using behaviour as a management structure (see Moyes *et al*, 1985). The practice of this negative punishment procedure was limited by a '15% rule', whereby staff were not to deny patients – or, in other words, patients were not permitted to lose – more than 15% of their meals per month. Where insufficient tokens were held for purchasing either a 'full' or 'part' meal, a milk-based nutritious substitute (Complan) was offered. The intention of this procedure was not to starve an individual patient but to create an attitude that meals, like many other things that some people take for granted, are something to be earned or worked for by a display of good, cooperative behaviour.

The need for patients to *earn* a meal has always been seen by some as a contentious ethical issue. On the other hand, staff of various disciplines concerned with the residents behavioural unit felt that the use of solid food as a back-up reinforcer was not only ethically justified but an essential part of the therapeutic regime. The discontinuation of this procedure in early 1985 made it possible to evaluate the efficacy of it retrospectively. Two main questions were addressed. First, the pragmatic issue of whether or not the use of a food substitute served its purpose of motivating individuals to work towards their target behaviours, thereby making the use of food effective as a reinforcer. Secondly, there was the ethical issue of whether one is justified, in the long-term interests of the patient, to 'deprive' patients of solid food.

Method

Data from the five behavioural units within the hospital operating TEPs were used. Unit 1 accommodates young people between the ages of 15 to 25 with behaviour disorders, some of which are secondary to psychiatric illness. Most of those who are admitted are detained under Section 3 of the Mental Health Act or a Secure Care Order and have usually proved unacceptable for placement in other establishments. Unit 2 takes similarly aged, behaviourally disordered youngsters who are at a lower level of functional and social skills. These patients have a mild-to-moderate degree of mental impairment and are likely to be always in need of some minimal community care. Unit 3 accommodates adults presenting a disturbed behaviour pattern, either as part of a psychotic illness or a personality disorder. The majority are referred from the courts either on remand or on Sections 37 or 41 of the Mental Health Act. Unit 4 caters for a wide age-range of behaviourally disordered mentally handicapped individuals, while Unit 5 is a rehabilitation unit for adults who have sustained brain injury (usually in road traffic accidents) and whose behavioural sequelae generally preclude their acceptance for rehabilitation elsewhere. All units are secure and all are of mixed sex. With the exception of the Unit 5, they contain a rather heterogenous group of patients.

The 29 patients studied (20 males, nine females) had a mean IQ of 73 (s.d. = 19) and a mean length of stay of 22 months (s.d. = 12). The number of patients in Units 1, 2, 3, 4, and 5 were 7, 7, 3, 6, and 6, respectively. By diagnostic category, three patients were behaviourally disordered with schizophrenia, 12 were behaviourally disordered with mental handicap (IQ<70), six were behaviourally disordered with head injury, and eight demonstrated other behaviour disorders (hysteria, personality disorders, etc.)

The various units terminated the use of Complan as a food substitute at different dates within a 4-month period. Only patients who had been on their respective behavioural units for 10–20 weeks (X = 18.55; s.d. = 2.698) before and 10–20 weeks (X = 15.53; s.d. = 3.100) after Complan was stopped were included in this study (n = 29). Patients transferred from one unit to another within the hospital during this period were not included. A period of 15 weeks before and after discontinuing Complan yields data from over 600 meals per patient. Due to the fact that a change in hospital policy meant that Complan could not be reintroduced, the experimental design was not amenable to anything other than a 'before and after' paradigm.

Procedure

It was a hospital requirement that all incidents where Complan (or part-meals) were given, be recorded by staff in a book specifically for this purpose and which is countersigned at least once per week by the psychiatrist or psychologist in charge of the treatment. In addition, all failures to earn tokens are recorded on the individual patients' charts. Cumulative token earnings are summated every week and documented as a percentage of possible earnings. Such data is therefore readily available for subsequent analysis. These percentages are quantitative reflections of a patient's level of general behaviour. Similarly, acts of aggression, leading to 5 minutes in a Time-Out Room are recorded by staff, together with dates, times and a description of the behaviour. There is, therefore, a clear record of incidents of actual physical aggression and other behavioural disturbances of a violent kind.

If a 'square meal' can be used to motivate and/or reinforce desirable behaviour, then we can evaluate the effectiveness of a food substitute as a form of negative punishment within a behavioural system by hypothesising that after food ceased being a contingent reinforcer, behavioural indices would alter to reflect this, probably by showing an escalation of the frequency of inappropriate behaviour. Specifically, token earnings would be expected to decrease while Time-Out Room incidents for aggression would increase for a period after the withdrawal of contingent food reinforcement compared with the period immediately before.

Results

Token earnings

Analysis (one-tailed t-tests) of mean weekly token earning percentages for the five units before and after termination of the use of Complan revealed that only two of the five units (Units 4 and 5) showed a trend in the expected direction. In addition, the only significant difference was in Unit 2 and that was in the direction opposite to that predicted ($t=1.96$; d.f. $=6$; $P<0.05$).

Analysing patients by category (behaviour disorder with mental handicap, behaviour disorder with schizophrenia, other behaviour disorders) as opposed to analysing by units, reveals that only those with a degree of mental handicap showed a significant difference although, again, in the direction opposite to that predicted ($t=-1.847$; d.f. $=11$; $P<0.05$).

Time-Out Room incidents

The differences in mean weekly Time-Out Room recordings for units before and after termination of food as a reinforcer, shows that only in Unit 1 was a significant difference found ($t=1.995$; d.f. $=6$; $P<0.05$). Once more, however, this was not in the direction predicted. Analysing differences in mean weekly Time-Out recordings by patient category as opposed to units, fails to show any significant changes.

Discussion

It was hypothesised that if the use of a food substitute (Complan) in lieu of adequate tokens for a 'full-' or 'part-meal' was an effective component in the behavioural system, then this would have been reflected by changes in behavioural indices before and after its cessation. In particular, it would be expected that some behaviours (Time-Out Room incidents) would increase, while positive aspects of behaviour (weekly percentage token earnings) would decrease.

The analysis of results by units and by patient categories, showed that few significant differences emerged. These were found to be quite dissimilar to those predicted – suggesting that using food as a privilege to be earned might be associated with a slightly punitive social milieu which reduces patient motivation and co-operation. It is clear that the use of food substitute *per se* did not have a substantial role in creating behavioural change. This is in contrast with beliefs held by many staff members of the hospital under study.

Behaviour modification arose from the study of animal behaviour in controlled settings. The evidence from both the theory and practice of behavioural approaches clearly indicates that private events play an important role in the determination of human behaviour (Lowe & Higson, 1983). In a social context the patient is systematically provided with information concerning his actions and their likely outcome for himself and others. Behaviour thus comes about through an informed appraisal of social consequences rather than via a hypothetical conditioning process or through an attempt to regain pleasures and privileges which are the patient's by right. ". . . We can not continue to defend coercive systems by reference to their results since we have clearly demonstrated that programmes which involve no deprivation of basic rights and privileges achieve comparable results to those achieved in token economies. In treatment of any kind the procedures that cause least distress to the patient should always take priority".

Hall & Baker (1986) summarise four major contributions of behavioural methods to present-day psychiatric rehabilitation: firstly, an increased emphasis on careful and comprehensive assessment of the patient and his environment, using behavioural methods and relating to regular monitoring procedures; secondly, a broadening range of treatment procedures which *may* use individual or group token programmes; thirdly, a clearer formulation of patient–staff and patient–patient interactions for ward milieux; and fourthly, better guidance on the design of both patient treatment programmes and staff training programmes so that positive results of the programme generalise to the real world – "although the token economy itself, in its original 'pure' form, has fallen into abeyance".

One does not necessarily have to agree with Hall & Baker. It would be of interest to examine various other aspects of the reinforcement system, e.g. social praise, contact with staff, cigarettes for smokers, leisure time etc., in an attempt to tease out which particular components can, in themselves, demonstrate changes in behaviour. There seems little doubt that the system *in toto* modifies behaviour and that changes so gained are maintained at follow-up (see Moyes *et al*, 1985). It may be that *no one item alone* contains that essential quality for change. Rather, when various components are combined together in a 'behavioural package', the sum is greater than the total of the parts.

A Study of Schneider's First-Rank Symptoms of Schizophrenia in Nigerian Patients

A prospective evaluation of Schneider's first-rank symptoms in 56 Nigerians with RDC schizophrenia gave a prevalence of 73%. The presence of first-rank symptoms was unrelated to schizophrenic subtypes, duration or severity of illness. While some of the symptoms correlate with age of patients, the pattern of inter-correlations among them supports previous views about their empirical heterogeneity.

The first-rank symptoms of Schneider continue to be of considerable interest with regard to their value in the diagnosis of schizophrenia (Carpenter *et al*, 1973) and their prognostic implications (Carpenter & Strauss, 1972). Even though Schneider regarded these 11 symptoms as pathognomonic of schizophrenia in the absence of organic brain dysfunction, recent evidence has brought into question the validity of this claim (Carpenter *et al*, 1973).

In spite of the remarkable stability in the frequency of FRS across schizophrenic samples in many studies (Mellor, 1970; Carpenter *et al*, 1973; Carpenter & Strauss, 1974; Ndetei & Singh, 1983), there is evidence that these symptoms do not form an empirically homogenous symptom group (Mellor, 1970). Also, while there is suggestion that schizophrenics with FRS may have a more severe illness as indicated by a higher overall psychotic symptom rating and disruption of instrumental role performance (Silverstein & Harrow, 1981), many studies have shown that these symptoms have no prognostic implications (Carpenter & Strauss, 1972). Thus, so far, the most appropriate status of the FRS remains to be determined.

Only very few studies of FRS have been done among African patients (Carpenter & Strauss, 1974; Ndetei & Singh, 1983). Specifically, apart from the evaluation of the prevalence of eight FRS in patients included in the International Pilot Study of Schizophrenia (Carpenter & Strauss, 1974), there is as yet no report of any systematic study of FRS among Nigerian patients.

This report investigates the prevalence of FRS among Nigerian schizophrenics, the relationship of FRS to each other and to the major diagnostic subtypes of schizophrenia, age at presentation, duration of illness, and the severity of the illness at presentation.

Method

The subjects were 56 consecutive new patients seen at Aro Hospital over a period of 3 months. Only patients were included in the study who (a) met the Research Diagnostic Criteria (RDC) for definite schizophrenia (Spitzer *et al*, 1975), (b) had informants with them who could give a detailed description of their behaviour during current illness, and (c) were not on active medication with a known psychotropic drug. All the patients were seen by one of the authors (O.G.) either immediately or within 48 h of contact with the hospital. This was to allow for accurate assessment of symptoms before they had been substantially modified by treatment. The informant was first asked for a general description of the patient's current level of functioning. This was rated on the Global Assessment Scale (Endicott *et al*, 1976). Using the listing by Mellor (1970) but assessing 'made impulse' and 'made affect' together, the presence of FRS was established by following the interview format described by Carpenter *et al* (1973) for eight of the symptoms, and Present State Examination style routine questions for two types of auditory hallucination: voices commenting, and voices arguing. The questions in these formats were found quite easy to give in Yoruba, the local language in which most of the patients were interviewed. Yoruba is the interviewer's first language and was the language used for the Nigerian section of the IPSS. Delusional percept was established during the overall mental state assessment and from the informant's report. Special care was taken in assessing all the FRS bearing in mind the ambiguity that may arise in delineating their boundaries. Only symptoms rated as definitely present were considered positive and all other ratings, including questionably present, were considered negative.

Results

The group comprised 27 men and 29 women with mean age of 27.8 years (s.d. 8.25). Analysis into RDC schizophrenic subtypes gives 25 (45%) mixed, 21 (38%) paranoid, nine (16%) disorganised, and one (2%) catatonic. There was no significant difference among the three commoner subtypes with regard to the presence of FRS ($\chi^2=3$; d.f. $=2$, NS). Fifteen patients had no FRS, six had one, seven had two, 11 had three, ten had four, three had five, and four had six (mean $=2.41$; s.d. $=1.89$). Thus, one or more FRS were present in 41 of the 56 patients giving a prevalence of 73%. The commonest FRS were made volition, thought insertion, and voices commenting. Delusional percept was the least common (Table I).

TABLE I
Distribution of individual FRS

FRS	*No. of patients*	%
1. Audible thoughts	7	13
2. Somatic passivity	15	27
3. Thought insertion	19	34
4. Thought withdrawal	11	20
5. Thought broadcast	13	23
6. 'Made affect and/or 'Made' impulse	11	20
7. 'Made' volition	22	39
8. Voices commenting	19	34
9. Voices arguing	15	27
10. Delusional percept	3	5

Even though there were a few significant correlations among FRS, there was no consistent pattern of association between either the special forms of auditory hallucinations or those symptoms said to represent a disturbance of the ego boundary.

Of eight significant correlations, none was within the former group and only three were within the latter group: thought withdrawal with thought broadcast ($r=0.36$; $P<0.02$), made affect/impulse with made volition ($r=0.43$; $P<0.02$), and somatic passivity with made affect/impulse ($r=0.30$; $P<0.05$).

Only two symptoms showed significant positive associations with age: voices commenting ($r=0.36$; $P<0.02$) and somatic passivity ($r=0.30$; $P<0.05$). The correlations with duration of illness did not attain statistical significance.

There were also no significant correlations with the severity of illness as rated on the GAS although there was a trend for thought insertion to correlate with less severity, and delusional percept with greater severity.

Discussion

The prevalence of FRS of 73% obtained in this sample bears close similarity to the 72% obtained by Mellor (1970) among British patients and 73% by Ndetei & Singh (1983) in their Kenyan sample. An earlier study of FRS among Nigerian patients (Carpenter & Strauss, 1974) found a prevalence of 63%. The difference between that report and the present one may be due in part to the fewer number of FRS (eight of the 11) assessed in that study, and differences in the diagnostic criteria used. The high frequency of made volition and thought insertion, noted in the present study, is similar to the observation of Carpenter & Strauss (1974) and Ndetei & Singh (1983). However, their results suggesting voices commenting as the least common are dissimilar to our finding. Delusional percept is present in 5% of the current sample, similar to the 6% obtained by Mellor (1970). Unlike Carpenter *et al* (1973), we found no significant associations between FRS and the four RDC subtypes of schizophrenia present in the studied sample. We believe, as Mellor (1970) says, that "it would be fortuitous if first-rank symptoms, selected solely for their diagnostic value, were central to syndromes of the theoretical interest."

Our results suggest that even though the presence or absence of FRS in general may not bear significant relationship to age, there may be some individual FRS that do so. This finding needs further clarification by other studies. The lack of significant association between FRS and duration of illness noted in this sample is similar to the observation of Carpenter *et al* (1973). There has been a suggestion that FRS-positive patients may have a more severe illness than those without (Silverstein & Harrow, 1981). We only noticed such a trend with regard to patients having delusional percept.

The pattern of intercorrelations among FRS in this study further supports the view that FRS are an empirically heterogenous group of symptoms and that this point bears remembering in determining their clinical and research use.

Books Reconsidered

Cognitive therapy and the emotional disorders: A. T. Beck*

Beck's original book on cognitive therapy was published in the USA in 1976 but not reviewed in the *Journal* until December 1979 (**139**, 582–583). The review was favourable. A second book (Beck *et al*, 1979) was not reviewed, although by then there was a substantial and growing literature on cognitive approaches to treatment.

Beck is a psychiatrist and former psychoanalyst who came to be increasingly dissatisfied with psychoanalytic theories and the results of therapeutic interpretations based on them. His earlier book on depression, published in 1967, was one of the first modern works concerned with the disorder. In it he reviewed the literature and some studies of his own, with an emphasis on symptom phenomenology. He also reported work with a symptom inventory which he had developed earlier and which has since been used widely.

Subsequently, his cognitive theories evolved from a more direct look at the depressive thought content, with considerable therapeutic contributions from behaviour therapy. In the late 1960s in the USA, moves away from psychoanalysis were gaining momentum, but were still not easy for the committed; I can remember the cool reception which a rather muted lecture at Yale around 1970 from Dr Beck (a kindly and courteous man) evoked in the senior figures in the audience.

The 1976 book set out the theoretical structure evolved by Beck and his group. The 1979 work, larger but very readable, is more a treatment manual. The theories centre around conscious ideation, moving away, as Beck pointed out, both from the unconscious thought processes of the psychoanalysts and from the neglect of thought content by the behaviour therapists. Beck directed attention to the presence of automatic thoughts, negative in content. These thoughts were regarded as preceding and giving rise to negative moods. He made a detailed analysis of what he described as systematic logical errors in thinking, such as arbitrary inferences and over-generalisation. He postulated underlying cognitive schemes which might give rise, when activated, to disorders such as depression. A method of therapy focusing on thought processes was described, aimed at recognition and control of the negative thoughts. The therapy uses techniques such as recording of thoughts, reality testing, and cognitive rehearsal. It is verbal, but in its structure and use of techniques such as homework exercises and self-monitoring has a clear behavioural component.

The 1976 book ended with the forthright claim that in comparison with psychoanalysis, cognitive therapy was readily comprehensible to patients, economical with regard to therapists' time, testable in research, and easily teachable to others.

On rereading this book one is struck by the clear, economical style. It consists of firm statements by a man who knows what he wants to say, and who is conscious of setting out for others an authoritative statement of a new theory which will have a memorable impact. Also, it is apparent that Beck was not just talking about depression. He deals with thoughts in relation to the normal emotions of sadness, euphoria, anxiety, and anger, and to the full gamut of emotional disorders: depression, anxiety, phobic and obsessional states, psychosomatic disorders, and hysteria. Only when he moves to treatment does he focus on depression.

It is not yet easy to assess the place of Beck's work: it has not reached a final point of equilibrium. It certainly took off with great success. By the late 1970s a vigorous group of young therapists and researchers were attending conferences and presenting data with some fervour. More recently, cognitive therapy has become part of the general armamentarium of the clinical psychologist. A number of controlled trials in depression have been carried out, which show the treatment to be at least as effective as drug therapy. It has led to further books, by various authors, to at least one journal, and to some distinguished research by psychologists in this country, clustering in Cambridge, Edinburgh, and Oxford.

However, its practical place in depression is still far from clear, and it is possible that reaction will set in. The treatment is intensive in its use of therapist time: drug treatment is considerably cheaper. On the other hand, there are early hints that cognitive therapy may reduce relapse rates. Studies have largely been confined to the milder range of depression, particularly general practice patients and out-patients. There has been little comparison of cognitive therapy with drugs or ECT in more severe depression. Most cognitive therapists are reluctant to tackle chronic and resistant depressions, although it is here that the need for alternative treatments is greatest. It is not certain whether the therapeutic effects are specific or reflect non-specific effects of the considerable therapeutic contact. Most studies do not show the effects particularly on thought content rather than other aspects of depression. Results so far available from the recent large American collaborative trial comparing cognitive therapy, interpersonal psychotherapy, drug therapy, and placebo suggest that all active treatments have approximately equal and similar effects but that cognitive therapy may have less effect in the severe depressions. Comparisons of recovered depressive patients with controls do not show the proposed abnormalities of thinking which might predispose to depression. This has led to a greater emphasis on the latent nature of the depressive schemas: a dangerous move towards the unverifiability of unconscious processes. Beck's own position appears to have changed over the years from regarding negative cognitions as causing depression to the view that they are not necessarily causal but part of the depressive syndrome and a convenient point of leverage for effecting change in it.

---

*International Universities Press, New York, 1976.

These are more than mere cavils, but less than fatal flaws: they are current hesitations. The real place of cognitive hypotheses and of cognitive therapy in depression will take longer to establish. Meanwhile, there is no doubting that the impact has been enormous. We have seen the birth of a modern movement. Others, particularly among clinical psychologists, were moving towards cognitive approaches at the same time as Beck, but it was his early work and his formulation which brought the therapy into being. Whatever its ultimate place as a treatment in depression, it has brought thought content back to centre stage in concepts of disorder. It has produced a new acceptance that psychological treatments can have major effects in a disorder where biological mechanisms appear important. It is also rapidly extending outside depression, for instance in the treatment of appetite disorders, and in a common disorder where alternative treatments are not satisfactory: generalised anxiety. Cognitive approaches are a major part of the currently evolving packages of anxiety management programmes. The approach itself may turn out to be the greatest contribution.

Consensus Statement: Panic Disorder

SIR: We welcome the consensus statement (*Journal*, April 1987, **150**, 557–558) from a group of British psychiatrists that the status of panic disorder as a separate entity is not strongly supported by available clinical and scientific evidence.

Their statement, arising from a meeting arranged by a pharmaceutical company, devotes a fair amount of space to drug therapy for panics, but very little to non-drug methods of treatment. It omits to mention that systematic exposure lastingly relieves the most common type of panic – phobic panic. Evidence for the durable value of systematic exposure rests on numerous controlled studies and follow-ups four to seven years later: far longer than after any drug study. In chronic panic, enduring improvement after exposure was achieved without the side-effects and with less of the relapse on ceasing medication that can be troublesome in drug treatment.

Temperament, Personality and Personality Disorder

SIR: Rutter (*Journal*, April 1987, **150**, 443–458) discusses a paper we have written on the subject of childhood temperament (Graham & Stevenson, in press). We have suggested that temperamental characteristics can be helpfully viewed as minor variations of behaviour which, in extreme form, can be regarded as psychiatric disorders, and have put forward evidence to support this view. We have not, as Rutter suggests, conceptualised temperamental characteristics as "mini-disorders" (his term, not ours) and indeed, in minor form, we see no good reason at all to think of such characteristics in pathological terms. Rutter rejects our view on five grounds, none of which, for reasons we state here, seems to us to constitute a valid objection.

Extremes of temperamental traits do not in themselves constitute disorder: This categorical statement by Rutter carries with it little meaning without definition of the terms concerned. We would argue that temperamental traits, such as activity, emotionality and 'socialisability', when shown in extreme form, do indeed represent handicapping forms of behaviour, and have cited evidence in the paper to which he refers.

Most of the symptoms of child psychiatric disorder are not part of temperamental concepts: We have not argued that *all* psychiatric disorder can be viewed as extremes of temperamental characteristics. Such a view would be absurd, and we have made this clear in our paper in which we cited anorexia nervosa and autism as two disorders that could not be so conceptualised. We have argued that extremes of the common varieties of temperament do constitute common disorders, and that much childhood depression, anxiety, hyperactivity, and antisocial behaviour can usefully be conceptualised in this way.

Patterns of correlation with change in behaviour rather than current disorder do not fit easily with our hypothesis: We are unaware of any significant body of work examining the relationship between background factors such as family disharmony or school failure with *change* of behaviour, although some such work certainly exists. Indeed, our own longitudinal study (Richman *et al*, 1982) represents one of the most substantial in this area. Most examination of background factors in relation to childhood disorder has concerned disorders of varying duration. There is no reason, however, why, given our hypothesis, change in background factors should not relate to a change in behaviour along a continuum from everyday behaviour to trivial, mild, moderate, or severe disorder, nor why temperament construed in the way we suggest should not be related to later behavioural change.

Our suggestion bypasses evidence on the indirect path by which temperament may lead to disorder via influences on other peoples' reactions: In fact, our hypothesis would have no difficulty in accommodating such evidence. If, for example, everyday but subclinical behaviour of an irritating type leads to parental rejection of child A more than everyday behaviour of a less irritating type in child B, it would not be surprising if child A's reaction to rejection involved a more extreme and disordered form of the same behaviour.

Our hypothesis fails to take account of the repeated finding that the effects of temperament may vary by sex: We are not suggesting that our hypothesis can be used to explain all phenomena that relate to temperament – it would be highly suspect if it did. On the other hand, the hypothesis is certainly not disconfirmed by differential responses to temperamental characteristics in boys and girls.

GRAHAM, P. & STEVENSON, J. Temperament and psychiatric disorder – the genetic contribution to behaviour in childhood. *Australian and New Zealand Journal of Psychiatry* (In press).

RICHMAN, N., STEVENSON, J. & GRAHAM, P. (1982) *Pre-school to School: A Behavioural Study*. London: Academic Press.

SIR: I am sorry that Graham & Stevenson feel that my use of the term 'mini-disorder' does not represent their concept of temperament. Nevertheless, it does seem in keeping with their argument in the earlier paper I cited (Stevenson & Graham, 1982). With respect to the observed association between temperament and the later development of behaviour disorder, they stated: "in fact we are merely observing a mild (or not-so-mild) problem turning into a larger one".

Their letter is helpful in clarifying their theoretical position, but let me comment briefly on the implications of the view that "much" child psychiatric disorder constitutes extremes of temperament. Firstly, the notion that psychiatric disorder implies more than just the extreme of a single behavioural trait is not just mine. The criteria for most psychiatric disorders in both ICD–9 and DSM–III require patterns of multiple symptomatology and social impairment. Moreover, as noted in my paper (Rutter, 1987), many *common* disorders are defined in terms of types of behaviour that are not part of any concept of temperament.. That is obviously the case with problems such as enuresis or encopresis, but it is also so with many conditions, such as phobic states, that have a closer connection with temperamental features. The development of, say, school phobia or agoraphobia involves something different from a general escalation in anxiety; that is why they are differentiated from anxiety states.

Secondly, with acute disorders there is the need to account for onset and remission. It does not seem likely that this is accountable for in terms of accentuations and reductions in temperamental features. Nevertheless, I agree that evidence both for and against is lacking. Also, it is common for psychiatric disorders in childhood to exhibit considerable situation-specificity. This phenomenon requires a form of explanation that does not fit readily into a concept of extremes of temperament.

Thirdly, with pervasive chronic disorders there is the assumption of continuity between normal variations in the temperamental feature and its apparent equivalent in the pathological condition. Again, the empirical evidence is sparse, but it seems likely that often this is not the case. For example, Graham's demonstration that some cases of the hyperkinetic syndrome respond to an oligoantigenic diet (Egger *et al*, 1985) suggests that the disorder is not just the manifestation of a high level of temperamental activity.

Fourthly, I appreciate that the Graham & Stevenson view by no means excludes circular processes involving interactions with environmental influences. However, what it surely finds more difficult to encompass are processes that have results that involve the emergence of types of behaviour that are different from accentuations or diminutions of temperamental features.

Finally, there is the most basic point of all: the assumption that, if psychiatric disorder is just an extreme of temperament, both should share the same set of correlates. But is that so? Certainly there is a lack of supporting evidence. The implication, for example, is that the genetic basis of the two is the same and that the environmental features associated with psychiatric disorder should apply similarly to temperament.

I chose to discuss Graham & Stevenson's concept because of my high respect for their research and I would like to take the opportunity of publicly thanking them for their courtesy and helpfulness in letting me see and comment on their paper in advance of its publication. Our views on temperament differ in crucial respects but we are entirely at one in the view that empirical evidence will decide between our concepts. Such evidence is being obtained by them (as well as by other investigators), and I await their findings with great interest.

Huntington's Chorea

SIR: Martindale (*Journal*, March 1987, **150**, 319–323) has raised an important issue that is relevant not only to Huntington's chorea but also to child psychiatry. It is well known that parents often have difficulty in recognising depression in their children. Professional responses to child psychiatric difficulties are less often discussed, and it seems worth drawing attention to a suggestion recently put forward by Emde *et al* (1986). Childhood depression was described many years ago, but it took a long time to gain general acceptance both by clinicians and by research workers. Emde *et al* hypothesised that this might be because depressed children threaten to arouse painful feelings in the professionals with whom they come into contact, and this may lead the professionals to fail to recognise the condition.

We are all familiar with 'observer effects' in research and these often seem to be regarded as contaminations which prevent us from discerning the truth. Both Martindale and Emde *et al* seem to suggest that this is only partially true and that some emotional responses (such as denial) will blind us to the truth, but others, such as the ability to tolerate feelings of hopelessness, helplessness and sadness in ourselves, may enable us to make a diagnosis which would otherwise elude us.

If this is correct it would seem to have several implications. Firstly, regarding teaching, perhaps we should spend more time helping our trainees to be more aware of their emotional responses to their patients; and secondly, as regards research, it would at least seem worth recording the emotional reactions of the interviewer to the patient.

My clinical impression is that patients often evoke similar emotional responses in a large number of professionals, and it could be that we should be taking more notice of this.

Anorexia and Antidepressants

SIR: We wish to take up and extend Crisp's theme (*Journal*, March 1987, **150**, 355–358) regarding the mode of action of antidepressant drugs in patients with anorexia nervosa. We have recently studied a group of four male patients with eating disorder, depressive symptoms, and obsessional behaviour.

All four have several features in common, including early age of onset (13–15 years), dietary restriction with consequent weight loss, and obsessional, repetitive exercise routines. One patient exercises with such force that he has sustained several muscle injuries. Three of the patients have been admitted to hospital in the past with transient weight gain. All patients have experienced marked anxiety in relation to loss of control of body weight. This has occurred, for example, when exercise was disrupted by injury or infection, and has led to anticipatory ruminations about the risk of contracting illness and losing control over body weight or body 'fat content'.

In all four, obsessional behaviour has extended beyond the spheres of diet, preparation of food, and preoccupation with exercise to the extent that they are unable to make simple decisions – almost amounting to 'folie de doute'. Three of the four patients are high-achievers academically, pursuing courses in tertiary education; the fourth has been sufficiently ill to interrupt his schooling, although he was regarded premorbidly as being of above average potential. Their academic success has been jeopardised by their obsessional insistence on studying every subject in excessive detail, which leads to their falling behind in their study schedules, causing anxiety and precipitating further ruminations.

All four are currently improved in their academic and social functioning (but not in their core anorexic psychopathology) following the administration of drugs which block 5HT re-uptake with varying degrees of specificity (e.g. fluvoxamine or clomipramine).

Crisp justifies the use of clomipramine by drawing attention to the possible primary phobic and secondary avoidance behaviour and obsessional features within anorexia nervosa. We concur with the view that in some anorexic patients obsessional features play an important role (Dally, 1969), particularly in male patients (Beumont, 1972), and such symptoms contributed significantly to the difficulties encountered by our patients. Taking Crisp's argument that tricyclic drugs have an immediate effect on drive behaviour further, we suggest that in addition they reduce repetitive, 'stereotyped' behaviour as manifested in impaired decision-making seen in these patients.

It is likely (Dally, 1969) that many such patients do not seek, or even actively avoid, in-patient treatment and in these circumstances the prescription of 5HT re-uptake blocking drugs may prove to be of considerable value in their academic and social functioning, although not in their core anorexic psychopathology.

Zinc in Senile Dementia

SIR: McLoughlin (*Journal,* March 1987, **150,** 409) appears to have selected information from various studies quoted by Srinivasan (1984) and concluded that lower zinc levels are present in the elderly functionally ill and in those with confusion. These studies cover a wide range of diagnoses and relate both to adult and psychogeriatric populations.

Our paper clearly describes the work of Bunker *et al* (1984), who suggest that the mean level of plasma zinc in healthy elderly adults is 11 μmol/litre (s.d. = 1.2). The levels reported in our study compare well with Bunker's elderly group. It is reasonable, therefore, to imply that the low levels of zinc in senile dementia which McLoughlin suggests he would have demonstrated using a healthy elderly control group would not have materialised.

Life Events and Mania

SIR: We are surprised that the *Journal* published an article which purports to measure life events prior to the onset of mania (*Journal,* February 1987, **150,** 235–240) when the method of life event assessment is simply that of searching case notes. Ambelas makes some important deductions from his assessment of life events, but we believe that the weakness of the life event assessment method is such that these could be misleading.

We are in the early stages of measuring life events prior to the onset of mania and are using the reliable method of Brown & Harris (1978) (LEDS). After assessment of only 11 patients two factors have become clear. Firstly, in the year prior to onset of mania 26 life events (according to the LEDS) have been elicited at interview, but only two of these were recorded in case notes. Secondly, the time between onset of symptoms and admission varied between 2 and 90 days (median 13 days), which indicates that measuring life events prior to admission, as performed by Ambelas, could be grossly misleading as there will be many illness-related events following the onset of a manic illness.

Khat-Induced Paranoid Psychosis

SIR: In February 1984 we reported (Gough & Cookson, 1984) a case of khat-induced psychosis in a 27-year-old man originally from North Yemen who presented with paranoid delusions and thought broadcasting similar in nature to those described by Critchlow & Seifert (*Journal,* February 1987, **150,** 247–249). In our patient a urine drug screen at admission was positive for amphetamines but negative for opioids, cannabinoids, cocaine metabolites, and barbiturates. This is to be expected, as khat contains a number of amphetamine-like substances such as d-norpseudoephedrine.

Our patient's family stated that khat is widely used by Yemeni people in Liverpool, fresh supplies being flown in daily. It commonly produces some degree of elation and hyperactivity, but not frank psychotic symptoms.

In January 1985 we were contacted by journalists from *The Sunday Times* (20 January 1985) in connection with an investigation they were carrying out into the use of khat in Britain. They had found out that large quantities of the substance were being imported into London without restriction.

The Regional Drug Information Service informs us that no further cases have come to light in Liverpool, and it would appear that at present the use of the drug is mainly confined to certain ethnic communities. Possibly because of this it may be less likely to come to the attention of medical services.

GOUGH, S. P. & COOKSON, I. B. (1984) Khat-induced schizophreniform psychosis in the UK. *The Lancet*, *i*, 455.

SIR: This case report (Critchlow & Siefert, *Journal*, February 1987, **150**, 247–249) does not accurately describe a typical case of khat psychosis. We reported three cases of catha (khat) psychosis (Dhadphale *et al*, 1981): our patients had paranoid psychosis with florid delusions which occurred in clear consciousness, and excessive use of khat was suspected as a possible causal agent. In a five year follow-up we did not find any relapse of psychosis in our subjects. Since then we have seen more than a dozen patients with khat psychosis, and all of them have shown a similar clinical picture as well as outcome.

As khat chewing is blamed for every social evil in our society by the lay press, our department has been involved in substantial research on various aspects of khat chewing (Omolo, 1985; Omolo & Dhadphale, 1987*a*). Our country grows and exports good quality khat leaves and a substantial number of our people in khat-growing areas chew khat for its amphetamine-like stimulant effect. Many use alcohol to counteract the sleeplessness which inevitably follows khat use (Omolo & Dhadphale, 1987*b*).

Critchlow & Seifert's case appears to us to be a mixed psychosis, probably toxic in origin, and due to several factors such as respiratory infection, possible morphine or dihydrocodeine use or abuse, or subtle malnutrition due to poor appetite and sleep deprivation – the latter two being the result of chewing khat. The authors should have inquired about the quantity of leaves chewed by the patient during the weeks prior to admission.

However, they have rightly alerted the medical and psychiatric communities in the UK to the possibility of khat being involved when a young person presents with a paranoid psychosis. Evidence of khat use may be found if the clinician examines the oral cavity of the patient for evidence of ulcers or stained teeth, which are common among habitual users.

Capgras' Syndrome in a Patient with Dementia

SIR: We report a patient who typifies some of the issues raised by Kumar (*Journal*, February 1987, **150**, 251).

Case report: A 79-year-old woman presented with a three-year history of the gradual onset of impaired memory. Two years after onset her husband was admitted to hospital for a few days for a minor operation. On his return he noticed that his wife made repeated references to her 'first' husband, whom she claimed had died some years before. She now referred to her husband as her second husband, despite acknowledging the very close resemblance in physical appearance, name, and profession between the two. Even though the husband could not convince her of his true identity, she showed no hostility towards him; as she said, "the new man is quite nice to be with". The husband's attempts to remind her of their earlier married life were always met with the reply: "but I was married to John in those days". At the time of presentation this belief had persisted unchanged for six months.

On examination, she had moderate impairment of memory for recent and remote events. She was mildly dysphasic and dyspraxic and could not name, or recognise as familiar, any of the subjects in a Famous Faces test. She did not score above chance level on a forced choice test of facial recognition. There was no evidence of depression or other abnormal beliefs, and her insight was limited to concern about her poor memory. CT brain scan revealed mild ventricular dilatation and sulcal widening but other investigations were normal, and a presumptive diagnosis of senile dementia of Alzheimer type was made.

This case emphasises some of the problems with regard to the nosological status of Capgras' syndrome in the cognitively impaired. There may be a spectrum of disorders of recognition. In our case there was no suggestion that the patient believed her husband was an imposter or that he had been maliciously replaced. Our case is similar to those described by Pick (1903) in introducing the concept of reduplicative paramnesia. While resisting a psychoanalytical interpretation, and in the absence of evidence of focal brain lesions (Lewis, 1987), the sequence of events in the genesis of our patient's belief might be as follows: the couple are reunited after a separation but because of a combination of poor visual memory and failure of facial recognition the wife does not recognise her partner's face. However, a sense of familiarity is retained because of other cues, e.g. mannerisms, and has to be explained. The patient's interpretation of events may then take one of two paths: either a confabulation involving a 'duplication' of the same person experienced at two different points in time (or in two different settings as with Pick's cases), or a delusional elaboration that the original partner has been replaced by an imposter. This latter is the classic Capgras' syndrome and may arise more readily in patients with premorbid paranoid traits (Burns, 1986). The status of such phenomena in the cognitively impaired may have implications for treatment and requires further elucidation.

ECT in the Elderly

SIR: The report by O'Shea *et al* (*Journal*, February 1987, **150**, 255–257) of cognitive improvement in a very elderly depressed patient treated with ECT is useful in that it reminds us that elderly people should not be denied an effective treatment solely on the grounds of age.

Clinical features which predict a good response to ECT in younger patients also predict a good response to ECT in the elderly (Fraser & Glass, 1980), and the presence of co-existing dementia does not adversely affect the efficacy and safety of ECT (Weiner, 1982). Age alone is not a contra-indication to the use of ECT (Benbow, 1985).

The clinical details quoted by O'Shea *et al* give little support to a diagnosis of dementia in their 91-year-old patient. She had previously responded to dothiepin, and the episode which led to the use of ECT seems to have been of less than 12 months duration. Her cognitive function was impaired as tested by the Mini-Mental State at a time when she had a frankly psychotic depressive illness, and improved as she recovered in response to treatment. This is not surprising. Fraser and Glass (1980) studied 29 elderly patients (aged 64–86 years) treated with ECT and found that they all had impaired memory function before treatment. Three weeks after ECT all scores had reached levels acceptable as normal. The clinical experience of many psychogeriatricians bears this out.

One problem is that the literature regarding the use of ECT in the very elderly is limited. In a study of 122 patients treated with ECT by the psychogeriatric service at the University Hospital of South Manchester only 16 were aged over 80 years and the oldest was a woman of 88 years (Benbow, 1987).

It is important that ECT is made available to elderly people with depressive illnesses, where the clinical features suggest a likely response and antidepressant drugs have not been successful or cannot be tolerated. Babigian & Guttmacher (1984) demonstrated a substantially decreased mortality risk in women over 75 years of age treated with ECT in comparison with a non-ECT group. Perhaps age could be regarded as an indication for ECT, rather than the reverse?

Admission Rates and Lithium

SIR: The argument seems to be about the 'efficacy' and perhaps the 'efficiency' of this drug (*Journal*, February 1987, **150**, 264–265). We would like to add further data to this discussion.

Recently, we examined infradian rhythms of mood and allied factors in out-patients with major affective disorders and matched healthy controls (Eastwood *et al*, 1985). Each person was interviewed with the Schedule for Affective Disorders and Schizophrenia, and the index group had to meet the Research Diagnostic Criteria. A sub-group from this study consisted of 11 patients who had been on lithium for an average of seven years, and these were contrasted with 22 healthy controls. These patients were treated independently by other psychiatrists and took only lithium during the study period. Patients, all of whom had bipolar affective disorders, and controls completed visual analogue scales daily (Eastwood *et al*, 1984) for 14 months. The mood ratings for index and control groups were compared using the means, standard deviations, and delta squares. The variability of mood, using chi-square analysis, was significantly skewed towards zero in the lithium group, compared with controls, for the standard deviations and delta squares.

So cases of bipolar affective disorder had less mood variability over 14 months on lithium than normal controls. The Folstein *et al* (1982) short-term finding in this regard (one month) is more than confirmed. Our study speaks to efficacy, in some cases, but says nothing about efficiency. Elsewhere we have shown that prescribing is not completely efficient, since in Toronto approximately two-thirds of patients with bipolar affective disorders receive lithium and two-thirds of those on lithium have bipolar affective disorders (Eastwood *et al*, 1981).

The very effectiveness of lithium could create problems by making patients overly controlled, without spontaneity and creativity (Jamison *et al*, 1979), and cause them to stop taking it. This would fit with Kendell's idea of withdrawal causing relapse and ever more mania. How ironic if patients' non-compliance in this disruptive illness was a function of effectiveness of treatment.

Psychiatric Morbidity and the Mentally Handicapped

SIR: Day's (1985) reported morbidity of 30% and 20% for psychiatric disorder in mentally handicapped patients of a mental handicap hospital and a day hospital respectively, may be equally valid with respect to mentally handicapped out-patients.

In a random analysis of one year's attendance of mentally handicapped patients at a small community-based mental handicap out-patient clinic (January–December, 1982) I found that 19% of the 115 out-patients seen were suffering from a significant mental illness: depressive illness 10 (i.e. manic depressive 2, agitated depression 6, depression with epilepsy 1, depression after brain tumour 1); schizophrenia 9 (i.e. paranoid 6, hebephrenic 2, simple 1); and severe personality disorders 3. This excludes behaviour disorders which were present in 36%. Diagnoses were made on the basis of a comprehensive history (from patients' relatives, social workers and community nurses), appropriate clinical criteria and, in doubtful cases, by admission for assessment, observation, and follow-up.

Sturmey's claim (*Journal*, February 1987, **150**, 270) that the behaviour problems due to painful physical conditions (abscesses, nasal infection, etc.), learned behaviour, and anti-social behaviour (wandering, stealing, etc.) may inflate the serious psychiatric morbidity in the mentally handicapped is not borne out by the many well-conducted studies in this field. In fact, most of these studies include major psychiatric illnesses such as schizophrenia, affective disorder, and personality disorder, and exclude the behaviour problems which he mentions.

The diagnosis of major psychiatric illness in mentally handicapped patients has always been difficult, as the signs and symptoms of the illness may be masked by the behavioural expression, as illustrated below.

Case report: A young severely mentally handicapped patient attending a special needs unit expressed his mood changes in a regular pattern of periods of overactivity, agitation, aggression, sleeplessness, and exhaustion, which resulted in loss of weight, chest infections, etc. (hypomanic phase), alternating, after a brief period of stability on medication, with phases of withdrawal, irritability, loss of his usual sociability, and tearfulness (depressive phase). This cycle lasted between 9 and 15 months. His response to lithium therapy was remarkable, and showed in his physical and emotional well-being, as well as in improvement in his learning, social and personal skills.

I hope that Sturmey is not attempting to minimise the importance of the recognition of treatable major mental illness in mentally handicapped patients, many of whom have suffered greatly in the past from the lack of appropriate treatment (mainly psychotropic medication) simply because their mental disorders were unrecognised.

Is the Positive-Negative Distinction in Schizophrenia Valid?

SIR: The longitudinal study by Johnstone *et al* (*Journal*, January 1987, **150**, 60–64) raises questions on the validity of the concept of positive and negative symptoms in schizophrenia. Their original proposition that this dichotomy represents different pathogenic mechanisms had been predicated largely on the assumption that positive symptoms are treatment responsive, and hence reversible, whereas negative symptoms are not. The current findings indicate, however, that positive symptoms are not uniformly treatment responsive and that negative symptoms are not universally immutable.

Our longitudinal studies of schizophrenia also challenge the validity of the positive-negative model as originally proposed, and suggest that other dimensions, notably chronicity of illness and diagnostic sub-type, may interact with this construct. In a two year follow-up of young patients with acute schizophrenia (Lindenmayer *et al*, 1986), both positive and negative syndromes proved longitudinally unstable and showed changing patterns of external correlates over time. Contrary to assumptions from studies in the chronic phase, it was the base-line negative rather than positive presentation which anticipated a favourable outcome. A cross-sectional survey of 134 patients with schizophrenia classified as acute (up to 2 years history of illness), chronic (3–10 years), and long-term chronic (over 10 years) similarly suggested that an early negative syndrome carries a better prognosis. In patients with acute schizophrenia such a profile was associated with depressive and atypical catatonic features as well as absence of psychosis in first-degree relatives (Kay *et al*, 1986). Thus, the positive-negative dichotomy may have a quite different clinical significance in the acute phase of psychosis to that in the chronic phase.

Recent pharmacological analysis has suggested, moreover, that the positive-negative classification delineates homogeneous psychobiological sub-types in schizophrenia only if considered along with diagnostic sub-type (Singh *et al*, 1987). The addition of anticholinergic drugs to neuroleptic treatment in a mixed population of patients with acute, subacute and chronic schizophrenia produced a significant worsening of positive symptoms overall, but this occurred mainly among patients with catatonic symptoms. In paranoid patients, to the contrary, it was the negative symptoms that worsened significantly, whereas in hebephrenic patients neither syndrome was significantly affected. Cumulatively, our results suggested that the natures of positive and negative syndromes vary according to chronicity and subtype of schizophrenia, and perhaps only in the chronic patients and the non-paranoid forms of illness is the present concept of the positive-negative dichotomy applicable.

The data from Johnstone's group underscore qualifications on the generality of the construct. They observed that delusions – a cardinal feature of paranoid schizophrenia – were significantly more prevalent in neuroleptic-treated than neuroleptic-free patients with schizophrenia, as were also symptoms of anxiety and depression. The latter finding may be understood within the context of a post-neuroleptic emergence of dysphoria and elevation of tonic autonomic arousal, which characterises only non-paranoid patients and portends poor therapeutic response (Singh & Kay, 1979). Furthermore, our work has suggested that non-paranoid neuroleptic-resistant patients with schizophrenia may be distinguished from others by clinical worsening under blind wheat gluten challenge (Singh, 1978; Singh & Kay, 1984). Research on the psychobiology and course of schizophrenia, therefore, casts doubt on the sufficiency of the positive-negative model. Study of its interaction with diagnostic sub-type and phase of illness, on the other hand, may offer new insights not afforded by examining any of these dimensions separately.

Neuroleptic Malignant Syndrome (NMS) and Tardive Dyskinesia

SIR: Haggerty & Gillette (*Journal*, January 1987, **150**, 104–105) seem to have concluded that NMS developed while the patient was having reserpine and lithium. The details they give do not support such a conclusion, as they mention in their discussion. For example, they do not mention any alteration in consciousness after lithium and reserpine were started: besides rigidity, hyperpyrexia and autonomic dysfunction, alteration of consciousness in varying degrees is a *sine qua non* for the diagnosis of NMS (Caroff, 1980). Here, only autonomic dysfunction was noticed after starting lithium and reserpine. Moreover, the progression of NMS is known to be very rapid after onset. In more than 90% of 120 cases reviewed, the full syndrome developed within 48 hours of the first symptoms (Shalev & Munitz, 1986). It is naïve to conclude that mild NMS developed over a period of two weeks and that the full-blown syndrome began later, when thioridazine and haloperidol were started.

What is of interest in this report is the unusually long duration of the NMS episode (seven weeks). Generally, it is presumed that NMS lasts for 5–10 days after discontinuation of oral neuroleptics (Sternberg, 1986). I have come across another patient in whom the syndrome persisted for three weeks after cessation of haloperidol and remitted after a 17-day course of amantidine (Woo *et al*, 1986). Treatment was continued for a further period of five months. Such an abnormally long duration may have something to do with the patient's metabolic characteristics, as differences in absorption and first pass metabolism are known to cause wide inter-individual variations in the plasma levels of neuroleptics. Moreover, neuroleptics, being highly lipophilic, can be detected for weeks after discontinuation.

Caution is required before concluding that unexplained fever is due to NMS. This is clear when one considers the authors' suggestion that reports by family of transient diaphoresis and elevations of temperature in the months prior to admission were probably because of NMS in "milder form". In the absence of any alteration of consciousness such an interpretation is not justified. At the moment, there is not enough clinical data to justify the spectrum concept of neuroleptic toxicity (Corlon, 1986) which the authors seem to have in mind.

Continuum of Psychosis and the Gene

SIR: Crow's theory (*Journal*, October 1986, **149**, 419–425) bears a striking similarity to the theory of Britain's best-known psychologist, Hans Eysenck, to the effect that a heritable trait of psychoticism (*P*) underlies much psychotic (and indeed psychopathic) disturbance (Eysenck & Eysenck, 1976, 1985). Like Crow's continuum, Eysenck's *P* has sometimes been considered to be related to cerebral lateralisation of function (Brand, 1981) and to forms of creativity and achievement (Claridge, 1985) that might explain the persistence of high-*P* genes in the population despite the lowered average fertility of people who suffer outright psychotic disturbance.

I wonder, could the theories of Crow and Eysenck by any chance be related?

Koro-Like States

SIR: We have under our care a 25-year-old male patient with complaints of penis and testicles shrinking into his abdomen.

Case report: This man, from a working-class English background, initially presented in 1983 at the age of 21, with an anxiety state and reactive depression for which he was admitted to hospital for further assessment. He had had both psychic and somatic anxiety symptoms. At that stage there was no evidence of a major affective or schizophrenic illness. Like the patient described by Modai *et al* (*Journal*, October 1986, **149**, 503–506), this young man was physically well-built but emotionally immature. He presented a poor self-image and usually responded to any threat to his ego by being verbally aggressive. His parents' marriage broke up when he was nine. He was left with his father, whom he always perceived as being a domineering man. He could not forgive his mother for leaving him and still harbours a strong feeling of rejection. He had a history of faecal soiling and repeated hospital admissions for successive eye-operations (following an accidental injury) around the age of ten. He first complained of his penis and testicles retracting into his abdomen while in hospital in 1983, coincidental with the break-up of his first serious relationship with a girlfriend. His mood subsequently deteriorated. He was treated with amitriptyline (50 mg/day) and stelazine (15 mg/day). The depression improved, but his belief about his genitalia remained unaltered. He was re-admitted a year later, and again in 1986, with clear-cut episodes of hypomania. His hypomania has now remitted, but during both these admissions he maintained his belief about his retracting genitalia. His concern is such that he avoids places where his genitalia may be exposed and he despairs of ever having a girlfriend again.

In contrast to classical koro, there does not appear to be a cultural factor in this case. Although koro is rare in the Western hemisphere, koro-like states may not be uncommon and may be under-reported.

HIV and the Psychiatric Hospital

SIR: Most readers are aware of the controversy concerning the treatment of patients infected with the human immunodeficiency virus (HIV) presenting with various medical problems. There has been little discussion of the problems encountered when psychiatric disorder arises in these patients. Colleagues in virology and venereology assure us that the transmissibility of HIV by any route other than by sexual contact or transfusion is small. We may therefore rest assured that the aggressive self-mutilating or spitting patient presents little risk to staff or other patients provided that proper precautions are taken. I have been assured that needlestick injuries are ineffective in transmitting HIV, although I would still like to see some evidence of this, given the frequent need to sedate acutely psychotic and resistive patients by intramuscular injection.

The major problem in dealing with HIV-positive patients lies elsewhere, and has moral and practical dimensions. It is not uncommon for psychiatrically ill patients to be in a state of sexual hyperarousal, most often seen in mania. Equally, most long-stay facilities have a significant sexual sub-culture where intercourse is traded e.g. for the price of a few cigarettes. While staff try to prevent such activities, it is impossible to achieve 100% success. Introduction of HIV carriers to a psychiatric unit therefore poses the threat of transmission to patients whose judgement is impaired by virtue of mental illness.

Morally, detention of a patient under a section of the Mental Health Act implies a responsibility to guard that patient against the consequences of his or her impaired judgement. The sheer terror induced by being diagnosed as HIV positive, plus the profile of *some* high risk groups (promiscuous homosexuals and drug addicts), suggests that as the HIV epidemic continues, psychiatric hospitals will have a higher prevalence of HIV carriers than the population at large. Furthermore, HIV-associated dementia will probably require psychiatric placement, again increasing the prevalence. The moral question I would ask is: 'How can we defend detaining a patient who is at risk to his or herself by virtue of mental illness and whose condition entails a tendency to sexual promiscuity, in a facility where the prevalence of HIV carriers may be above that in the community?"

Practical problems abound. Closer supervision through augmented staff levels could, in theory, preclude the possibility of intercourse in hospital. If a middle line is taken and only those who are HIV positive are "specialed", we run into the problem of consent for screening. Also, it is a criminal offence to disclose the HIV status of a patient to unauthorised people (not the case with Australia Antigen).

I believe that the special problems faced in psychiatric units as a result of HIV merit urgent discussion by the College, the Mental Health Act Commission and the DHSS. In particular, I wonder whether Parliament needs to review the problem of consent for HIV screening when patients are to be admitted to psychiatric hospitals, and also the question of the degree to which the dissemination of their HIV status can be permitted. The use of 'high risk' categories in determining levels of surveillance, while still of use, cannot be considered adequate, given the spread of HIV into the heterosexual non-drug-abusing community.

First Admissions of Native-Born and Immigrant Patients to Psychiatric Hospitals

SIR: In their study of first admissions of native-born and immigrant patients to mental hospitals in South-East England, Dean *et al* (*Journal*, 1981, **139**, 506–512) found increased rates of admission for most immigrant groups, particularly for illnesses diagnosed as schizophrenia.

However, their findings, which were based on routine data from the four Thames Regions, differed from more locally organised studies in showing substantially smaller excesses, particularly for Asians. For example, for all diagnoses for Indians Dean *et al* found a 50% excess of first admissions for men and a 20% increase for women. For immigrants from Pakistan and the rest of the Asian New Commonwealth they found a 40% deficit.

By contrast, for example, Carpenter & Brockington (*Journal*, 1980, **137**, 201–205) found, for all Asian groups combined, excesses of 200–500% at different age groups. The only exception was the 15–24 year-olds, who showed a 50% excess.

A possible explanation for the discrepancy is the notorious incompleteness of the data source Dean *et al* used (Mental Health Enquiry (MHE)). The authors attempted to address this problem by organising a campaign to improve completeness of recording. However suspicion must remain that while overall they achieved quite good results – 91% completion of the place of birth field – this success may have been patchy, giving rise to systematic distortion in their conclusions. A closer examination of the data for one of the four Regions they studied for 1976 suggests this is likely.

Dean's study excluded all but first admissions so as to avoid multiple counting of individuals. This meant that it depended not only on the birthplace field in each record, but also on the previous admissions question. Permitted responses to this include "not known", and people so coded are not included in first admission statistics. A survey in Newham Health Authority (Glover, 1985) found that about two-thirds of admissions so coded almost certainly were first admissions. Dean also excluded records with the birthplace omitted.

A study of N. W. Thames regional MHE data for 1976 by the Area Health Authority showed that the urban Areas had a higher proportion of first admission records with birthplace uncoded (ranging from 1.4% in Bedfordshire (Beds) to over 10% in Ealing, Hammersmith and Hounslow (EHH) and in Kensington, Chelsea and Westminster (KCW). Urban Areas also had a higher proportion of records with previous admission status "not known" (ranging from 2% in Beds to 16% in Brent and Harrow and 33% in KCW).

In general, but particularly in EHH, birthplace was more frequently missing from records with previous admission status "not known". The same urban areas had rather higher proportions of immigrants in their resident populations than the rural ones.

It seems reasonable to imagine that language difficulty is one obstacle records clerks may encounter in eliciting a patient's previous admission status. Clerks may also be unwilling to ask about some patient's birthplace if racial tension is prominent in the district served. The hospitals serving the Notting Hill Gate area, one of the more racially disturbed at the time, had particularly low rates of birthplace recording.

These findings suggest that the figures Dean *et al* produced are probably a serious underestimate and that the local studies should be considered to be more reliable. They particularly call into question the widely quoted idea that Asians make less use of psychiatric services. This view is based mainly on MHE studies, and runs counter to the impression of many psychiatrists who have worked in areas with large Asian populations.

Dates of Acceptance

SIR: Readers with an eye for detail might have noticed a change in the March *Journal*. Would-be contributors are no longer allowed to muse over the gestation period of papers accepted for publication: the date which used to be given at the end of each article has disappeared. Eighteen months ago dates of receipt were transmuted into dates of acceptance. Since, notwithstanding, the *Journal* continues to enlarge, perhaps the next step might be to omit page numbers.

A HUNDRED YEARS AGO

A curious outbreak of convulsionist mania, analogous to those which occurred from time to time during the Middle Ages, is reported to have shown itself at Agosta, in the province of Rome. For some weeks past the country people have been labouring under the delusion that the district is under the immediate government of the Evil One, and before retiring to rest they carefully place on the threshold the broom and the salt, which are credited with the power of keeping off evil spirits. Many of the younger women have epileptiform attacks, during which they utter piercing shrieks, and are violently convulsed. So serious had the condition of things become, that the syndic of Agosta found it necessary to inform the Prefect, who sent detachments of soldiers into the district in order to calm the apprehensions of the inhabitants. The contrast between this strictly physical way of dealing with the disease and the more imposing but less effectual religious ceremonies formerly employed must be interesting to historical students. As a natural consequence of this condition of mental perturbation, the country is overrun with quacks who claim to possess the only infallible remedy for the seizures. One of these nostrums, the vendor of which was making a rich harvest from its sale, was found on analysis to consist of earth, snuff, and borax. Three medical men who were commissioned to investigate the cause and nature of this extraordinary affection, came to the conclusion that it was an epidemic of hysteria. They examined a number of the sufferers, mostly young women, some of whom were alleged to have vomited nails, horseshoes, and other equally indigestible substances, while others barked like dogs. Several of them were removed to Rome for treatment in the hospitals there, and measures have been taken to check the spread of the mischief. In a milder degree, this contagious form of hysteria is not infrequent, especially in places where ignorance and superstition favour manifestations of nervous disorder. The worst excesses of popular outbreaks, like the French Revolution, have been attributed to similar influences, and with every appearance of justice.

Book Reviews

Editor: Sidney Crown

The Breaking of Bodies and Minds: Torture, Psychiatric Abuse, and the Health Professions. Edited by ERIC STOVER and ELENA O. NIGHTINGALE. Oxford: W. H. Freeman. 1985. Pp 319. £21.95 (hb), £11.95 (pb).

This book is testimony to modern man's potential for physical and mental abuse and inhumanity to his fellow man – conducted usually under the jurisdiction of repressive regimes or institutions and, unfortunately, facilitated willingly, unwillingly, or unwittingly by medical and biomedical professionals. Psychiatrists and their powerful tools are liable to co-option by the state or by institutions, and their participant role may be central or supportive. Some non-participants subsequently may profess no knowledge about such acts; others may turn a blind eye; but there are the courageous few who (at considerable personal risk) note and protest such abuses and attempt to arouse international awareness.

Indubitably such acts abrogate universally accepted norms of human rights. Individual practitioners and medical associations are confronted with the challenge of abolishing and resisting complicity in state or institutional abuses. One way of helping such individuals is by the availability of internationally accepted guidelines and codes of ethics which define professional complicity, and which unequivocally assert that such abuses are morally wrong. For instance, the brief set of principles adopted by the United Nations General Assembly (18 December 1982) merits wide publicity. How many medical journals have troubled to publish these? And yet I believe they should be mandatory reading for all health workers.

While there should be no compromise about such codes of ethics in practice, the book hints at some unresolved issues. Firstly, the concept of misuse of medical resources to suppress political and religious dissent is often widened to include variations in quality of psychiatric care. However, a distinction needs to be made between misuse of medical skills and maldistribution of health resources to the poor in the face of their misery and powerlessness.

Secondly, there are the complex political issues. What constitutes a repressive regime? How should ideological differences be perceived and questions of infringment of national sovereignty be answered? How do endeavours which are aimed at political change differ from the health profession's action on behalf of human rights? A formula must be found for dealing with these issues in a non-political way: in particular, codes of ethics should be non-political. But what other means are available? Some of these issues were addressed at a recent meeting convened by the Royal College of Psychiatrists (White, C. (1986) *British Medical Journal*, **293**, 1524); they include "the anomalies of trying to bring pressure to bear while preserving dwindling contacts, and of the importance of being seen to be fair rather than sanctimonious, and professional rather than political".

Thirdly, what should be the reaction to a medical association in a particular country when a small core of their health professionals systematically abuse their medical skills? Excommunication of the whole association is likely to be counter-productive: it may stigmatise even those who silently or openly condemn such abuses.

Borrow or buy this book; it costs little enough. The chapter on 'Unwilling patients' by the psychiatrist Anatoly Koryagin provides compulsive reading; the reader may wish to dip further.

I. KOLVIN, *Professor of Child and Adolescent Psychiatry, Nuffield Psychology and Psychiatry Unit, Newcastle upon Tyne*

Professional Supervision in Group Care: A Contract-Based Approach. By JAMES S. ATHERTON. London: Tavistock. 1986. Pp 202. £6.95(pb).

James Atherton is a teacher of social studies who has led workshops on supervision. This book has arisen from the ideas and approaches used during these courses. It is aimed specifically at social work staff in residential homes and day centres. For this reason it is a practical and didactic work, rather than a reflective one, and at the level it is pitched it works well.

The book is divided into three parts. The first is the meat of the book, dealing with what supervision is all about and how it should be conducted. The short second part discusses some of the topics of supervision, and the third part looks at problematic areas and develops some of the themes touched on earlier in the book.

The writing is admirably clear, the approach to supervision is sensibly argued, and a wide range of accessible references for further reading are given. The two criticisms I have are very specific, but important. Firstly, the topic of transference is poorly dealt with, and I can only think that anyone coming upon the idea for the first time would end up with a very muddled view. Secondly, there is a fundamental error in the section devoted to evaluating supervision, where a specimen questionnaire is shown with a three-point scale in which one point signifies negative and two points positive evaluations. Such a scale is inherently biassing, as opposed, for example, to a five-point scale with a neutral mid-point.

Can a book targetted at so specific a readership be of interest to others, such as psychiatrists? I think it is not of general interest, but anyone contemplating supervising staff in a residential or day care setting (such as a therapeutic community) would find plenty of useful advice.

ERIC CROUCH, *Consultant Psychiatrist, St John's Hospital, Aylesbury*

Attack on the Self: Adolescent Behavioural Disturbance and their Treatment. By DEREK MILLER. Northvale, NJ: Jason Aronson. 1986. Pp 340. $32.50.

Miller suggests in this book that two crucial ideas are required if adolescent psychopathology is to be truly understood. The first is the biopsychosocial basis of all psychiatric disorders. The second is the need, particularly with adolescents, to view any disorder from a developmental perspective. It is because of the adolescent's particular phase in development that emotional disturbance is expressed overwhelmingly through visible behaviour. The severity of the behavioural problems may be quite out of proportion to the severity of that underlying emotional disturbance. Relieving the symptoms may, through its effects on those around the adolescent, truly cure the disease. The first three chapters expand on these arguments and deal with the developmental and social issues. The next two deal with general principles of assessment and treatment, and the remaining eight with specific disorders.

What comes over strongly in this book is the author's deep compassion and concern for the well-being of adolescents and his anger over the way they can be treated (or mistreated) by adults. Equally, the author's great clinical experience is apparent from the many brief clinical vignettes used to illustrate his points. Despite this, the book as a whole is surprisingly unsatisfactory. One major problem is the question of to whom it is addressed. The only hint is in the acknowledgements, where medical students at North Western University are thanked for their comments on the draft. The level is indeed appropriate for an undergraduate audience: the discussions on aetiology, prevention, and treatment are insufficiently detailed to be of any real help to professionals. I would however have great reservations about recommending it for an undergraduate class of medical or other students; there is a narrow selectivity in the choice of references used to illustrate the author's arguments. Key pieces of work which do not fit in with his thesis are ignored. In many places controversial statements are made with no attempt to support these with evidence from research. The book is really the philosophy of adolescent psychiatry of one experienced practitioner. I feel that by not defining a target audience, it has left itself without one. I would have enjoyed reading Miller's detailed thoughts behind some of the ideas he puts forward, which are often arguments going against conventional widsom. Alternatively, on a simpler level, the book could have been a useful guide for the perplexed parent or teacher. As it is, I can unfortunately think of no group to whom I would recommend it as an introduction to adolescent psychiatry.

STEPHEN WOLKIND, *Consultant Child Psychiatrist, Maudsley Hospital, London*

Handbook of Depression: Treatment, Assessment, and Research. Edited by E. EDWARD BECKHAM and WILLIAM R. LEBER. Chicago: The Dorsey Press. 1985. Pp 1079. £51.00, $72.00.

This is a big book; its 1079 pages are assembled into 27 chapters and are written by 51 American and 2 British authors. Obviously, in a multi-author work of this size there will be good parts and bad parts, but the editors should be congratulated for persuading all the contributors to come right up-to-date with their references; all the chapters are very well referenced. Both the editors are psychologists, and the emphasis is on the psychological aspects of depression; however, the biological aspects are not neglected and the chapter on biological processes (Thase, Frank & Kupfer) is one of the most concise and up-to-date accounts that exists anywhere.

The book starts with ten chapters on therapies: cognitive (Beck), behaviour (Hoberman & Lewisohn), long-term analytic, brief psychodynamic, interpersonal psychotherapy, family and marital, and alternative (transactional analysis, gestalt, and reality therapies). The common failing of all these accounts is that authors do not delineate the areas of clinical usefulness of their approaches; most of them seem to imply that the therapy they describe is generally effective in a condition termed 'depression' (without further qualification), although sometimes a caution is given about trying to treat the acutely suicidal patient by a psychotherapeutic approach. Bellack provides a useful overview of psychotherapy research and points out that little is known about how psychotherapies compare with one another, for whom and conducted by whom they are effective, and what they all hold in common; surprisingly, on the last of these issues he does not quote Jerome Frank, and nor does anyone else. Bellack points out that many of the claims of proponents of psychotherapies are not established, and he closes his chapter with a consideration of four broad 'mechanisms'; he omits a fifth, which is that most depressive disorders remit spontaneously and that natural recovery may well occur in the course of these expensive encounters. The conduct of somatic therapy (apart from lists of drugs) is poorly described, and the authors of a chapter on the management of refractory depression (Akiskal & Simmons) seem to spend a lot of time, and therefore their patients' patience and money, in taking them off drugs only to prescribe them again but without clear and well documented credentials for what they are doing; in the end they frequently prescribe the long delayed electroconvulsive therapy which "more often than not" proves effective.

The problem of definition of depressive disorders continues to becloud the whole area, despite all the grandeur of DSM–III and the Research Diagnostic Criteria. Some authors come close to acknowledging that these systems do not define homogeneous disorders and Kathol, in the chapter on depression in the medically ill, underlines their failure to identify a psychiatric disorder requiring treatment. Batteries of psychological and physical investigations lead to confusing results of uncertain application, because they are applied to heterogeneous disorders which hold in common only the universal term 'depression'. No author in this book has taken up the idea, put forward by Klein over a decade ago, of a biogenic depression styled 'endogenomorphic' which might be distinguished from other depressive states on clinical grounds. Until some such characteristics are firmly established, research and treatment of depression will continue to hobble along, swayed now by one and then by another enthusiasm; indeed, this book shows that this is exactly what is happening. The two British contributors, Bebbington and Wing, have provided a good chapter on epidemiology in which they acknowledge, partly due to this failure to identify homogeneous states, that "the epidemiology of depression has hardly begun".

I would recommend the book as a convenient source of up-to-date references, generally well written and very readable. It would be most useful in those clinical psychology departments which organise training courses, but all clinicians will find one or more of the chapters to be helpful.

PHILIP SNAITH, *Senior Lecturer in Psychiatry, University of Leeds*

Ethical Issues in Epidemiologic Research (Series in Psychosocial Epidemiology, Vol. 7). Edited by LAURENCE TANCREDI. New Jersey: Rutgers University Press. 1986. Pp 203. $15.00 (pb).

If you would like to ponder on some contemporary questions about psychiatry and research, this book could be a place to start. If, on the other hand, you already know a fair amount about ethics, epidemiology or sociology you should probably steer clear of it. In eight chapters, two of which have been published before, Tancredi has brought together authors from medical and legal backgrounds but without a unifying intellectual perspective. Tancredi himself starts with a thoroughly positivist view of epidemiological research designs, but later acknowledges the contribution, at least in forensic psychiatry, of ideas from the Frankfurt School philosophers. Other chapters include discussions on access to public records for longitudinal studies, confidentiality in clinical settings, and the patient's rights to refuse treatment – all issues current in Britain. Natalie Abrams, a lawyer, uses the example of research into the genetic basis of schizophrenia to raise the ethical question of such research: would or should our society take action as a result of the information gained? But a rambling discussion of the use of diagnoses in psychiatry by Walter Reich, once again presenting Soviet psychiatry as an Evil Empire and conveniently ignoring wider questions of how all States maintain social control, points to the failing of this book: it lacks critical sociological thought.

MARK MCCARTHY, *Senior Lecturer, Department of Community Medicine, University College, London*

Neuropsychological Assessment of Neuropsychiatric Disorders. Edited by IGOR GRANT and KENNETH M. ADAMS. Oxford: Oxford University Press. 1986. Pp 536. £40.00.

This is a major book which should find a permanent place in any neuropsychiatric reference library. It brings together a series of chapters on the neuropsychological assessment of different neuropsychiatric disorders. The references alone make its contribution valuable. Unfortunately, not enough of the authors are able to go beyond a detailed description of the literature to analyse the current conceptual position of their subject, and fewer still to use this analysis to carry understanding of the subject forward. One of the exceptions is Eric Caine, whose chapter on the neuropsychology of depression is the most forward-looking account of this subject currently available. The whole book is interesting historically in that different chapters represent both the traditional approach to psychology and psychiatry and the more recent neurological approach to these two disciplines. For example, Ralph Reitan on his neuropsychological test battery and Albert Carlin on the neuropsychological consequences of drug abuse still adhere to the nineteenth century model, equating mental with cortical function and localising psychological functions in topographical cortical areas. Pat McKenna and Elizabeth Warrington, in contrast, represent a more modern analytic approach to psychological assessment, and the Queen Square Battery, based on solid clinical research, deserves to become the standard adjunct to the WAIS for general neuropsychological assessment. It is only a pity that their assessment of impairment in psychiatric disorder is limited to describing it as 'functional', although they recognise that increasing knowledge of neuropsychological function increases the chances of being able to provide a cerebral basis for otherwise apparently bizarre symptoms. The attempt to distinguish between 'functional' and 'brain related' dysfunction by others such as Milterg, Hebben, and Kaplan on the Boston Process Approach to neuropsychological assessment and Larry Squire on the assessment of memory dysfunction is unworthy of a neuropsychiatric text. Allan Yozawitz, in his account of applied neuropsychology in a psychiatric centre, points the way forward in this respect. In the preface the editors place psychiatry firmly in the medical fold with neuropsychiatry as one of the neurosciences. They are to be congratulated in having produced a book worthy of this aspiration.

DANIEL ROGERS, *Consultant Neuropsychiatrist, Burden Neurological Hospital, Bristol*

A Handbook of Communication Skills. Edited by OWEN HARGIE. Beckenham: Croom Helm. 1986. Pp 480. £35.00 (hb), £14.95 (pb).

This is an important book for those who engage in professional encounters which demand a degree of skilled communication: it will be particularly enjoyed by those who recognise the need to improve social skills during processes of communication in order to achieve higher levels of verbal and non-verbal competence in their daily work.

There are 19 chapters under the four main headings of 'Background', 'Core communication skills', 'Group skills', and 'Dimensions of communication'. Topics covered range from communication as skilled behaviour to handling strong emotions, from questioning to case conference presentation. As a member of a professional group who spends much time communicating with patients, students, and colleagues I found this book very interesting. Most of the contributions are a pleasure to read, and offer useful summaries of the skills we need to be aware of when communicating with others. Some of the chapters also offer insights into areas that contain depths we may not always appreciate when we participate in the routine of our professional encounters. The book offers some critical analysis of social interaction, which many of us have recognised as important but have up until now perhaps treated only with anecdotal criticism.

As with most multi-author books there are chapters which fail to rise to the levels set by other contributors; these are usually recognisable by their uncomfortable written style. Perhaps writers who are intent on developing debate about social skills in verbal communication should ensure first of all that their written skills match their verbal aspirations! The chapter on questioning, for example, required great efforts on my part before meanings became clear. Occasionally the thinking of some writers appears to be woolly or only half-formulated. In the chapter on self-disclosure, for example, we are told that "Facts can be friendly. Judgements may or may not be." This seems awfully like one of those anecdotes we are used to hearing that hide more than they reveal. However, most of the chapters are of a high standard, and of these I would like to single out Chapter 2, written by Hargie & Marshall and entitled 'Interpersonal communication — a theoretical framework'. This chapter ranges over a wide field which the reader is able to follow effortlessly: there's much to consider, reflect upon, and take note! Possibly the best chapter was George Brown's 'Explaining'. Brown provides several informative examples, and supplies references to texts written specifically for different professions; the perceptive reader should pick up plenty of ideas for possible research topics. Another chapter which workers in health or education are likely to find helpful is that on 'Chairmanship'. It follows a main strand running through this book, which is to develop awareness of ways we communicate in order that such awareness might lead to changes for the better. It is this last pursuit which makes the book such an impressive and important one for anyone working in the health service.

B. A. WILSON, *Principal Clinical Psychologist, Charing Cross Hospital, London*

How to Stop Taking Tranquillisers. By PETER TYRER. London: Sheldon Press. 1986. Pp 96. £2.50.

This is Tyrer's third contribution to the Sheldon Press *Overcoming common problems* series. It is not the first self-help guide to tranquilliser dependence and withdrawal, but will be a useful addition to the literature available to the general public.

The first chapter, 'Tranquilliser dependence – the facts', describes what tranquillisers are and defines the concept of drug dependence. It concludes by assessing the frequency of tranquilliser dependence, putting it into perspective without raising the anxiety level of the readership. Chapter 2 provides reasonably comprehensive tables of commonly prescribed psychotropic medication, along with associated dependence risks. Through the use of seven convincing case histories the author describes possible responses to chronic tranquilliser (or hypnotic) usage. Chapter 3 is aimed at enabling readers to decide which of Tyrer's two approaches to withdrawal (rapid or slow) they should follow. They are able to give themselves scores on type, dosage, and length of usage of drugs, previous withdrawal symptoms, life problems, and personality in order to aid the decision. The following two chapters outline the two withdrawal programmes, and are on the whole clear and easy to follow, bringing in self-monitoring of symptoms as well as straight advice on dose reduction. Chapter 6 has a cognitive–behavioural flavour and is concerned with adjuncts to the withdrawal programme; it includes explanations of the body's response to stress and ways of dealing with anxiety and related symptoms, an essential component of the approach. It also mentions self-help groups, the possibility that depression may follow the withdrawal, and discussion of the withdrawal symptoms themselves. The final brief chapter discusses the possibility that the programmes may not be a success and emphasises that other addictions are far more dangerous. The appendix contains some useful addresses and a short list of references.

This is a non-sensational book with sensible advice for tranquilliser users. It is easy to read, and would be especially useful for patients seeking advice on the topic of withdrawal needing not intensive psychiatric input but rather encouragement to take responsibility for their drug intake and their symptoms.

ANNA HIGGITT, *Locum Consultant Psychiatrist, The Maudsley Hospital, London*

Handbook of Eclectic Psychotherapy. Edited by JOHN C. NORCROSS. New York: Brunner/Mazel. 1986. Pp 500. $47.50.

In some circles in the psychotherapy world, eclecticism is a dirty word; it is held to be synonymous with muddle-headedness or the last refuge for mediocrity. For others, it heralds the coming of a bright new future where rapprochement, convergence, and integration will still the clamouring of the dissenting psychotherapy tribes, who number more than 400 at the last count. In North America the Society for the Exploration of Psychotherapy Integration has been formed; several of its distinguished members have contributed to this somewhat grandiosely titled *Handbook of Eclectic Psychotherapy*. This substantial, well-referenced volume delineates the area to be explored – Norcross is to be commended for listing the chapter heading guidelines that he provided for contributers, a model of comprehensiveness and rigour – but demonstrates that we have a long way to go.

Eclecticism may mean the selective use of the most appropriate approach for a particular patient, or the integrative amalgam of what is best in various systems, or an idiosyncratic practice that takes from many sources and reflects the style of the therapist. Actually, most experienced therapists practice idiosyncratically, but the systematic eclectic looks to see how various orientations complement each other. The book itself may be seen as a series of Venn circles. In the centre there are nine chapters of the integrative-idiosyncratic variety; they include Lazarus on multi-model therapy, Beutler with a systematic approach, Garfield in iconoclastic form, and presentations on time-limited and family therapy and case work. The inward-looking attitude of many of these presentations is brought out in a critique by Dryden, and this is wrapped around by more crossed-referenced criticisms in excellent chapters on the concepts and history of eclecticism, possibilities and promises, training, relationship to outcome studies, and a lucid, astringent account by Messer of assumptions, problems, and trade-offs. I was particularly taken with Messer's analysis of the way in which different psychotherapies view the possibilities of life according to romantic, ironic, tragic, and comic visions.

While dynamic therapy, especially in its brief form, becomes more behavioural and behavioural therapy more dynamic, through its interest in cognition and its substrate, psychotherapy still lacks a comprehensive, integrated theory. Many hurdles need to be surmounted before the eclectic ideal, a direction which this reviewer generally supports, is reached. Not least is the problem of doing justice to concepts from different frameworks in a single language; at this stage, uniqueness may be revelatory. Much comparative and process research needs to be done before we will know if the future lies with selective eclecticism in which the best fit is made between patient, approach, and talent of that therapist, or, in recognition of the fact that technique only contributes 15% to the outcome variance, with an integrative summation of the best of the most. Futurologists will want to read this book; libraries will need it as the reference source of what may become a mighty river.

MARK AVELINE, *Consultant Psychotherapist, Nottingham Psychotherapy Unit*

Contemporary Perspectives on Psychotherapy with Lesbians and Gay Men. Edited by TERRY S. STEIN and CAROL J. COHEN. New York: Plenum. 1986. Pp 271. £29.50.

Stein and Cohen are practising psychodynamic psychotherapists in North America. Their starting point for this book is the belief that "homosexuality is a variation of human behaviour and is neither a sign of illness nor an underdeveloped form of sexual expression." As "homosexuality co-exists in individuals who also demonstrate psychopathology... it is essential for the psychotherapist to understand the relationship of homosexuality to identity." The papers collected here make it clear that it is also essential for the therapist to understand the implications of homophobia, not only in the outside world but also in his or her own practice.

The book includes papers on historical and theoretical considerations, but most of the papers use extensive clinical material to illustrate the issues that arise in therapy with lesbians and gay men. There are particularly interesting papers on the dynamics of merger in lesbian relationships; psychotherapy and AIDS; individual, couple, and group psychotherapy with gay men; and psychotherapy with lesbian mothers. Among the many important questions considered are the relevance of the sexual orientation of the therapist, and the effect of self-revelation by the therapist, on transference and counter-transference in the client-therapist relationship.

In spite of the rapidly changing situation with regard to HIV infection, the paper on psychotherapy and AIDS condenses into a short space most of the important issues to consider when dealing with gay men who have the disease. The impact of the AIDS epidemic on gay relationships is also considered in a paper on psychotherapy with gay couples. Any future edition would need to consider the impact of the availability of screening for HIV antibodies on therapy with gay men.

With few exceptions, the authors are clear about the issues that are particular to lesbian and gay relationships, although occasionally the distinction between these and issues common to all relationships are left blurred.

This book may be dismissed as irrelevant or unimportant by those who might benefit most from reading it, but it is an intelligent, sensitive, and stimulating book which should be essential reading for any therapist working with lesbian or gay clients.

JUDY BURY, *General Practitioner and Psychosexual Counsellor, Edinburgh*

Psychiatric Disorders: Neurotransmitters and Neuropeptides (Progress in Brain Research Vol. 65). Edited by J. M. VAN REE and S. MATTHYSSE. Amsterdam: Elsevier Biomedical Press. Pp 275. $83.25, Dfk225.00.

This volume continues the high standard of the *Progress in Brain Research* series. The individual chapters are for the most part well written and extensively referenced. Most of them are detailed examinations of neurochemical hypotheses, rather than general reviews, and this is to be welcomed. The topics examined are wide-ranging – from neuropeptide localisation in the CNS to nutrition and its role in psychosis. Most of the chapters start with a detailed description of an aspect of basic neuroscience and follow with a discussion of putative clinical applications, and in many instances a stimulating and rewarding account results.

However, the volume suffers from the usual symptoms of a multi-authored book in that coverage of many topics (for example Alzheimer's disease) is patchy and highly selective. The chapters are written by well-known proponents of various biological hypotheses of psychotic illness, but there is no exchange of views or sign of critical editing. Thus the dopaminergic, noradrenergic, and peptidergic hypotheses of schizophrenia are outlined, but run in parallel with no point of contact.

This volume can be highly recommended for those with a specific interest in a research topic related to the application of basic neuroscience to psychiatry; if there is a chapter in this book relating to their own research interest they should obtain a copy of that chapter, because it is guaranteed to be detailed and an excellent source of ideas and references. However, the volume should carry a health warning for both trainees in psychiatry and in neuroscience who wish to have a concensus or critical view of the current status of biological psychiatry.

I. N. FERRIER, *MRC Clinical Scientist and Honorary Consultant Psychiatrist, MRC Neuroendocrinology Unit, Newcastle*

Psychotherapy with Adolescent Girls (2nd edition). By DORIS LAMB. New York: Plenum. 1986. Pp 265. $29.50.

This is a practical guide to a form of psychotherapy in which the emphasis is on helping the adolescent girl to complete her developmental tasks rather than on the achievement of insight: attempts at the latter can impede progress more often than they assist. At a time when conjoint family therapy has become the fashion, this text illustrates the place for individual therapy, particularly when done in a family context. The chapter on advising parents is especially helpful. As the title indicates, the book is about psychotherapy with girls; it does not explain how this differs from that with boys, and most of the material seems to apply equally to both sexes. That many of the references were specific to boys strengthened this impression of an artificial distinction.

The author makes her points using a large number of vignettes as a basis. The style is that of a supervision session, and this resemblance is heightened by the conversational quality of the text. Although pleasantly free of jargon and easily digested, there is a rhetorical repetitiveness and gossipy informality which suggests that this is a transcription of a series of monologues. The same points are made repeatedly. Although this may be excusable in America where the cost of the book is slight, its more substantial cost here makes this lax presentation a major flaw. The work needs to be edited radically, with the obvious stated more tersely and points made less frequently. With the removal of irrelevant detail, a review of the grammar, and careful proof-reading the reader would be free to enjoy the content of this book without the distraction of the form in which it has been thrown at him.

Overall this is a very useful book for anyone starting to learn the skills necessary for the intimacy of adolescent psychotherapy. Although it is suggested by the introduction, I would not recommend this to parents. It does not have the breadth to leave a balanced impression of adolescence, particularly with parents whose perspective has been distorted by their own difficulties. This book does provide a good concrete framework for therapy and indicates the commoner pitfalls. As such I recommend it as a book which most adolescent services will find of use to their staff whatever the discipline.

T. P. BERNEY, *Consultant Psychiatrist, Prudhoe Hospital, Northumberland*

Clinical Gerontology: A Guide to Assessment and Intervention. Edited by T. L. BRINK. New York: The Haworth Press. 1986. Pp 517. $49.95.

This book is divided into five sections. Section I, 'The assessment of the geriatric patient', begins with a chapter about the reason for the low utilisation of mental health services by the elderly, questioning traditional, 'ageist', and self-fulfilling assumptions about the type of care older patients need. There are chapters on assessment of spatial competence, neuropsychological test batteries, and the use of projective techniques. Section II, 'Depression scales for use in later life', contains an excellent chapter on clinical psychosocial assessment of depression in the elderly. Section III is titled 'Therapy in later life'. The first article reviews psychodynamic therapy with the aged, a neglected subject. A chapter on cognitive therapy has vivid case illustrations, with an encouraging description of an 83-year-old with forgetfulness, hearing, and visual problems who nevertheless benefited from cognitive therapy for depression. The article on group psychotherapy with cognitively impaired older adults is welcome. Section IV, 'Family therapy', includes a chapter on the techniques and contexts of multigenerational therapy with emphasis on practical aspects of therapy with extended families. Section V, 'Related topics', is a miscellany of articles ending with a chapter discussing ethical issues in dementia care. Care examples illustrate the difficult decisions that can face those involved in the care of cognitively impaired individuals.

The editor's introduction to each chapter and the author's conclusion at the end provide a good summary. This would be a good library book, but is probably not for personal shelves.

JANE GARNER, *Consultant Psychiatrist, Chase Farm Hospital, Enfield*

Police Selection and Training: The Role of Psychology (NATO Advanced Science Institutes Series. Series D: Behavioral and Social Science). Edited by JOHN C. YUILLE. Dordrecht, The Netherlands: Martinus Nijhoff. 1986. Pp 379. Dfl 200.00, $97.00, £63.00.

Until recently there were few texts on police psychology and none evaluating the role of psychology in the selection and training of police officers. This book, which documents the proceedings of a conference attended by 63 police officers and psychologists from eleven nations, aims to remedy this deficiency. Its special interest lies in the recognition that despite local and national differences, police psychologists share a wide variety of common concerns, and indeed have an important role to play – not least in the areas of stress management, therapeutic intervention, selection procedures, and aspects of training such as communication skills, de-escalation techniques, community relations, and interviewing techniques.

Several chapters report the findings of current research projects. While the majority of the contributions focus on selection and training, the book traverses a far wider field, providing a broad overview of the complexities of contemporary policing. A number of initiatives recorded were introduced partly as a response to criticisms that the police were becoming distanced from the communities they served and partly as a result of an increased awareness of the significance of the service role of the police.

Although the papers are of variable texture and depth and the index is somewhat rudimentary, in view of the burgeoning interest in exploring ways of enhancing the quality of interactions between the police and the public this text is a welcome addition to all those concerned with police training and selection, as well as to academics and researchers in related disciplines.

DIANNA M. YACH, *Lecturer in Law, Queen Mary College, London*

Family Care of Schizophrenia. By IAN R. H. FALLOON, JEFFREY L. BOYD and CHRISTINE W. MCGILL. New York: The Guilford Press. 1984. Pp 451. £28.50.

The title of this book reflects the positive attitude of the authors to the potential role of families in the treatment of schizophrenia. They review the literature on the aetiology and management of schizophrenia, noting how the family has been implicated and often berated, and conclude that negative attitudes are unwarranted. Instead, a model is adopted of schizophrenia as a chronic illness that increases stress in the family; the other family members are seen as potentially able to provide the best support for the patient.

Therapy with the family has as its cornerstones education about schizophrenia, enhancement of communication skills, and development of problem-solving ability as individuals and as a family. The aim is to reduce stress levels for patients in their day to day lives, by improving the quality of family interactions and by training in skills to manage stressful life-situations.

This behavioural family therapy is in addition to an intensive rehabilitation programme that includes careful monitoring of medication, and also careers advice. Results are reported of a two-year treatment study, with a control group receiving individual instead of family therapy. It is concluded that the family therapy sessions had a major impact in areas such as compliance with treatment, lower rates of readmission, and improved quality of life for patients and other family members.

The authors note that psychotherapy as they practice it may lack charisma and be "a little tedious". Unfortunately the book seemed to be tarred with the same brush: its text of well over 400 pages has few illustrations to break up the otherwise dense prose, making for difficulty in maintaining good concentration; and repetitions in the text are of a sort more suited to training workshops and family sessions.

It is not clear for whom this book was written: at times it is simple enough for a lay readership, but at others clearly aimed at experienced professionals. The first part of the book provided an account of schizophrenia that was satisfyingly balanced and level-headed, suitable for most students and trainees, while the sections describing their methods of working with families have much of value for those working not just with schizophrenics but also most other child and adult psychiatric patients. Above all, this is a book about good clinical practice and realisation of a broad scientific understanding in a caring partnership with patients and their families.

HUGH BARNES, *Consultant Child and Adolescent Psychiatrist, Bristol Royal Hospital for Sick Children*

Proceedings of the 15th European Conference on Psychosomatic Research. Edited by HUBERT LACEY and D. A. STURGEON. London: John Libbey. 1986. Pp 372. £35.00, $62.00.

The proceedings of the 15th European Conference on Psychosomatic Research contain sections on topics such as psychotherapy, liaison psychiatry, illness behaviour, eating disorders, cardiovascular disorders, hypertension, respiratory and malignancy, psychodermatology, and sleep. There are 95 contributors with a high overall standard both from Europe and North America. Practically every conceivable problem is covered, and thus the volume provides a miniature work of reference on the subject.

It is difficult to single out contributors, but there is a particularly strong section on cardiovascular disorders and hypertension. Price and Friedman describe their work in attempting to modify Type A behaviour to reduce coronary recurrence rates. They conclude that Type A behaviour can be reduced and such reduction is associated with a diminished risk of myocardial infarction.

Hawkins catalogues the decline of psychoanalysis in liaison psychiatry, and makes an eloquent plea for its resuscitation as "the most useful and comprehensive human psychology at present."

Lipsitt describes the changing role of the general hospital as a teaching centre for psychosomatic medicine. He describes the conflict generated in physicians attempting to practice the "new medicine" – i.e. the more regulated, cost-conscious, technologically driven and pressurised form. The physician is beset with contradictions and ambivalent demands to be both caring and "cost-effective". The difficult ethical and emotional problems for the doctor have resulted in an apparently increased demand in the US for liaison psychiatrists, who find themselves sought after for advice on bioethics, instrumentation and patient care, and support for colleagues frightened by the technological imperative in medicine.

The section on eating disorders is strong, particularly with contributions from the St George's Hospital Department. Arthur Crisp's 'Some psychopathological aspects of obesity' is a useful and comprehensive contribution.

This volume is recommended for all libraries interested in the area of psychosomatic research.

R. J. DALY, *Professor of Psychiatry, University College, Cork, Ireland*

Supervision and Training: Models, Dilemmas, and Challenges. Edited by FLORENCE W. KASLOW. New York: The Haworth Press. 1986. Pp 259. $32.95.

Good supervision is essential in psychotherapy practice. However, the literature on supervision is sparse in comparison with that on theory and technique. Rather than being specifically educated into their role, supervisors generally assume the position. The arguments in favour of better preparation and improved clarity in conceptual models are partially made by the volume under review. The editor published two books on the subject in the 1970s, and has now assembled a broad range of approaches which were first published as two issues of the journal *The Clinical Supervisor* in 1986. Most of the contributors are psychologists working in America, although one chapter comes from Cardiff and Sydney and another from Tel Aviv. Part I addresses the ecological context of place, the mechanics of obtaining supervision, and common fears of therapists. Part II has two good chapters on the stages that supervisor and supervisee mature through, one on private practice stressing the legal liability that a supervisor may, unwittingly, have for the therapist's work, and five presenting a cornucopia of techniques from rotating peer supervision to *in vivo* sequential therapy. In similar vein, Part III considers family and behaviour therapy and altering institutional structures.

The content of this book falls awkwardly between two stools. Despite attempting to be panoramic, it fails to include chapters on group and marital therapy or on supervision for supervisors, and while giving most space to supervision of individual therapy, it does not provide a detailed, integrated model that will guide and support supervisors in their role. Too many alternatives are presented. Experienced supervisors wanting the stimulus of new ideas will find it interesting.

MARK AVELINE, *Consultant Psychotherapist, Mapperley Hospital, Nottingham*

Contents of
THE AMERICAN JOURNAL OF PSYCHIATRY

Volume 144, Number 5 **May 1987**

Special Articles

543 The psychodynamic formulation: its purpose, structure, and clinical application. *Samuel Perry, Arnold M. Cooper and Robert Michels*

551 Psychiatric aspects of AIDS. *Michael E. Faulstich*

Regular Articles

557 Use of ECT in the United States in 1975 and 1980. *James W. Thompson and Jack D. Blaine*

563 Relationship between Russian roulette deaths and risk-taking behavior: a controlled study. *David A. Fishbain, James R. Fletcher, Timothy E. Aldrich and Joseph H. Davis*

567 Sources of conflict in the medical marriage. *Glen O. Gabbard, Roy W. Menninger and Lolafaye Coyne*

573 Effects of amantadine and trihexyphenidyl on memory in elderly normal volunteers. *Joseph P. McEvoy, Michael McCue, Bonnie Spring, Richard C. Mohs, Philip W. Lavori and Russell M. Farr*

578 Post-traumatic stress disorder: The etiologic specificity of wartime stressors. *Naomi Breslau and Glenn C. Davis*

584 Psychiatric disorders in a community sample of adolescents. *Javad H. Kashani, Niels C. Beck, Edwin W. Hoeper, Carolyn Fallahi, Colleen M. Corcoran, Jeanne A. McAllister, Tomas K. Rosenberg and John C. Reid*

590 Twelve-month follow-up of psychotherapy for opiate dependence. *George E. Woody, A. Thomas McLellan, Lester Luborsky and Charles P. O'Brien*

597 Adrenocortical function and depressive illness in mentally retarded patients. *Stephen L. Ruedrich, Charles V. Wadle, Harriet S. Sallach, Rhoda K. Hahn and Frank J. Menolascino*

Special Section: Prospective Payment Issues

603 An analysis of DRG-based reimbursement for psychiatric admissions to general hospitals. *Marc P. Freiman, Janet B. Mitchell and Margo L. Rosenbach*

610 Bringing psychiatric patients into the medicare prospective payment system: alternatives to DRGs. *Janet B. Mitchell, Barbara Dickey, Benjamin Liptzin and Lloyd I. Sederer*

616 Differences in resource use and cost among facilities treating alcohol, drug abuse, and mental disorders: implications for design of a prospective payment system. *Thomas G. McGuire, Barbara Dickey, Gerald E. Shively and Ira Strumwasser*

Commentary

621 The future of psychiatry. *Thomas Detre*

Editorials

626 Are specialized psychiatric services worth the higher cost? *Howard H. Goldman and Steven S. Sharfstein*

628 The family history in clinical psychiatric practice. *Michael Swift*

Brief Communications

630 Family diagnoses missed on a clinical inpatient service *Neil J. Baker, Sandra L. Berry and Lawrence E. Adler*

The dexamethasone suppression test and prediction of outcome in patients receiving ECT; C. L. E. Katona *et al* 315–318
Depression, physiopathology: Changes in auditory P3 event-related potential in schizophrenia and depression; D. H. R. Blackwood *et al* 154–160
A combined study of cortisol, ACTH and dexamethasone concentrations in major depression: multiple time-pointing sampling; B. G. Charlton *et al* 791–796
Plasma levels of β-endorphin in depressed patients with and without pain; R. J. Daly *et al* 224–227
Depression, prognosis: The prognosis of primary depressive illness: its relationship to the dexamethasone suppression test; P. C. W. Bowie *et al* 787–790
Prediction of outcome in depressive illness by the Newcastle diagnosis-scale: its relationship with the unipolar/bipolar and DSM-III systems; M. W. P. Carney *et al* 43–48
Predictions of outcome in depressive illness; John M. Eagles (C) 715

The prognosis of depression in old age; Elaine Murphy (C) 268

Five risk factors for depression; A. Roy 536–541

Depression, psychology: The influence of depression on the processing of personal attributes; P. I. Clifford and D. R. Hemsley 98–103

Depression, therapy: A comparative trial of a new antidepressant, fluoxetine; S. Levine *et al* 653–655

Further studies of vanadium in depressive psychosis; G. J. Naylor *et al* 656–661

Electroconvulsive therapy and cognitive improvement in a very elderly depressed patient; Brian O'Shea *et al* (*Brief report*) 255–257

Dexamethasone: The prognosis of primary depressive illness: its relationship to the dexamethasone suppression test; P. C. W. Bowie *et al* 787–790

A combined study of cortisol, ACTH and dexamethasone concentrations in major depression: multiple time-point sampling; B. G. Charlton *et al* 791–796

The dexamethasone suppression test in depression: a World Health Organization collaborative study; Alec Coppen and Maryse Metcalfe 459–462

The dexamethasone suppression test and prediction of outcome in patients receiving ECT; C. L. E. Katona *et al* 315–318

Down's syndrome: Down's syndrome with mania; Edwin H. Cook Jr and Bennett L. Leventhal (*Brief report*) 249–250

Gilles de la Tourette's syndrome in Down's syndrome; John Corbett (C) 569

Drugs see **Anticonvulsants, Antidepressants, Anti-manic agent, Neuroleptics, Psychotropic drugs.**

See **Benzodiazepine, Caffeine, Carbamazepine, Chlorpromazine, Clomipramine, Clonidine, Dexamethasone, Ephedrine, Ethanol, Fluoxetine, Flupenthixol, Lithium, Lofepramine, Mianserin, Nifedipine, Oxygen, Paraldehyde, Phenelzine, Pimozide, Procyclidine, Sodium valproate, Sulpiride, Tiapride, Trazodone** and **Vanadium.**

DSM-III (Diagnostic and Statistical manual of Mental disorders, 3rd edn): Prediction of outcome in depressive illness by the Newcastle diagnosis scale: its relationship with the unipolar/bipolar and DSM-III systems; M. W. P. Carney *et al* 43–48

DSM-III personality disorder clusters in three populations; J. Reich and W. Douglas Thompson 471–475

Reliability of the psychosocial axes of DSM-III in an adolescent population; J. M. Rey *et al* 228–234.

Dyscrasias: Mianserin and blood dyscrasias; R. J. Ancill (C) 569–570

Dysmorphophobia: Anorexia nervosa and dysmorphophobia; George Cohen (C) 406–407; Christopher S. Thomas (C) 406

Anorexia nervosa or dysmorphophobia?; Laurence Jerome (C) 560–561

Eating disorders: Folate and vitamin B12 in eating disorders; M. T. Abou-Saleh and K. O. Chung-A-On (C) 133

Edinburgh: Suicide and parasuicide among further education students in Edinburgh; S. D. Platt 183–188

Edinburgh postnatal depression scale: Detection of postnatal depression: development of the 10-item Edinburgh postnatal depression scale; J. L. Cox *et al* 782–786

Education: Specific and non-specific effects of educational intervention with families living with a schizophrenic relative; J. V. Smith and M. J. Birchwood 645–652

Elderly: Depression in the elderly living in the community: its presentation and features; O. Ben-Arie *et al* 169–174

ECT in the elderly; S. M. Benbow (C) 877; Patrick Bracken *et al* (C) 713

Range of mental illness among the elderly in the community: prevalence in Liverpool using the GMS-AGECAT package; J. R. M. Copeland *et al* 815–823

The mental health of elderly couples. I. The effects of a cognitively impaired spouse; J. M. Eagles *et al* 299–303

II. Concordance for psychiatric morbidity in spouses; J. M. Eagles *et al* 303–308

The psychological well-being of supporters of the demented elderly; J. M. Eagles *et al* 293–298

The structure of depressive symptoms in the elderly; W. R. Good *et al* 463–470

Depression, dementia and disability in the elderly; R. A. Griffiths *et al* 482–493

Comparison of the sensitivity of three instruments for the detection of cognitive decline in elderly living at home; A. Little *et al* 808–814

Mental health and psychological well-being among the old and the very old living at home; K. Morgan *et al* 801–807

The prognosis of depression in old age; Elaine Murphy (C) 268

Electroconvulsive therapy and cognitive improvement in a very elderly depressed patient; Brian O'Shea *et al* (*Brief report*) 255–257

Hydroxylated metabolites of tricyclic antidepressant in the elderly; Robert C. Young *et al* (C) 131–132

Electroconvulsive therapy: ECT in the elderly; S. M. Benbow (C) 877; Patrick Bracken *et al* (C) 713

Mania following head injury: a report of two cases and a review of the literature; A. F. Clark and K. Davison 841–844

The dexamethasone suppression test and prediction of outcome in patients receiving ECT; C. L. E. Katon *et al* 315–318

Electroconvulsive therapy and cognitive improvement in a very elderly depressed patient; Brian O'Shea *et al* (*Brief report*) 255–257

Post-ictal syndrome after ECT; Allan Scott and Idwal Evans (C) 409–410

Electrodermal response as a monitor in electroconvulsive therapy; C. J. Simpson and C. E. Hyde (*Brief report*) 549–551

Oxygen saturation during electroconvulsive therapy; Steven R. Swindells and Karen H. Simpson (*Brief report*) 695–697

Electrodermal response: Electrodermal response as a monitor in electroconvulsive therapy; C. J. Simpson and C. E. Hyde (*Brief report*) 549–551

Electrodermal responding and chlorpromazine treatment in schizophrenia; Stavroula Yannitsi *et al* (*Brief report*) 850–853

Emergency services: Alcohol-related psychiatric emergencies: their characteristics and care at a walk-in-clinic; Eric F. Mendelson (*Brief report*) 121–124

Emotional disorders: *Cognitive therapy and the emotional disorders:* A. T. Beck (E. S. Paykel, *Books reconsidered*) 870–871

Emotions: Influence of emotional distress among supporters on the outcome of psychogeriatric day care; C. J. Gilleard 219–223

Expressed emotion in the families of the mentally handicapped: a pilot study; Drone Greedharry (*Brief report*) 400–402

The Nithsdale schizophrenia survey. VI. Relatives' expressed emotion: prevalence, patterns and clinical assessment; R. G. McCreadie and A. D. T. Robinson 640–644

England: Suicide in England and Wales, 1975–1984; G. M. G. McClure 309–314

Ephedrine: Ephedrine psychosis rediscovered; Andrew M. Whitehouse and Janice M. Duncan (*Brief report*) 258–261

Epilepsy: Epilepsy and psychosis – ask the family; David J. Clarke *et al* (*Brief report*) 702–703

Fictitious epilepsy associated with amnesia; J. R. Jones and F. R. Horrocks (*Brief report*) 257–258

Brain imaging in a case of Capgras' syndrome; Shôn W. Lewis (*Brief report*) 117–121

Post-ictal syndrome after ECT; Allan Scott and Idwal Evans (C) 409–410

Ethanol: Ethanol retards desensitisation of simple phobias in non-alcoholics; O. G. Cameron *et al* 845–849

Ethnic groups: Ethnic labels in South Africa: Beverley J. Dickman and Leslie Swartz (C) 566

Schizophrenia and ethnicity; Roland Littlewood (C) 272–273

The compulsory detention of males of different ethnic groups, with special reference to offender patients; D. McGovern and R. Cope 505–512

Ethnic differences in self-poisoning: a comparison of West Indian and White groups; J. Merrill and J. Owens 765–768

Evoked potentials, auditory: Changes in auditory P3 event-related potential in schizophrenia and depression: D. H. R. Blackwood *et al* 154–160

Factitious disorders: Fictitious epilepsy associated with amnesia; J. R. Jones and F. R. Horrocks (*Brief report*) 257–258

Factor study: Factor study of a psychiatric child rating scale based on ratings made by clinicians on child and adolescent clinic attenders; G. Thorley 49–59

Family see also **Relatives, Spouse** and **Supporters**

The burden of care: the impact of functional psychiatric illness on the patient's family; G. Fadden *et al* (*Review article*) 285–292

Expressed emotion in the families of the mentally handicapped: a pilot study; Drone Greedharry (*Brief report*) 400–402

Huntington's chorea: some psychodynamics seen in those at risk and in the responses of the helping professions; B. Martindale 319–323

Fluoxetine: A comparative trial of a new antidepressant, fluoxetine; S. Levine *et al* 653–655

Flupenthixol: Clomipramine and flupenthixol-additive antidepressants? Peter Connelly and Graham J. Naylor (C) 721–722

The Scottish first episode schizophrenia study. II. Treatment: pimozide versus flupenthixol; The Scottish Schizophrenia Research Group 334–338

Folic acid: Folate and vitamin B12 in eating disorders; M. T. Abou-Saleh and K. O. Chung-A-On (C) 133

Folie-à-deux: Delusional parasitosis: successful non-pharmacological treatment of a *folie-à-deux;* Norman D. Macaskill (*Brief report*) 261–263

Food substitutes: The role of food substitutes in a token economy system; Derek W. Scott and Rodger H. Wood (*Brief report*) 864–867

France: French lunatic asylums; Henry Rollin (*A hundred years ago*) 571

Gamma glutamyl transpeptidase: Gamma glutamyl transpeptidase and mean cell volume in alcoholics; David M. Hambridge (C) 568

'Gaslight Phenomenon': 'Imposed psychosis': a case variant of the Gaslight Phenomenon; R. Cawthra *et al* (*Brief report*) 553–556

Gastric rugal hyperplasia: Anorexia nervosa and gastric rugal hyperplasia; A. D. Cockett (*Brief report*) 697–700

General Health Questionnaire: The psychological effects of service in British Antarctica: a study using the General Health Questionnaire; J. Bell and P. H. Garthwaite 213–218

Psychiatric disorder in the community and the General Health Questionnaire; P. G. Surtees 828–835

Genes: Continuum of psychosis and the gene; Christopher R. Brand (C) 880–881; Gordon Claridge (C) 129; C. M. H. Nunn (C) 129; M. J. Owen and V. L. Nimgaonkar (C) 566–567

Genetic marker: Genetic markers in late paraphrenia: a study of HLA antigens; Mohsen Naguib *et al* (*Brief report*) 124–127

Gilles de la Tourette's syndrome: Gilles de la Tourette's syndrome in Down's syndrome; John Corbett (C) 569

Tics and heredity: a study of the relatives of child tiqueurs; D. M. Zuasmer and M. E. Dewey 628–634

Gluten: Gluten sensitivity in schizophrenia; F. A. Jenner and D. N. Vlissides (C) 559. Man Mohan Singh and Stanley R. Kay (C) 130–131

GMS-AGECAT (Geriatric Mental State). Range of mental illness among the elderly in the community prevalence in Liverpool using the GMS-AGECAT package; J. R. M. Copeland *et al* 815–823

Head injury: Mania following head injury; Patrick Bracken (*Brief report*) 690–692

Mania following head injury: a report of two cases and a review of the literature; A. F. Clark and K. Davison 841–844
Health personnel: Huntington's chorea: some psychodynamics seen in those at risk and in the responses of the helping professions; B. Martindale 319–323
HIV (human immunodeficiency virus); HIV and the psychiatric hospital; D. R. Davies (C) 881–882
Hormones see also **ACTH, Cortisol,** and **L. H.**
Characteristic plasma hormone changes in Alzheimer's disease; J. E. Christie *et al* 674–681
Hospitalisation: Chronic schizophrenia and long-term hospitalisation; J. K. Wing (C) 129–130
Hospitals, general: The impact of a liaison psychiatry service on patterns of referral in a general hospital; A. Brown and A. F. Cooper 83–87
Psychiatric disorder in the general hospital; Adityan Jee *et al* (C) 131
The impact of a liaison psychiatric service on patterns of referral in a general hospital; David Jones (C) 715–716
Hospitals, mental handicap: Anticonvulsant medication in a mental handicap hospital: 1972–1982; L. C. Sheppard *et al* 513–517
Hospitals, psychiatric: The persistence of prescribing habits: a survey and follow-up of prescribing to chronic hospital in-patients; A. F. Clark and N. L. Holden 88–91
HIV and the psychiatric hospital; D. R. Davies (C) 881–882
First admissions of native-born and immigrant patients to psychiatric hospitals; Gyles Glover (C) 882
No fixed abode: a comparison of men and woman admitted to an East London psychiatric hospital; J. L. Herzberg 621–627
Improving the quality of care on psychiatric hospital rehabilitation wards: a controlled evaluation; A. Lavender 476–481
A comparative hospital survey of psychotropic drug prescribing; M. Muijin and T. Silverstone 501–504
An epidemic of suicide attempts by burning in a psychiatric hospital; Z. Zemishlany *et al* (*Brief report*) 704–706
Hundred Years ago, A: Causes of idiocy; Henry Rollin 725
Convulsionist mania; Henry Rollin 883
French lunatic asylums; Henry Rollin 571
Lunacy and pauperism; Henry Rollin 413
Notes and news – "After-care Ladies Working Society"; Henry Rollin 273
Huntington's chorea: Huntington's chorea: some psychodynamics seen in those at risk and in the responses of the helping professions; B. Martindale 319–323
Huntington's chorea; Howard Roberts (C) 874
Husbands: Influence of husbands on the outcome of their agoraphobic wives' therapy; K. Oatley and D. Hodgson 380–386
Hyperventilation: Panic attacks and hyperventilation; Christopher Bass (C) 563–564; M. G. Gelder (C) 564
Hypervitaminosis D: Case report: severe depressive illness in the context of hypervitaminosis D; Kenneth M. G. Keddie (*Brief report*) 394–396
Hyponatraemia: Hyponatraemia and lofepramine; Derek O'Sullivan and Femi Oyebode (C) 720–721
Hyponatraemia masquerading as malignant neuroleptic syndrome; W. P. Tormey *et al* (C) 412
Hysteria: Psychological complications following a misdiagnosis of deafness; L. A. Hewson and P. Morris (C) 570–571
Hysterical personality disorder. The process of diagnosis in clinical and experimental settings; D. J. Thompson and D. Goldberg 241–245

Idiocy: Causes of idiocy; Henry Rollin (*A hundred years ago*) 725
Immigrants: First admissions of native-born and immigrant patients to psychiatric hospitals; Gyles Glover (C) 882
Intestinal permeability: Abnormal intestinal permeability: an aetiological factor in chronic psychiatric disorders? N. C. Wood *et al* (*Brief report*) 853–856
Israel: Koro in an Israeli man; H. V. Kumar (C) 133

Khat: Khat-induced paranoid psychosis; Stephen Critchlow and Ruth Seifert (*Brief report*) 247–249; Manohar Dhadphale and H. N. K. Arap Mengech (C) 876; S. P. Gough and I. B. Cookson (C) 875–876
Khat psychosis; Paul McLaren (C) 712–713
Koro: Koro and schizophrenia in Singapore; G. S. Devan and Ong Seng Hong (*Brief report*) 106–107
Koro in an Israeli man; H. V. Kumar (C) 133
Koro-like states; Tapati Mukherjee (C) 881

Laterality: Chronic schizophrenic disorder. I. Psychophysiological responses, laterality and social stress; C. White *et al* 365–373
Lectures: Assessment of suicide risk; K. Hawton (based on Maudsley Bequest series February 1985) 145–153
Behavioural psychotherapy in general psychiatry. Helping patients to help themselves. I. Marks (*Maudsley Bequest Lecture 1986*) 593–597
Is there really a split in schizophrenia? The genetic evidence; P. McGuffin *et al* (based on lecture July 1985) 581–592
Temperament, personality and personality disorder; M. Rutter (based on lecture October 1986) 443–458
Changes in the incidence of schizophrenia? Eric Strömgren (Maudsley lecture 1985) 1–7
LH (luteinizing hormone): Increased plasma LH in manic-depressive illness: evidence of a state-independent abnormality; L. J. Whalley *et al* 682–684
Liaison psychiatry: The impact of a liaison psychiatry service on patterns of referral in a general hospital; A Brown and A. F. Cooper 83–87; David Jones (C) 715–716
Life events: Life events and mania: a special relationship? A. Ambelas 235–240
Life events, vulnerability and onset of depression: some refinements; G. W. Brown *et al* 30–42
Mania following bereavement; Stephen Rosenman (C) 268
Life events and mania; Paul Sclare and Francis Creed (C) 875

Lithium: Lithium in the treatment of aggression in mentally handicapped patients: a double-blind trial. M. Craft *et al* 685–689
Admission rates and lithium; M. B. Eastwood and A. M. Peter (C) 878; Paul Grof (C) 264–265; R. E. Kendell and W. E. Dickson (C) 265
Is there a lithium withdrawal syndrome? S. P. Hawkins and C. L. Shepherd (C) 273; A. J. Mander (C) 714
Neuroleptic malignant syndrome or lithium neurotoxicity; Adityan Jee (C) 568–569
A long-term retrospective follow-up study of patients treated with lithium carbonate; C. Page *et al* 175–179
The effect of carbamazepine and lithium on remission from affective illness; S. E. Watkins *et al* 180–182
Liverpool: Range of mental illness among the elderly in the community: prevalence in Liverpool using the GMS-AGECAT package: J. R. M. Copeland *et al* 815–823
Lofepramine: Hyponatraemia and lofepramine; Derek O'Sullivan and Ferni Oyebode (C) 720–721
London: No fixed abode: a comparison of men and women admitted to an East London psychiatric hospital; J. H. Herzberg 621–627
Five-year outcome and prognosis in schizophrenia: a report from the London Field Research Centre of the International Pilot Study of Schizophrenia; R. Prudo and H. Munroe Blum 345–354
Long-stay patients: Long-stay patients in a psychiatric day hospital; G. McGrath and D. Tantam 836–840
Louvain: Influence of the day of the week and the weather on people using a telephone support system; E. Hribersek *et al* 189–192
Lunacy: Lunacy and pauperism; Henry Rollin (*A hundred years ago*) 413

Mania: Life events and mania: a special relationship? A. Ambelas 235–240; Paul Sclare and Francis Creed (C) 875
Mania following head injury; Patrick Bracken (*Brief report*) 690–692
Mania following head injury: a report of the two cases and a review of the literature; A. F. Clark and K. Davison 841–884
Down's syndrome with mania; Edwin H. Cook Jr and Bennett L. Leventhal (*Brief report*) 249–250
Convulsionist mania; Henry Rollin (*A hundred years ago*) 883
Mania following bereavement; Stephen Rosenman (C) 268
Manic-depressive disorders: Manic depressive psychosis with mental retardation and flexion deformities; a clinical and cytogenetic study; A. H. Reid *et al* 92–97
Increased plasma LH in manic-depressive illness: evidence of a state-independent abnormality; L. J. Whalley *et al* 682–684
Masochism: Behavioural treatment of life-threatening masochistic asphyxiation: a case study; P. Haydn-Smith *et al* 518–519
Measles: Schizophreniform episode following measles infection; M. Stoler *et al* (*Brief report*) 861–862
Memory: Clinical tests of memory as sensitive and specific signs of dementia; M. G. Binks (C) 719–720
The Memory Clinic: a new approach to the detection of dementia; T. J. M. Van der Cammen *et al* 359–364
Mental handicap: A standardised assessment of personality disorder in mental handicap; Brian R. Ballinger and Andrew H. Reid (*Brief report*) 108–109
Lithium in the treatment of aggression in mentally handicapped patients: a double-blind trial. M. Craft *et al* 685–689
A case of mosaicism with fragile-X and XXY components; Saumitra Deb *et al* (*Brief report*) 700–702
49 Chromosome anomaly; S. Ganeshananthan and I. Gonsalves (C) 409
Expressed emotion in the families of the mentally handicapped: a pilot study; Drone Greedharry (*Brief report*) 400–402
Cotard's syndrome in a mentally handicapped man; Anthony Kearns (*Brief report*) 112–114
Manic depressive psychosis with mental retardation and flexion deformities; A. H. Reid *et al* 92–97
Psychiatric morbidity and the mentally handicapped; T. Hari Singh (C) 878–879; Peter Sturmey (C) 270
Mental health: The mental health of elderly couples. I. The effects of a cognitively impaired spouse; J. M. Eagles *et al* 299–303
The mental health of elderly couples II. Concordance for psychiatric morbidity in spouses; J. M. Eagles *et al* 303–308
Mental health and psychological well-being among the old and the very old living at home; K. Morgan *et al* 801–807
Mental processes: The influence of depression on the processing of personal attributes; P. I. Clifford and D. R. Hemsley 98–103
Mianserin: Mianserin and blood dyscrasias; R. J. Ancill (C) 569–570
Montgomery-Åsberg Depression Rating Scale: Depression assessment in Brazil: the first application of the Montgomery-Åsberg Depression Rating Scale; L. Dratcu *et al* 797–800
Mood alterations: Relationship of mood alterations to bingeing behaviour in bulimia; Sally Browning (C) 273
Morbidity: The mental health of elderly couples. II. Concordance for psychiatric morbidity in spouses; J. M. Eagles *et al* 303–308
Psychiatric morbidity and the mentally handicapped; Peter Sturmey (C) 270
Multi-authorship: Multi-author papers; Sydney Brandon and David Clayton (C) 408
Munchausen's syndrome: Munchausen's syndrome and drug dependence; Brian O'Shea (C) 407

Neuroleptic malignant syndrome: Neuroleptic malignant syndrome and compulsive water drinking; D. N. Anderson (C) 723–724
Neuroleptic malignant syndrome superimposed on tardive dyskinesia; John J. Haggerty Jr *et al* (*Brief report*) 104–105

Neuroleptic malignant syndrome (NMS) and tardive dyskinesia; Adityan Jee (C) 880

Neuroleptic malignant syndrome or lithium neurotoxicity; Adityan Jee (C) 568–569

The neuroleptic malignant syndrome, so-called: a survey of the world literature; A. M. P. Kellam (*Review article*) 752–759

Hyponatraemia masquerading as malignant neuroleptic syndrome; W. P. Tormey *et al* (C) 412

Neuroleptics: Prolonged oculogyric crisis on addition of nifedipine to neuroleptic medication regime; I. Singh (*Brief report*) 127–128

Neuropeptides: CSF neuropeptides in euthymic bipolar patients and controls; W. H. Berrettini *et al* 208–212

Neuropsychiatry: Neuropsychiatry; D. Rogers (*Annotation*) 425–427

Neurosyphilis: Water intoxication in congenital neurosyphilis; Bisa Haeger (C) 722–723

Newcastle diagnosis scale: Prediction of outcome in depressive illness by the Newcastle diagnosis scale: its relationship with the unipolar/bipolar and DSM-III systems; M. W. P. Carney *et al* 43–48

An American validation study of the Newcastle diagnostic scale. II. Relationship with clinical, demographic, familial and psychosocial features; M. Zimmerman *et al* 526–532

Nifedipine: Prolonged oculogyric crisis on addition of nifedipine to neuroleptic medication regime; I. Singh (*Brief report*) 127–128

Nigeria: A study of Schneider's first-rank symptoms of schizophrenia in Nigerian patients; Oye Gureje and E. A. Bamgboye (*Brief report*) 867–869

Nithsdale: The Nithsdale schizophrenia survey: VI. Relatives' expressed emotion: prevalence, patterns, and clinical assessment; R. G. McCreadie and A. D. T. Robinson 640–644

No fixed abode: No fixed abode: a comparison of men and women admitted to an East London psychiatric hospital; J. L. Herzberg 621–627

Nuclear magnetic resonance: Nuclear magnetic resonance brain imaging in chronic schizophrenia; J. A. O. Besson *et al* 161–163

Brain imaging in a case of Capgras' syndrome; Shôn W. Lewis (*Brief report*) 117–121

Obsessive-compulsive disorder: Neurological factors in obsessive-compulsive disorder; N. S. Harvey (C) 567–568

Obsessive-compulsive disorder – a complication of benzodiazepine withdrawal; Helen P. Matthews and Lynne M. Drummond (C) 272

Oculogyric crisis: Prolonged oculogyric crisis on addition of nifedipine to neuroleptic medication regime; I. Singh (*Brief report*) 127–128

Offenders: The compulsory detention of males of different ethnic groups, with special reference to offender patients; D. McGovern and R. Cope 505–512

Female sex offenders; Art A. O'Connor 615–620

Ontario: Autocastration in Ontario Federal Penitentiary inmates; G. Neil Conacher and George H. Westwood (C) 565–566

Out-patients: Deliberate self-harm and predictors of out-patient attendance; G. O'Brien *et al* (*Brief report*) 246–247

Oxygen: Oxygen saturation during electroconvulsive therapy; Steven R. Swindells and Karen H. Simpson (*Brief report*) 695–697

Pain: Plasma levels of β-endorphin in depressed patients with and without pain; R. J. Daly *et al* 224–227

Panic disorders: Panic attacks: new approaches to an old problem; Sandy Bourne (C) 265–266

Panic attacks and hyperventilation; Christopher Bass (C) 563–564; M. G. Gelder (C) 564

Caffeine and panic attacks; M. W. D. Rowlands (C) 720

Consensus statement: panic disorder; Isaac Marks and Andrew Matthews (C) 872

Paraldehyde: Use of paraldehyde; T. J. Holden and W. G. Cavanagh (C) 564–565

Paraphrenia: Late paraphrenia or the paraphrenias? A descriptive study with a 10-year follow-up; N. L. Holden 635–639

Genetic markers in late paraphrenia: a study of HLA antigens; Mohsen Naguib *et al* (*Brief report*) 124–127

Parasitosis: Delusional parasitosis; N. J. Hunt and V. R. Blacker (C) 713–714

Delusional parasitosis: successful non-pharmacological treatment of a folie-à-deux; Norman D. Macaskill (*Brief report*) 261–263

Parietal lobe: Senile dementia and parietal lobe dysfunction; C. J. Gilleard *et al* (*Brief report*) 114–117

Senile dementia and parietal lobe dysfunction; Raymond Levy (C) 558–559

Parkinson's disease: Dementia in Parkinson's disease; D. Peter Birkett (C) 560

Personality disorders: A standardised assessment of personality disorder in mental handicap; Brian R. Ballinger and Andrew H. Reid (*Brief report*) 108–109

Temperament, personality and personality disorder; P. J. Graham and J. E. Stevenson (C) 872–873. Michael Rutter (C) 873–874

DSM-III personality disorder clusters in three populations; J. Reich and W. Douglas Thompson 471–475

Temperament, personality and personality disorder; M. Rutter (*Lecture*) 443–458

Hysterical personality disorder: the process of diagnosis in clinical and experimental settings; D. J. Thompson and D. Goldberg 241–245

Phenelzine: A pilot study of phenelzine in the treatment of post-traumatic stress disorder; Jonathan Davidson *et al* (*Brief report*) 252–255

Phobic disorders: Ethanol retards desensitisation of simple phobias in non-alcoholics; O. G. Cameron *et al* 845–849

AIDS-phobia; K. S. Jacob *et al* (C) 412–413

Depression in school phobia; Israel Kolvin *et al* (C) 268–270

Delineating social phobia; Michael R. Liebowitz (C) 718–719

Influence of husbands on the outcome of their agoraphobic wives' therapy; K. Oatley and D. Hodgson 380–386

Physical examination: An evaluation of the performing and recording of physical examinations by psychiatric trainees; J. C. Rigby and A. G. Oswald 533–535

Physicians: Suicide in physicians; Isaac Sakinofsky (C) 267–268

Pimozide: The Scottish first episode schizophrenia study II. Treatment: primozide versus flupenthixol; The Scottish Schizophrenia Research Group 334–338

Placebo: Psychotherapy and placebo; H. J. Eysenck (C) 266–267

Points of view: Depression in the general population: comparability of survey results; T. K. J. Craig *et al* 707–708

The concepts of mild depression; R. P. Snaith 387–393

Pregnancy: A schoolgirl with onset of anorexia nervosa during a concealed pregnancy; J. E. Foster and M. E. Jenkins (*Brief report*) 551–553

Bulimia nervosa: the impact of pregnancy on mother and baby. J. Hubert Lacey and G. Smith 777–781

Premorbid Adjustment Scale: Premorbid Adjustment Scale as a prognostic predictor for schizophrenia. E. Alvarez *et al* (C) 411

Prescribing habits: The persistence of prescribing habits: a survey and follow-up of prescribing to chronic hospital in-patients; A. F. Clark and N. L. Holden 88–91

Present State Examination Change Rating Scale: K. H. Tress *et al* 201–207

Primary care: Depressive disorder in primary care; C. V. R. Blacker and A. W. Clare (*Review article*) 737–751

Procyclidine: Procyclidine abuse; G. P. Pullen (C) 567

Psychiatric child rating scale: Factor study of a psychiatric child rating scale based on ratings made by clinicians on child and adolescent clinic attenders; G. Thorley 49–59

Psychiatric disorders see also **Morbidity, Psychoses, Vulnerability**

Range of mental illness among the elderly in the community: prevalence in Liverpool using the GMS-AGECAT package; J. R. M. Copeland *et al* 815–823

The burden of care: the impact of functional psychiatric illness on the patient's family; G. Fadden *et al* (*Review article*) 285–292

Psychiatric disorder in the general hospital; Adityan Jee *et al* (C) 131

Communicability and thought disorder in schizophrenics and other diagnostic groups: a follow-up study; A. Barnett Ragin and T. F. Oltmanns 494–500

Psychological disorders in obstetrics and gynaecology; D. Ridley-Siegert (C) 717–718

Psychiatric disorder in the community and the General Health Questionnaire; P. G. Surtees 828–835

Abnormal intestinal permeability: an aetiological factor in chronic psychiatric disorders; N. C. Wood *et al* (*Brief report*) 853–856

Psychiatric status rating scales see **BITE, Edinburgh postnatal depression scale, General Health Questionnaire, GMS-AGECAT, Montgomery-Åsberg Depression Rating Scale, Newcastle diagnois scale, Premorbid adjustment scale, Present State Examination Change Rating Scale** and **Psychiatric child rating scale**

Psychophysiological disorders: Chronic schizophrenic disorder. I. Psychophysiological responses, laterality and social stress; C. White *et al* 365–373

Chronic schizophrenic disorder. II. Reaction time, social performance and arousal; C. White *et al* 374–379

Psychoses: Continuum of psychosis and the gene; Christopher R. Brand (C) 880–881; Gordon Claridge (C) 129; C. M. H. Nunn (C) 129; M. J. Owen and V. L. Nimgaonkar (C) 566–567

'Imposed psychosis': a case variant of the Gaslight Phenomenon; R. Cawthra *et al* (*Brief report*) 553–556

Epilepsy and psychosis – ask the family; David J. Clarke *et al* (*Brief report*) 702–703

Khat-induced paranoid psychosis; Stephen Critchlow and Ruth Seifert (*Brief report*) 247–249; Manohar Dhadphale and H. N. K. Arap Mengech (C) 876. S. P. Gough and I. B. Cookson (C) 875–876

Khat psychosis; Paul McLaren (C) 712–713

Epidemiology of puerpheral psychoses; R. E. Kendell *et al* 662–673

Compensation psychosis; A. C. White *et al* (*Brief report*) 692–694

Ephedrine psychosis rediscovered; Andrew M. Whitehouse and Janice M. Duncan (*Brief report*) 258–261

Psychosocial axes: Reliability of the psychosocial axes of DSM-III in an adolescent population; J. M. Rey *et al* 228–234

Psychotherapy: Psychotherapy and placebo; H. J. Eysenck (C) 266–267

Assessing the benefits of psychotherapy: the economic approach; G. McGrath and K. Lowson 65–71

Psychotropic drugs: A comparative hospital survey of psychotropic drug prescribing; M. Muijen and T. Silverstone 501–504

Puerperium: Detection of postnatal depression. Development of the 10-item Edinburgh postnatal depression scale; J. L. Cox *et al* 782–786

Epidemiology of puerperal psychoses; R. E. Kendell *et al* 662–673

Red blood cells: Gamma glutamyl transpeptidase and mean cell volume in alcoholics; David M. Hambridge (C) 568

Rehabilitation: Improving the quality of care on psychiatric hospital rehabilitation wards: a controlled evaluation; A. Lavender 476–481

Relatives: The Nithsdale schizophrenia survey: VI. Relatives' expressed emotion; R. G. McCreadie and A. D. T. Robinson 640–644

The Scottish first-episode schizophrenia study. IV. Psychiatric and social impact on relatives; The Scottish Schizophrenia Research Group 340–344

Research design: Gluten sensitivity in schizophrenia; Man Mohan Singh and Stanley R. Kay (C) 130–131

Review articles: Depressive disorder in primary care; C. V. R. Blacker and A. W. Clare 737–751

The burden of care: the impact of functional psychiatric illness on the patient's family; G. Fadden *et al* 285–292

Hostility and deliberate self-poisoning: the role of depression; R. Farmer 609–614
The neuroleptic malignant syndrome, so-called: a survey of the world literature; A. M. P. Kellam 752–759
Amnesia: organic and psychogenic; M. D. Kopelman 428–442
Biological and neuropsychological approaches to childhood autism; Margot R. Prior 8–17
Prevalence studies in schizophrenia; E. Fuller Torrey 598–608
'Rising Tide, The'; Measuring the 'Rising Tide'. How many dementia cases will there be by 2001? B. Ineichen 193–200

S-adenosylmethionine: Switch mechanism in affective illness and oral S-adenosylmethionine (SAM); M. W. P. Carney *et al* (C) 724–725
Saudi Arabia: Cousin marriages and schizophrenia in Saudi Arabia; Kutaiba Chaleby and T. A. Tuma (*Brief report*) 547–549
Schizophrenia, classification: Is the positive-negative distinction in schizophrenia valid? Man Mohan Singh and Stanley R. Kay (C) 879–880
Schizophrenia, complications: Autocastration and biblical delusions in schizophrenia; David Ames (C) 407; Larry Culliford (C) 407
Koro and schizophrenia in Singapore; G. S. Devan and Ong Seng Hong (*Brief report*) 106–107
Difficulties in assessing tardive dyskinesia; R. G. McCreadie *et al* (C) 410–411
An epidemic of suicide attempts by burning in a psychiatric hospital; Z. Zemishlang *et al* (*Brief report*) 704–706
Schizophrenia, diagnosis: Diagnostic value of Schneider's first rank symptoms in schizophrenia; H. D. Chopra and M. Gunter (C) 132
A study of Schneider's first-rank symptoms of schizophrenia in Nigerian patients; Oye Gureje and E. A. Bamgboye (*Brief report*) 867–869
The Scottish first episode schizophrenia study. I. Patient identification and categorisation; The Scottish Schizophrenia Research Group 331–333
Schizophrenia, familial and genetic: Cousin marriages and schizophrenia in Saudi Arabia; Kutaiba Chaleby and T. A. Tuma (*Brief report*) 547–549
Is there really a split in schizophrenia? The genetic evidence; P. McGuffin *et al* (Lecture 1985) 581–592
Schizophrenia, occurrence: Schizophrenia and ethnicity; Roland Littlewood (C) 272–273
Changes in the incidence of schizophrenia? Eric Strömgren (*Maudsley lecture 1985*) 1–7
Prevalence studies in schizophrenia; E. Fuller Torrey (*Review article*) 598–608
Schizophrenia, pathology: Nuclear magnetic resonance brain imaging in chronic schizophrenia; J. A. O. Besson *et al* 161–163
Cerebral ventricular enlargement in chronic schizophrenia; consistencies and contradictions; A. Farmer *et al* 324–330
Schizophrenia, physiopathology: Changes in auditory P3 event-related potential in schizophrenia and depression; D. H. R. Blackwood *et al* 154–160
Gluten sensitivity in schizophrenia; F. A. Jenner and D. N. Vlissides (C) 559
Chronic schizophrenic disorder. I. Psychophysiological responses, laterality and social stress; C. White *et al* 365–373
II. Reaction time, social performance and arousal; C. White *et al* 374–379
Schizophrenia, prognosis: Premorbid adjustment scale as a prognostic predictor for schizophrenia; E. Alvarez *et al* (C) 411
Five-year outcome and prognosis in schizophrenia: a report from the London Field Research Centre of the International Pilot Study of Schizophrenia; R. Prudo and H. Munroe Blum 345–354
Schizophrenia, therapy: A case of resistant schizophrenia; P. K. Bridges (C) 406
A patient with resistant schizophrenia; Ian R. H. Falloon (C) 717; Max Fink (C) 562–563; John Gunn *et al* (C) 716–717
The effect of sulpiride on negative symptoms of schizophrenia; Michel Petit *et al* (C) 270–271
Gluten sensitivity in schizophrenia; Man Mohan Singh and Stanley R. Kay (C) 130–131
The Scottish first episode schizophrenia study. II. Treatment: pimozide versus flupenthixol; The Scottish Schizophrenia Research Group 334–338
Chronic schizophrenia and long-term hospitalisation; J. K. Wing (C) 129–130
Electrodermal responding and chlorpromazine treatment in schizophrenia; Stavroula Yannitsi *et al* (*Brief report*) 850–853
Schizophrenic psychology: The influence of depression on the processing of personal attributes; P. I. Clifford and R. Hemsley 98–103
The relative stability of positive and negative features in chronic schizophrenia; E. C. Johnstone *et al* 60–64
The Nithsdale schizophrenia survey. VI. Relative's expressed emotion: prevalence, patterns and clinical assessment; R. G. McCreadie and A. D. T. Robinson 640–644
Communicability and thought disorder in schizophrenics and other diagnostic groups: a follow-up study; A. Burnett Ragin and T. F. Oltmanns 494–500
The Scottish first episode schizophrenia study. III. Cognitive performance; The Scottish Schizophrenia Research Group 338–340
The Scottish first episode schizophrenia study. IV. Psychiatric and social impact on relatives; The Scottish Schizophrenia Research Group 340–344
Specific and non-specific effects of educational intervention with families living with a schizophrenic relative; J. V. Smith and M. J. Birchwood 645–652
Schizophreniform episode: Schizophreniform episode following measles infection; M. Stoler *et al* (*Brief report*) 861–862
Schneider's first rank symptoms: Diagnostic value of Schneider's first rank symptoms in schizophrenia; H. D. Chopra and M. Gunter (C) 132

A study of Schneider's first-rank symptoms of schizophrenia in Nigerian patients; Oye Gureje and E. A. Bamgboye (*Brief report*) 867–869
Scotland see also **Edinburgh** and **Nithsdale**
The Scottish first episode schizophrenia study. I. Patient identification and categorisation 331–333; II. Treatment: pimozide versus flupenthixol 334–338; III. Cognitive performance 338–340; IV. Psychiatric and social impact on relatives 340–344; The Scottish Schizophrenia Research Group
Self-harm: Deliberate self-harm and predictors of out-patient attendance; G. O'Brien *et al* (*Brief report*) 246–247
Self mutilation: Autocastration and biblical delusions in schizophrenia; David Ames (C) 407. Larry Culliford (C) 407
Autocastration in Ontario Federal Penitentiary inmates; G. Neil Conacher and George H. Westwood (C) 565–566
Self-poisoning: Hostility and deliberate self-poisoning: the role of depression; R. Farmer (*Review article*) 609–614
Ethnic differences in self-poisoning: a comparison of West Indian and White groups; J. Merrill and J. Owens 765–768
Sex offences: Female sex offenders; Art. A. O'Connor 615–620
Singapore: Koro and schizophrenia in Singapore; G. S. Devan and Ong Seng Hong (*Brief report*) 106–107
Social phobia: Delineating social phobia; Michael R. Liebowitz (C) 718–719
Social support: Influence of the day of the week and the weather on people using a telephone support system; E. Hribersek *et al* 189–192
A list of the social support hypothesis; G. Parker and B. Barnett 72–77
Sociobiology: *Sociobiology, the new synthesis:* Edward O. Wilson; Edward Hare (*Book reconsidered*) 709–711
Sodium valproate: The effect of sodium valproate on tardive dyskinesia – revisited; G. G. Fisk and S. M. York 542–546
South Africa: Ethnic labels in South Africa; Beverley J. Dickman and Leslie Swartz (C) 566
Schizophrenia and ethnicity; Roland Littlewood (C) 272–273
Spouse: The mental health of elderly couples. I. The effects of a cognitively impaired spouse; J. M. Eagles *et al* 299–303
The mental health of elderly couples. II. Concordance for psychiatric morbidity in spouses; J. M. Eagles *et al* 303–308
Influence of husbands on the outcome of their agoraphobic wives' therapy; K. Oatley and D. Hodgson 380–386
Stress, psychological: The psychological effects of service in British Antarctica: a study using the General Health Questionnaire; J. Bell and P. H. Garthwaite 213–218
Influence of emotional distress among supporters on the outcome of psychogeriatric day care; C. J. Gilleard 219–223
Chronic schizophrenic disorder. I. Psychophysiological responses, laterality and social stress; C. White *et al* 365–373
Stress disorders, post-traumatic: A pilot study of phenelzine in the treatment of post-traumatic stress disorder; Jonathan Davidson *et al* (*Brief report*) 252–255
Students: Suicide and parasuicide among further education students in Edinburgh; S. D. Platt 183–188
Substance use disorders see also **Butane** and **Toluene**
Is there a lithium withdrawal syndrome? S. P. Hawkins and C. L. Shepherd (C) 273
Obsessive-compulsive disorder – a complication of benzodiazepine withdrawal; Helen P. Matthews and Lynne M. Drummond (C) 272
Munchausen's syndrome and drug dependence; Brian O'Shea (C) 407
Procyclidine abuse; G. P. Pullen (C) 567
Suicide: Assessment of suicide risk; K. Hawton (*Lecture*) 145–153
Suicide in England and Wales, 1975–1984; G. M. G. McClure 309–314
Suicide risk factors: a comparison of suicide attempters with suicide completers; K. Michel 78–82
Suicide and parasuicide among further education students in Edinburgh; S. D. Platt 183–188
Suicide in physicians; Isaac Sakinopsky (C) 267–268
Suicide, attempted: Parasuicide and unemployment; Donald Bermingham (C) 408
Classification of parasuicide by cluster analysis. Types of suicidal behaviour, therapeutic and prognostic implications; A. Karz *et al* 520–525
Suicide risk factors: a comparison of suicide attempters with suicide completers; K. Michel 78–82
Deliberate self-harm and predictors of out-patient attendance; G. O'Brien *et al* (*Brief report*) 246–247
Suicide and parasuicide among further education students in Edinburgh; S. D. Platt 183–188
An epidemic of suicide attempts by burning in a psychiatric hospital; Z. Zemishlany *et al* (*Brief report*) 704–706
Sulpiride: The effect of sulpiride on negative symptoms of schizophrenia; Michel Petit *et al* (C) 270–271
Supporters: The psychological well-being of supporters of the demented elderly; J. M. Eagles *et al* 293–298
Influence of emotional distress among supporters on the outcome of psychogeriatric day care; C. J. Gilleard 219–223
Sweden: Infantile autism in children of immigrant parents. A population-based study from Göteborg, Sweden; Christopher Gillberg *et al* (*Brief report*) 856–858

Tardive dyskinesia: Nuclear magnetic resonance brain imaging in chronic schizophrenia; J. A. O. Besson *et al* 161–163
The effect of sodium valproate on tardive dyskinesia – revisited; G. G. Fisk and S. M. York 542–546
Neuroleptic malignant syndrome superimposed on tardive dyskinesia; John J. Haggerty Jr *et al* (*Brief report*) 104–105
Neuroleptic malignant syndrome (NMS) and tardive dyskinesia; Adityan Jee (C) 880
Difficulties in assessing tardive dyskinesia (C) R. G. McCreadie *et al* 410–411

Telephone support: Influence of the day of the week and the weather on people using a telephone support system; E. Hribersek *et al* 189–192

Temperament: Temperament, personality and personality disorder; P. J. Graham and J. E. Stevenson (C) 872–873; N. Rutter (*Lecture*) 443–458, (C) 873–874

Tiapride in the long-term management of alcoholics of anxious or depressive temperament; G. K. Shaw *et al* 164–168

Therapies see **Art therapy, Behavioural therapy, Cognitive therapy, Psychotherapy** and **Rehabilitation**

Tiapride: Tiapride in the long-term management of alcoholics of anxious or depressive temperament; G. K. Shaw *et al* 164–168

Tics. Tics and heredity: a study of the relatives of child tiqueurs; D. M. Zausmer and M. E. Dewey 628–634

Token economy: The role of food substitutes in a token economy system; Derek W. Scott and Rodger H. Wood (*Brief report*) 864–867

Toluene: Patterns of use and related harm with toluene-based adhesives and butane gas; A. C. Evans and D. Raistrick 773–776

Phenomenology of intoxication with toluene-based adhesives and butane gas; A. C. Evans and D. Raistrick 769–773

Tomography, X-ray computed: Cerebral ventricular enlargement in chronic schizophrenia: consistencies and contradictions; A. Farmer *et al* 324–330

Trainees, psychiatric: An evaluation of the performing and recording of physical examinations by psychiatric trainees; J. C. Rigby and A. G. Oswald 533–535

Trazodone: Allergic type response to trazodone; James Maguire and Ashok N. Singh (C) 271–272

Tuberous sclerosis: Epilepsy and psychosis – ask the family; David J. Clarke *et al* (*Brief report*) 702–703

Tuberous sclerosis and the autistic syndrome; B. A. Lawlor and R. G. Maurer (*Brief report*) 396–397

Unemployment: Parasuicide and unemployment; Donald Bermingham (C) 408

Unipolar/bipolar system: Prediction of outcome in depressive illness by the Newcastle diagnosis scale: its relationship with the unipolar/bipolar and DSM-III systems; M. W. P. Carney *et al* 43–48

A long-term retrospective follow-up study of patients treated with prophylactic lithium carbonate C. Page *et al* 175–179

Vanadium: Further studies of vanadium in depressive psychosis; G. J. Naylor *et al* 656–661

Videotapes: Difficulties in assessing tardive dyskinesia; R. G. McCreadie *et al* (C) 410–411

Vitamins: Folate and vitamin B12 in eating disorders; M. T. Abou-Saleh and K. O. Chung-A-On (C) 133

Case report: severe depressive illness in the context of hypervitaminosis D; Kenneth M. G. Keddie (*Brief report*) 394–396

Vulnerability: Psychiatric vulnerability and cerebellar haemangioblastoma. A case report; D. A. Summerfield (*Brief report*) 858–860

Wales: Suicide in England and Wales, 1975–1984; G. M. G. McClure 309–314

Water: Neuroleptic malignant syndrome and compulsive water drinking; D. N. Anderson (C) 723–724

Water intoxication in congenital neurosyphilis; Bisa Haeger (C) 722–723

Weather: Influence of the day of the week and the weather on people using a telephone support system; E. Hribersek *et al* 189–192

Wives *see* **Spouse**

Zinc: Zinc in senile dementia; Chris Kenn and Elizabeth Gibb (C) 875; I. J. McLoughlin (C) 409
